SAE TRANSACTIONS

JOURNAL OF PASSENGER CARS

A publication of the
Society of Automotive Engineers, Inc.

This Transactions volume contains the best 383 technical papers of all those presented in 1997. Each has been reviewed according to the established review procedures of the Engineering Meetings Board of SAE. These are the best quality SAE Passenger Cars papers presented in 1997 and have been judged by technical experts to be worthy of preserving in the permanent technical literature.

The reviewing procedures require a technical review of all SAE papers by at least four well-qualified individuals who are technically competent within the scope of the papers' subject/discipline and who are experienced in reviewing papers.

Each paper is evaluated in four areas – long term reference value; presentation of technically new and innovative materials or constructive and in-depth review; professional integrity; and clarity of presentation. Based on the results of this review process, papers are selected for publication.

Objective Ride and Handling Goals for the 1997 Chevrolet Corvette

Joseph P. Ryan, Steven P. Fuja, and Henry A. Schmid
General Motors Corp.

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

The process of gathering information, analysis, and selection of ride and handling goals for the 1997 Chevrolet Corvette is described. The goals consist of measurable objective metrics and standardized subjective evaluation. The input elements of the process are: the Voice of the Customer, Engineering Direction and Competitive Assessment. As values are developed for the each metric, synthesis and analysis methods are used to confirm the full set of metrics are consistent and non-exclusive. The targets selected guided the chassis design and development of the 1997 Chevrolet Corvette to insure outstanding customer satisfaction in handling and ride.

INTRODUCTION

OVERVIEW - The fifth generation Chevrolet Corvette introduced in 1997 (C5) is a completely new vehicle, featuring significant design changes in all areas compared to the fourth generation Chevrolet Corvette of 1984-96 (C4).

Four papers have been written that summarize the Systems Engineering approach to the suspension design of the 1997 Chevrolet Corvette. This paper reviews the customer research, Engineering Direction, human factors and analytical evaluation that established the objective Ride and Handling targets for the vehicle. The second paper [1] describes the "flow down" of the vehicle level performance targets to specific subsystem attributes and parameters for the suspension, steering, and tires. The third paper [2] reviews the execution of the front and rear suspension in production hardware that complies with the specifications established in the previous two steps. The fourth paper [3] summarizes the final development tuning of the suspension, steering and tires. Careful execution of the procedures and techniques discussed in this series of papers was critical in producing the highly optimized suspension of the 1997 Chevrolet Corvette and assurance of high customer satisfaction for ride and handling performance.

PAPER ORGANIZATION - The material presented is organized into six major topics: Vehicle Level Metrics, Voice of the Customer, Engineering Direction, Mule Vehicles, Competitive Assessment and Targets and Synthesis/Analysis. An Appendix contains charts of supporting Competitive Assessment data for each metric discussed.

VEHICLE LEVEL METRICS

The objective metrics established at the beginning of a new vehicle program provide crucial guidance to the design process. Without numerical values assigned to measurable (and simulation compatible) objective performance metrics, efficient synthesis of subsequent design specifications would be impossible. Metrics were chosen in response to the Voice Of the Customer or Engineering Direction, and were formalized in the Vehicle Technical Specification (VTS), the document that states vehicle performance requirements and guides all subsequent design and development steps.

By rigorously following the Systems Engineering process established, there is very high confidence the first "out of the box" vehicles will exhibit overall performance close to the final desired package, and require a minimum of tuning or modification to the fundamental suspension. The goal of the Ride and Handling engineer is to meet all of the performance targets, but above all, produce a balanced, pleasing vehicle.

As the vehicle architecture matured, many suspension configurations were investigated for compatibility with the targets. All suspension designs pursued beyond a preliminary assessment were required to demonstrate the potential to meet all the Ride and Handling metrics.

During design and development, frequent assessments were made of vehicle progress by running laboratory and road tests. Laboratory tests verified suspension and tire performance parameters. Full

vehicle road tests were conducted to verify compliance with the Ride and Handling metrics.

HANDLING

There are hundreds of metrics that may be derived from instrumented vehicle tests. The key to efficient design synthesis is to reduce the list to the minimum set necessary to establish the fundamental handling character of the vehicle.

The Ride and Handling metrics selected for guiding C5 suspension, steering and tire design are shown in Table I. Four categories are listed: Linear Range handling (directional control below 0.3 g lateral acceleration), Non-linear Range handling (vehicle ultimate cornering and limit stability), On-Center handling (straight-ahead steering performance below 0.15 g) and basic Ride. General Motors test methods and metrics for handling have been previously described for Directional Control by Kunkel and Leffert [4], and On-Center handling by Norman [5].

Table I. C5 Ride and Handling Metrics.

LINEAR HANDLING	Understeer Gradient	deg/g
	Steering Sensitivity	g/100 deg
	(Steering Sensitivity) Linear Range	g
	Lateral Acceleration Response Time	s
	Roll Gradient	deg/g
	Roll Damping	--
	Yaw Velocity Damping	--
	Pitch Gradient - Acceleration & Braking	deg/g
NON-LINEAR HANDLING	Maximum Lateral Acceleration	g
	Dropped Throttle Stability	g
	Single Bump Roadholding	deg
ON-CENTER	Minimum Steering Sensitivity	g/100 deg
	Steering Sensitivity Ratio	--
	Steering Hysteresis	deg
	Lateral Acceleration at 0 Torque	g
	Steering Torque Gradient Ratio	--
	Steering Work Sensitivity	g^2/100 Nm
	Static Steering Effort	N
	Curb-to-Curb Turning Circle	m
RIDE	Front Ride Frequency	Hz
	Ride Frequency Ratio (Rear/Front)	--
	Impact Harshness	*
	Vertical Damping	*

* Subjective rating plus experimental metrics.

A "cross-over" test that provides both handing and ride information is a single-bump roadholding test, which has been previously described by various sources. Typically, the testing procedure establishes the vehicle in a constant radius turn and then encounters a single, fixed profile bump. The derived metric is usually based on yaw velocity deviation caused by the bump. The scope of the vehicle dynamics being exercised is limited, but simplicity and repeatability make this test very useful. Chassis contributors to roadholding may be evaluated, in addition to control of the unsprung mass, which is also fundamental ride consideration.

Measuring continuous roadholding in objective terms is more difficult. Test repeatability is hampered by the ability to provide a consistent road input to the vehicle (path, profile, coefficient of friction, etc.). Experimental tests and metrics are currently under development, but subjective evaluation is still the primary means for assessing continuous roadholding.

RIDE

Objective definition of ride is not as mature as handling. For C5, objective metrics from road test and simulation combined with subjective evaluation of vehicles formed the basis for defining ride. New test and analysis techniques that produce objective metrics are continuously being developed, evaluated, and adopted when appropriate.

Metrics from road tests generally fall into two areas: vehicle response to single events and continuous response over sections of standard Proving Ground roads. Single event tests are easily reduced to mechanical terms such as maximum displacements, settling times, damping levels, etc. Extended road response tests are typically reduced to a single cumulative parameter such as Power Spectral Density or an integrated area under a curve.

Subjective evaluations are used for vehicle attributes that do not have a reliable objective metric assigned, and are most beneficial in tabulating relative rankings of vehicles or tuning configurations by the same driver under similar conditions. The inherent limitations (such as driver-to-driver variability) and inability to simulate subjective ratings illustrate the difficulties of relying on subjective methods for efficient design synthesis.

Control - Control describes rigid body motions of the sprung mass (1-2 Hz) and the unsprung masses (10-15 Hz). Guidelines for rigid body ride have been in existence since the 1930's based on pioneering work by Olley [6]. Concepts such as ride frequency, oscillation centers, sprung mass damping and wheel control were explored. Objective description of Control includes natural frequencies, damping, sprung and unsprung mass motions, etc. Vehicle parameters that benefit rough road handling also tend to improve Control attributes of ride (i.e. head toss) and useful ride information may be gathered from the roadholding test described above.

Isolation - Higher frequency responses (above 15 Hz) that impact the driver as vibration or noise are also more difficult to reduce to simple metrics. Typical Isolation issues are: impacts, rough road shake and

coarse road isolation. The beneficiary of improved Isolation are the passengers, and a meaningful Isolation metric must comprehend the human element. Human Factors studies are continually being developed to quantify the perception of isolation, which can vary significantly from one individual to another. Development of Isolation metrics are maturing (as a result of increasingly complex computer simulations, new test procedures, sophisticated data analysis techniques and ongoing Human Factors studies) but are not in wide use.

VOICE OF THE CUSTOMER

The C5 Engineering Team and Chevrolet researched customer desires and expectations through clinics held at various locations across the country. In focus groups, C4 owners ranked "well built" and "performance" as their two most critical desires for the new Corvette. Well-built was ranked slightly ahead of performance, which in turn was further defined as primarily handling. Owners of other high-end sports cars also expressed a strong penchant for handling performance, but not at the sacrifice of ride quality.

In general, the positive comments of owners relating to C4 chassis performance included: high handling limits, predictable control at handling limits, and the suspension's ability to take the punishment of hard driving (including race track and autocross sessions). Dislikes included: harsh ride and poor straight-ahead tracking.

Customer comments used for C5 Ride and Handling metric development are shown in Table II as the "input" side of a sample QFD (Quality Function Deployment) table. The "output" side lists the C5 ride and handling metrics. In practice, the QFD chart is further detailed by identifying known relationships between input and output items, and rating each as strong, medium or weak.

Another source of customer input are J. D. Powers surveys. Data from C4 owners indicated extremely high levels of satisfaction for handling, and somewhat lower opinions for overall ride. These overall impressions of the C4 contributed to the early direction set for the C5 to provide best-in-class ride but not at the expense of handling.

ENGINEERING DIRECTION

OBJECTIVE METRICS - The Chief Engineer and the Ride and Handling Development Engineers defined the targets for specific metrics considered important to achieve the desired C5 performance and pleasability envelope.

TABLE II. QFD - Voice of the Customer to Objective Metrics.

METRIC / VOICE OF THE CUSTOMER	Steering Wheel Torque at 0 g	Curb to Curb Turning Circle	Steering Sensitivity Ratio	Static Steering Effort	Off Center Steering Torque Gradient Ra	Strg wheel Torque at 0 g	Lateral Acceleration Response Time	Understeer Gradient	Steering Sensitivity	Roll Gradient	Maximum Lateral Acceleration	Yaw Velocity Damping	Pitch Damping	Pitch Gradient - Acceleration	Pitch Gradient - Braking	Single Bump Disturbance	Impact Isolation	Vertical Damping	Front Ride Frequency	Ride Frequency Ratio
HANDLING																				
Performance, braking and handling allow driver to safely control car																				
Car feels heavy and sturdy																				
Car's handling allows for fast cornering																				
Car has good handling and stability at highway speeds																				
Car handles well over poor roads																				
Car handles well during all weather conditions																				
Car's handling provides a total feel of the road																				
Car maneuvers in and out of traffic with ease																				
Car responds well to steering wheel movement																				
Car is easy to park																				
Car comes to a smooth stop																				
Car has smooth ride over bumpy roads																				
RIDE																				
Car has smooth ride over bumpy roads																				
Car does not shake or vibrate over bumpy roads																				
Road and wind noises are absent from the car																				
Vehicle noise is absent form the car																				
Car has no squeaks and rattles																				

Values for "tuning" type metrics such as Steering Sensitivity and Roll Gradient were recommended. Maximum Lateral Acceleration was given special emphasis in part due to wide public acceptance of this metric as a key benchmark

Chassis Engineering was the liaison to other corporation resources to provide necessary support for the evolution of C5 Ride and Handling. The cumulative corporate knowledge base for many areas (customer usage, durability, manufacturability, liability, Human Factors, performance, technology, etc.) were integrated and applied to the C5 design.

Throughout design and development, the Ride and Handling Engineering Team periodically reviewed progress against performance targets in the VTS. When necessary, design or tuning changes were implemented to insure compliance of the C5 to the specified performance targets.

VEHICLE ARCHITECTURE

Several different vehicle concepts and layouts were considered for the C5. These included: mid-engine, integral powertrain and chassis structure, all-wheel-drive, and others. As the vehicle architecture matured, several overall vehicle features adopted for the C5 were strongly supported by the Ride and Handling Engineering Team. New features of the C5 that benefit Ride and Handling include: longer wheelbase, reduced overhang, wider tracks, rear transaxle, mid-car tandem fuel tanks, highly optimized body structure, structural front and rear crossmembers, and Extended Mobility Tires (EMT) tires.

Wheelbase - The 208 mm longer wheelbase helps in many areas of vehicle dynamics, including quicker response times for lateral acceleration, yaw velocity and sideslip; reduced sideslip; reduced phase lag between yaw velocity and lateral acceleration; reduced pitch under braking and acceleration; and flat ride tuning.

Track - The front track is 103 mm wider, and the rear track is 62 mm wider. Wider tracks improve roll stiffness efficiency and promote longer suspension links for more robust geometry.

Weight Distribution - The heritage of the Corvette strongly influenced the decision to keep the engine in the front, yet careful packaging produced a 50/50 weight distribution. The 50/50 weight distribution enables reduced front cornering compliance and understeer and enhances Maximum Lateral Acceleration by taking weight off the front tires.

Reduced Moments of Inertia - Moving the transmission to the rear of the vehicle reduced weight on the front axle and was a major contributor to the 50/50 weight distribution, which located the center of gravity at the midpoint of the wheelbase. (Another benefit of moving the transmission was to improve passenger compartment room, driver ergonomics, and place the driver further ahead of the rear axle, contributing to improved ride quality.) The C5 differential design locates the pinion gear on the rear side of the ring gear, which reduced the overall length of the transaxle assembly and allows less rear body overhang. The spare tire, which would have been located behind the rear axle, was eliminated by adopting EMT tires. The fuel tank was moved (from behind the rear axle on the C4) to tandem mid-car fuel tanks, located each side of the center tunnel, ahead of the rear axle.

As a result of the overall packaging of the transaxle, fuel tanks, and elimination of the spare tire, the yaw and pitch moments of inertia were reduced approximately 7%. Reduced yaw inertia provides quicker response times for lateral acceleration, yaw velocity and sideslip; and eliminates sideslip reversal during steer initiation from straight ahead, improving the driver's perception of a crisp turn-in.

Tires - C5 tire sizes are P245/45ZR17 front and P275/40ZR18 rear (Standard tires on the 1996 Corvette were P255/40ZR17 and P285/40ZR17, respectively). The narrower tread of the C5 tires help reduce vehicle sensitivity to lateral disturbances from uneven or cambered roads (i.e. truck grooves or troughs).

The required rear tire cornering stiffness is over two times higher than the front to achieve the target front and rear cornering compliances, which are absolutely critical for establishing the fundamental handling character of the vehicle. To achieve the required cornering stiffnesses with equal weight on each tire, different sizes are mandatory. There must be no possibility of intermixing front and rear tires, and optimization of cornering, ride, traction, and rolling resistance are more readily achieved in unique size tires for the front and rear.

C5 tires were required to provide high mileage and good value to the customer in addition to excellent vehicle performance. The Ride and Handling Engineering Team specifically avoided the use of soft tread compound (low mileage) tires, which is an easy way to increase cornering stiffness and compensate for a poor chassis design.

Structure - The C5 body structure features hydroformed side rails and large structural tunnel. The new body structure is 450% stiffer torsionally and has greatly improved local stiffnesses [7]. Suspension interfaces benefit from increased vertical and lateral stiffness of the body attachment points and hard mounted structural crossmembers.

Springs, shock absorbers and bushings are more efficient and tunable when the series compliances of the attaching structure are minimized.

MULE VEHICLES

Four mule vehicles were used in early development work. The first was built in 1990, a C4 with a Short-Long Arm (SLA) rear suspension. The second was also a modified C4 with SLA suspensions in front and rear that featured the longer C5 wheelbase and bell-crank actuated, horizontal coil-over-shock springing. When the overall C5 vehicle architecture was established, two "pre-Alpha" vehicles were built from the ground up, incorporating all of the mainstream design features.

Evaluation of specific components and suspension configurations provided valuable feedback for setting the ride and handling targets. Areas investigated were: ride frequencies, roll rates, suspension anti's, camber geometry, roll steer, spring configurations, fore-aft compliance, tires, fundamental damping, braking and acceleration steer and steering system tuning. Invaluable feedback was collected for fundamental ride, roll, isolation, pitch under braking and acceleration, steering isolation, cornering stability under braking and acceleration and roadholding.

COMPETITIVE ASSESSMENT AND TARGETS

COMPARISON VEHICLES - From an extensive database of instrumented vehicle tests maintained by the NAO Vehicle Dynamics Laboratory, a group of 45 peer vehicles and 22 production and development C4 Corvettes were selected. Appendix I contains scatter plots for selected Ride and Handling metrics. Measured values for the comparison vehicles plus the C5 target value or range are shown. Targets are identified either as a range, minimum or maximum.

LINEAR RANGE HANDLING

Understeer Gradient - The target range was determined by the Handling Synthesis method described below, to achieve the targeted Lateral Acceleration Response Time and Yaw Velocity Damping. The target range falls near the median value for comparison vehicles.

Steering Sensitivity - The target range was recommended by Engineering Direction based on many years of experience with the C4, to provide an appropriate balance between responsiveness and ease of highway driving. Human Factors studies [10,11] were also consulted to optimize driver-vehicle performance in path following, which eases the stress of the everyday driver and helps the precision of the autocrosser and racer.

Steering Sensitivity Linear Range - The target value was selected to place the C5 at best-in-class. A high linear range enhances the driver's perception of linear, predictable handling as lateral acceleration increases on a highway on-ramp or a decreasing radius turn.

Lateral Acceleration Response Time (LART) - The target value was selected to place the C5 at best-in-class. The driver perceives LART as a primary cue of vehicle responsiveness. Human Factors studies [8,9,10,11] recommend a short LART is important for driver controllability, path following, and obstacle avoidance.

Roll Gradient - The target range was recommended by Engineering Direction to achieve a desired level of overall vehicle motion on the road. This range is "softer" than a typical C4, in an effort to improve ride quality and rough road handling.

Allowing more roll enables smaller stabilizer bars, and closes the gap between one wheel and two wheel ride rate, enhancing the ability of a passive damper to control wheel motions over a wider range of roads. (Two wheel ride rate refers to parallel jounce where only the ride spring(s) resists vertical motion. One wheel ride rate refers to one side only jounce where the ride spring plus the stabilizer bar resist vertical motion.)

Roll Damping - The target value was chosen as a complement to the roll gradient. In general, more roll may be allowed if it is well damped, to minimize head-toss and avoid abrupt transients in tire lateral load transfer during cornering.

Yaw Velocity Damping (YVD) - The target value was chosen to place the C5 at best-in-class. Human Factors studies [8,9,10,11] recommend increased YVD is important for stability in severe maneuvers, path following and obstacle avoidance.

Pitch Gradient, Acceleration and Braking - The targets were also chosen to soften the body motions of the C5. Most chassis parameters that allow more body pitch under braking and acceleration also are enablers for better ride. Lower ride rates may be used in front and rear to enhance ride. Reduced anti-dive and less side-view swing arm maybe used in the front suspension, increasing rearward wheel motion in jounce, and improved impact harshness. The longer wheelbase of the C5 helps offset the effect of reduced ride rate and front anti-dive.

NONLINEAR RANGE HANDLING

Maximum Lateral Acceleration - The target was selected by Engineering Direction to place the C5 among the best-in-class. A high cornering limit not only maximizes autocross and racetrack performance, but

also provides a larger maneuvering envelope to the everyday driver in emergency situations.

Dropped Throttle Stability - The target was recommended by Engineering Direction based on C4 experience, and also maximizes the overall stable envelope of the vehicle to aid the driver in emergency situations.

Single Bump Roadholding - Targets were chosen for path deviation caused by a single bump in three modes: the contribution of the front axle, rear axle, and net (front - rear) to assess rough roadholding, ride, and uneven road disturbance rejection.

ON-CENTER HANDLING

Minimum Steering Sensitivity - "Crispness". The target was chosen to place the C5 at best-in-class for front engine vehicles, and was verified by Steering System Synthesis methods as realistic. (Comparison vehicles measuring higher are rear-engine and lower front mass or have unusually low steering gear ratios. The mass effect was also observed by Norman in [5]).

Steering Sensitivity Ratio - "Gain Linearity". The target was chosen to place the C5 at best-in-class for front engine power steering vehicles. (Comparison vehicles measuring higher are rear-engine and manual steering). A vehicle with a low value would be subjectively described as having a steering "dead zone" on-center.

Steering Hysteresis - "Friction". The target was chosen as an appropriate goal verified by Steering System Synthesis methods. High levels of friction adversely affect returnability and straight-tracking ability. Low levels of friction may decrease yaw velocity damping in a free-control situation.

Lateral Acceleration at 0 Steering Wheel Torque "Returnability". The target range was chosen as an appropriate goal verified by Steering System Synthesis methods. This metric is an indicator of the vehicle's ability to return to center, which similarly can be too great or too little.

Steering Torque Gradient Ratio - "Effort Linearity". The nominal target was chosen to place the C5 at best-in-class for power steering vehicles. (Comparison vehicles measuring higher are manual steering).

Steering Work Sensitivity - "Gain and Effort Balance". The target range was chosen as being representative of the appropriate balance of steering gain and effort for a vehicle in this class. Vehicles with lower values tend to be "heavy and sluggish", and vehicles with higher values tend to be "light and darty".

Static Steering Effort - The target was chosen to provide a comfortable parking effort for all drivers. The standard Magnasteer™ II variable effort steering system enables low parking effort without over-boosting the steering at higher speeds.

RIDE

Front Ride Frequency - The target range of 1.0-1.2 Hz for the undamped Ride Frequency was recommended by Engineering Direction from C4 experience.

Ride Frequency Ratio - The target range of 1.13-1.2 Hz for the undamped Rear/Front Ride Frequency ratio was recommended by Engineering Direction from C4 experience, plus Synthesis/Analysis studies anticipating the effect of the longer C5 wheelbase.

Impact Harshness and Vertical Damping - Target subjective ratings were chosen based on Engineering Direction. Experimental objective metrics were also considered as they were developed and verified.

BALANCING PERFORMANCE

It is certainly possible to build a car that exceeds all others in terms of a specific metric. The challenge of good chassis design is to strike a balance between all areas of performance to produce a car that will exceed the expectations of both the novice and expert driver. The C5 was targeted to be best-in-class in all areas, with justifiable expectations that all metrics were achievable.

SYNTHESIS AND ANALYSIS

All metrics were scrutinized by various analytical methods to verify each was achievable. Also, the full set of metrics were continuously monitored to insure preliminary chassis design parameters did not exclude any metric at the expense of meeting others.

HANDLING

Analysis - There are a wide variety of handling simulations (developed at the GM NAO Vehicle Dynamics Laboratory) that can reproduce all the standard road tests. "Raw" data is generated, then fed into the same data reduction software used for road test data. Simulated vehicles may then be evaluated in the same objective metric terms as actual vehicles.

Synthesis - An extension of the group of handling simulations is the family of Chassis Synthesis tools. These tools facilitate the synthesis of intermediate chassis parameters given specific vehicle performance metrics to be met.

FUNDAMENTAL HANDLING SYNTHESIS

The first level of chassis parameter synthesis is to identify the fundamental vehicle characteristics that yield the steady-state and dynamic handling behavior described by the target metrics.

Understeer Gradient is a mathematical description of the fundamental stability of the vehicle during cornering. In simple terms, the sign and magnitude of the numerical value describes the slip angle of the center of gravity of the vehicle during cornering, which may be subjectively described as the attitude of the vehicle in a corner. Also, for an understeer vehicle on a fixed radius path, as speed increases, additional steering input is required to maintain path. (A neutral steer vehicle requires no change in steering input, and an oversteer vehicle requires decreasing steering input.)

Normalizing the vehicle (center of gravity) slip angle to lateral acceleration defines the Understeer Gradient in deg/g. The magnitude varies as lateral acceleration increases, due to chassis tuning and the nonlinear characteristics of the tires. The amount of variation in Understeer Gradient as lateral acceleration increases affects the subjective impression of handling linearity. The C5 was targeted to have no significant change in understeer gradient, until a very high lateral acceleration, where tire saturation becomes dominant, and terminal understeer results.

To further define vehicle behavior, the individual axle contributions to Understeer Gradient may be expressed as individual Front and Rear Cornering Compliances, as described by Bundorf and Leffert [12]. Similar to Understeer Gradient, the Cornering Compliance is the slip angle of the vehicle at each axle. Mathematically, Understeer Gradient is Front minus Rear Cornering Compliance. The Cornering Compliance is also a lumped parameter representation of each axle's tire, mass and suspension effects that contribute to understeer.

There are an infinite number of Cornering Compliance combinations that yield the same linear range Understeer Gradient (steady state behavior). The individual magnitudes of the Front and Rear Cornering Compliances have profound effect on the dynamic behavior of the vehicle. For C5, the two primary indicators used for dynamic performance were Lateral Acceleration Response Time (LART) and Yaw Velocity Damping (YVD).

In Figure 1, LART versus YVD is shown for the group of comparison vehicles, plus the C5 target point. When these two modes of dynamic behavior are reviewed together, the target performance for the C5 is clearly breaking new ground for responsiveness and stability, where no other vehicles have demonstrated capability.

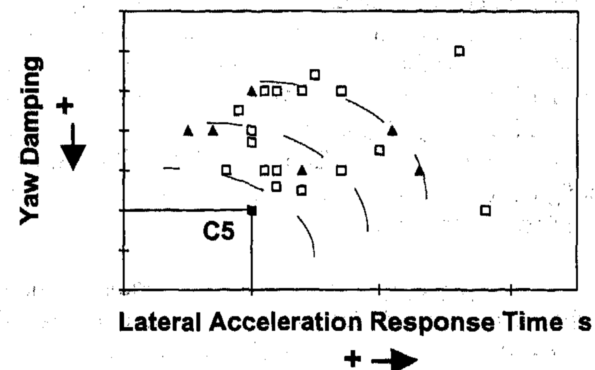

FIGURE 1. Lateral Acceleration Response Time and Simultaneous Yaw Velocity Damping, C5 and Comparison Vehicles.

A useful synthesis technique determines the Understeer Gradient and Front and Rear Cornering Compliances required to simultaneously achieve the target LART and YVD. The graphical representation of this concept is known as a Handling Map and was first described by Mackovjac and Lang [13]. A Handling Map used for the C5 is shown in Figure 2.

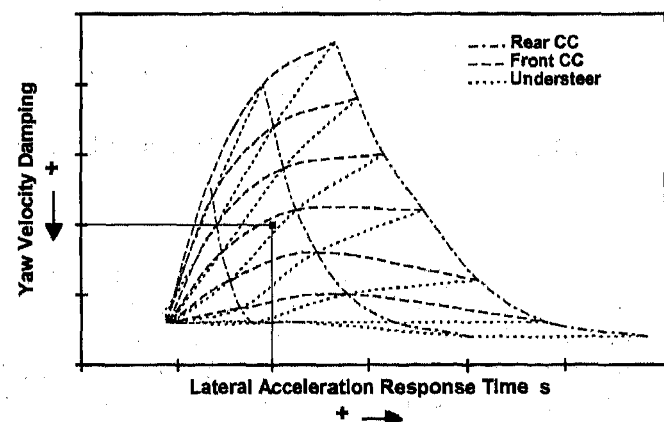

FIGURE 2. C5 Handling Map.

In this example, the target LART and YVD values were located on the horizontal and vertical axes to locate the simultaneous point on the chart. The location of this point on the parametric surface identifies the required Front and Rear Cornering Compliances and Understeer Gradient. All subsequent chassis design was strictly controlled to assure the target front and rear Cornering Compliances are maintained. With these values established, analysis can proceed more efficiently, by then turning attention to the individual contributors that make up the Front and Rear Cornering Compliances, as described in [1].

Parameter Variation - In addition to analyzing the mainstream chassis design, evaluations were made of alternatives and variations. Checks were made to verify the sensitivity of LART and Yaw Damping to various chassis parameters. If a specific suspension architecture exhibited a tendency to allow wide variations in a particular suspension characteristic (i.e. Roll Steer), and the Handling Map indicated there was unacceptable degradation in LART, YVD or Understeer Gradient, that configuration would be rated poorly for robustness in handling performance.

Case Study - An example parameter evaluation is shown in Figure 3. On the Handling Map the baseline chassis tuning is shown, plus eight other points representing the variation in vehicle response due to Front and Rear Roll Steer variations of 0.08 deg/deg.

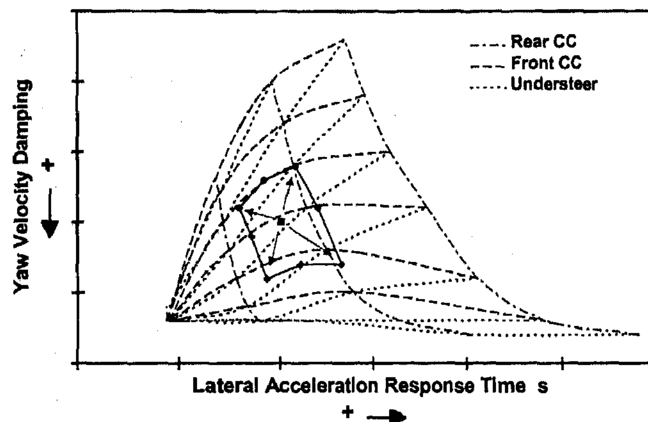

FIGURE 3. Roll Steer Variation Effects on Dynamic Behavior.

For proposed suspension "X", it was found that the assembly operation would allow geometric variation of point "Y" of +/- 1.0 mm which in turn produced a roll steer variation of +/- 0.08 deg/deg. Within the resulting performance envelope, the LART can vary as much as 0.05 s, YVD 8 percent, and Understeer Gradient 1.2 deg/g. Variations of this magnitude would be easily detected by the driver and result in vehicles with handling performance outside the acceptable range for C5. In conclusion, this configuration be rated poorly for robustness in handling performance.

RIDE - Lumped parameter simulations checked the viability of ride improvements. Tire stiffness, vertical damping and various suspension parameters were assessed for ride quality.

CONCLUSION

Using customer research, Engineering Direction, and competitive assessment, objective Ride and Handling goals were established for the 1997 Chevrolet Corvette. This was the first critical step in the Systems Engineering process used for suspension design. All subsequent design and development [1,2,3] was focused to produce a final vehicle that met all of the Ride and Handling targets.

Dynamic handling behavior was carefully assessed and specified in terms of Lateral Acceleration Response Time and Yaw Velocity Damping. From these targets, the Front and Rear Cornering Compliances were synthesized, establishing the basis for finalizing the kinematic and compliant properties of the suspension.

ABSTRACT

This paper describes the hardware execution of the front and rear suspensions of the all new 1997 Chevrolet Corvette. Topics covered include: alternative design trade-off, mass optimization, alignment and trim, structural interfaces, shared components, component design and a review of the overall design of the front and rear suspensions. Two case studies are detailed for the front upper and rear lower control arms. The systems engineering process used for suspension design is described throughout the paper.

INTRODUCTION

VEHICLE TERMINOLOGY - The fifth generation Chevrolet Corvette introduced in 1997 (C5) is a completely new vehicle, featuring significant design changes in all areas compared to the fourth generation Chevrolet Corvette of 1984-96 (C4).

DESIGN DOCUMENTATION - The first paper in the series [1] describes the initial step of setting vehicle level goals for ride and handling. The second paper [2] describes how the vehicle level targets are "rolled down" to specific subsystem attributes for the suspension, tires, and steering system. This paper describes the execution of the front and rear suspension in production hardware, in compliance with the specifications established in the previous steps. The last paper [3] describes the final development tuning of the suspension, tires, and steering systems.

Together, the four papers describe the Systems Engineering approach to C5 suspension design. Customer preferences, engineering input and evaluation selected the C5's Ride and Handling targets, which are rolled-down to suspension specifications, and finally, design and development of the production hardware. Careful execution of the engineering process has produced a 1997 Chevrolet Corvette with best-in-class ride and handling, assuring a high degree of satisfaction for every C5 customer.

ARCHITECTURAL TRADE-OFFS

In addition to engineering review of the C4 suspensions, a series of trade-off studies were conducted of new alternative designs. Ranking criteria included: ability to meet performance attributes described in [2], packaging, mass, cost, serviceability, manufacturability, assembly, and durability. Each design proposal was ranked in each category, weighting factors applied, and a summary ranking of each design produced. Weighting factors were higher for attributes that enabled best-in-class handling, improved ride, and low mass.

The required suspension Static Design Factors (SDFs) (i.e. roll steer, aligning torque compliance steer) [2] were formalized in a Subsystem Technical Specification (SSTS) which guided hardware design. As the overall vehicle architecture evolved and new engineering, manufacturing, and assembly strategies were applied, criteria and weighting factors were revised accordingly. Relevant comments on design trade-off are included in each section below.

MASS OPTIMIZATION

During phase one of the C5 suspension program the Engineering Team established a target mass reduction versus C4 for the front and rear suspension subsystems. Since the C4 already used premium low mass materials, further mass efficiency in the C5 was particularly challenging. Mass reduction initiatives implemented on the C5 were: aluminum bar pins in the front upper control arm bushings, aluminum inner metals in the rear upper control arm bushings, bushings pressed directly into control arms without outer metals, glass reinforced resin stabilizer bar links, thin wall stabilizer bars, mass optimized 36 mm (standard) shock absorbers, FEA modeling targeted at mass optimization and extensive loads measurement for accurate structural optimization. All fasteners, bushings and ball joints were reviewed and subject to resizing for minimum mass.

WHEEL ALIGNMENT

OVERVIEW - Wheel alignment is an important consideration for any vehicle. Successful optimization of ride and handling relies on precise and consistent control of tire orientation. For a sports car with high cornering stiffness tires, relatively high lateral forces are developed at low camber and slip angles, which may be fed back to the driver as steering leads and pulls. Wheel alignment is critical for good on-center steering feel, minimized tire wear, steering isolation, vehicle insensitivity to uneven roads and ultimate handling performance.

GOALS - The overall vision of an alignment system consistent with the Corvette's sport car mission led to emphasis of four specific goals. First, 100% of shipped vehicles will conform to the four wheel alignment specification, verified by end-of-line inspection. Second, cross-caster and cross-camber will be significantly reduced over C4 levels. (Customer surveys indicated a significant opportunity to improve customer satisfaction by reducing steering wheel leads and pulls.) Third, implement a robust alignment mechanism that is compatible with assembly line operation and will maintain service alignment. Fourth, allow easy adjustment for caster, camber and toe, and additional negative camber capability for autocrossing and racing.

ALIGNMENT SYSTEM REQUIREMENTS- Early variation simulation modeling quantified body and chassis dimensional build capability and the resulting variation in suspension alignment. When added to other vehicle data potential steering leads or pulls were predicted. Pull predictions were evaluated against a complaint steering wheel torque threshold developed from Human Factors studies. Component dimensional control, cross-camber, cross-caster, and trim height tolerances were developed to avoid customer complaint vehicles.

SUSPENSION IMPLEMENTATION - Cams on the lower control arms were chosen primarily to facilitate assembly process strategy, as detailed below. The C4 front suspension used shims on the upper control arm, which suffers from some inherent disadvantages: higher cycle time, open loop pattern adjustment, and fairly coarse resolution for meeting nominal specifications. Also, an adjustment mechanism in the upper control arm shortens the cross-car length, degrading kinematics and robustness.

The cam bolts react against machined vertical slots in the crossmember. The front suspension uses two cam bolts at the fore and aft bushings for caster and camber adjustment. The rear suspension uses one cam bolt at the forward bushing for camber adjustment.

Cam bolts provide continuous adjustment which is required for the simultaneous automated adjustment system at each wheel. Additional considerations were plant cycle time, ease of adjustment and access from below the vehicle. Additional negative camber adjustment (beyond production and normal service specifications) was provided to accommodate Corvette drivers involved in production class auto-crossing and road racing.

ASSEMBLY PROCESS - Three alignment process strategies were considered: net build, pattern build and custom set. The process strategy selected was a hybrid pattern set with limited custom set. The pattern set process was automated into the crossmember to control arm build station, where the lower control arm to crossmember position is held, and cam bolt rotation is unconstrained prior to tightening. The limited custom set process provides cycle time for an end-of-line adjustment of one side only to minimize cross-camber and cross-caster. At least one side of the vehicle must arrive at the alignment station within specification for camber and caster. (For the C4 front suspension, each side was pattern set with shims to a nominal camber and caster. Normal assembly processing did not provide for adjustment of cross-camber and cross-caster.)

Figure 1 shows process first time quality of front camber and caster for a group of pilot phase vehicles. The data shown is the minimum of the left or right side deviation from nominal. 100% of vehicles exhibit at least one side of the vehicle within specification for camber and caster. The end-of-line adjustment can focus on minimizing cross-camber and cross-caster by automatic adjustment of <u>one side only</u>. The C5 alignment strategy resulted in a 50% reduction in the cross-camber and cross-caster specification compared to C4. Toe continues to be 100% set at the end-of-line on all four wheels.

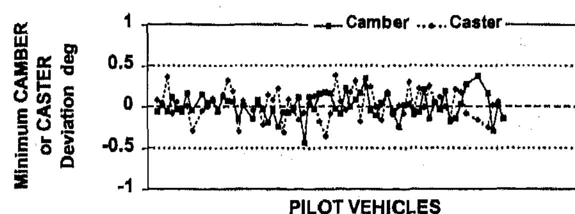

Figure 1. Minimum Front Camber and Caster Deviation, as Built, Pilot Phase.

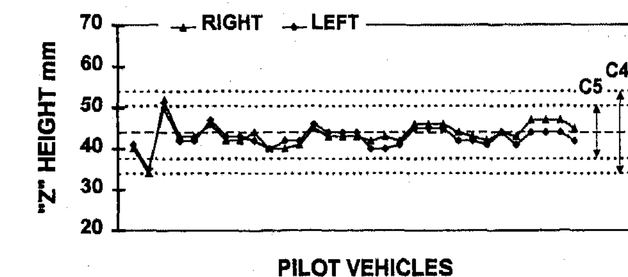
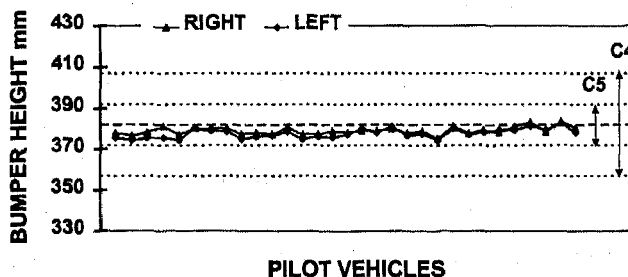


TRIM HEIGHT

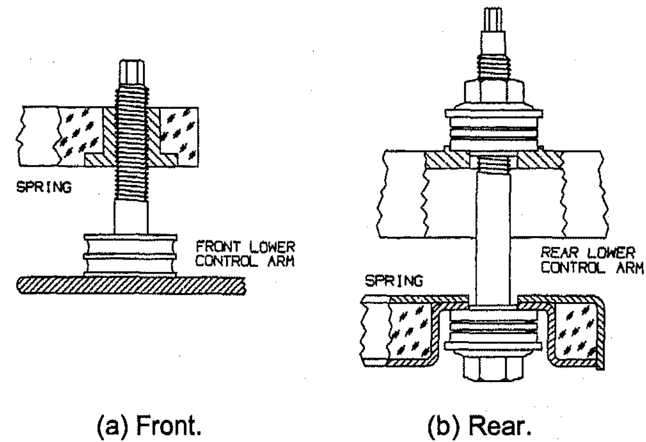
OVERVIEW - Trim height control is particularly important for a sports car with somewhat restricted ride travel. Inherent features of a sports car that limit ride travel include: low profile styling, large tires, dense component packaging and minimal changes in vehicle loading. Effectively managing limited ride travel demands minimized trim height variation: available ride



travel may be better utilized to avoid early jounce and rebound bumper engagement. Tire to wheel opening appearance is more consistent. Handling and ride optimization and robustness are improved due to less variation in suspension SDFs. Bumper design also benefits: C5 uses a unique bumper impact system, enabled by accurate control of bumper height - a direct beneficiary of accurate trim height control.

The improved trim height control of C5 allowed a 36% reduction in the trim height tolerance and a 60% reduction in the bumper height tolerance compared to C4. Figures 2a and 2b show front "Z" height and bumper height for a group of pilot phase vehicles. Also shown are the C4 and C5 tolerance bands for each.

STRATEGY - To meet these stringent requirements, variation simulation modeling indicated that a suspension height adjustment mechanism would be required. Contributors to trim variation include: mass variation due to option content, spring rate and load variation, dimensional variation and load offset from shock absorber gas charge. C5 suspension trim adjustment is implemented with threaded adjustable links that connect the spring to the lower control arm, as shown in Figures 3a and 3b.



(a) "Z" Height.

(b) Bumper Height.

Figure 2. Front Suspension and Bumper Height, as Built, Pilot Phase,

ASSEMBLY PROCESS - Assembly plant process tooling engineers devised an automated spring link adjustment procedure into the crossmember to spring sub-assembly station. Vehicle mass due to option content is determined, shock absorber preload (due to gas pressure for optional units) is identified and individual spring load is measured. The length of each spring link is then automatically adjusted to insure each vehicle is at the proper trim height.

INTERFACE REQUIREMENTS

GLOBAL STIFFNESS -The C5 exhibits a very high overall structural stiffness for an open roof production car, enabling significant improvements in ride, noise, squeaks and rattles. Static torsional stiffness is 450% higher than C4. Comprehensive structural modeling and managing of modal requirements were key contributors to the significant improvement in C5 ride quality and isolation performance [4].

LOCAL STIFFNESS - Improved local body stiffness at suspension interface points benefit handling, ride and noise. Insuring that local body stiffnesses are significantly higher than the corresponding suspension bushing rates improves the flexibility and robustness of bushing rate tuning. The efficiency of the spring and shock absorbers improve, due to reduced series compliance. Isolation and noise benefit from high impedance of the natural load paths into the body: bushings become more efficient for energy absorption and isolation. Early analytical work identified major noise paths and local stiffness targets were established with an appropriate input mobility mismatch across the interface for each isolator.

ENGINEERING PROCESS - Successful development of the C5 body structure illustrates the importance of cross-discipline cooperation and setting appropriate interface requirements. Targets for each local stiffness were assigned, tracked, and managed through the course of C5 development. Each interface was developed with extensive structural modeling, verification tests were conducted on early prototypes and component were redesigned as required.

A more subtle benefit of properly selecting and verifying interface stiffness targets is accuracy and effectiveness of the preliminary ride and handling synthesis and analysis. Performance predictability is greatly enhanced if appropriate stiffness ratios between suspension bushings and structural attachments are maintained. As a result, early C5 development vehicles demonstrated very good ride and handling, and required relatively minimal development work to optimize performance and pleasability.

COMMON COMPONENTS

The low volume of the C5 offered a unique challenge to design the front and rear suspension with shared components. Higher volumes reduce piece cost and deproliferation of components reduces investment. The components shared by the C5 front and rear suspensions are:

Knuckles (left front = right rear)
Wheel bearings
Ball joints
Stabilizer bar links
Inner spring insulators
Spring mount clamps

Upper and lower ball joints are a low friction, lubed-for-life design. Frictional characteristics in both ride and steer modes were specified and monitored because of their effect on ride comfort and steering performance. Stabilizer bar links are dual ball joint to minimize system compliance and provide a linear roll response. The body of the link is glass reinforced resin for low mass and design simplicity.

ALUMINUM COMPONENTS

All upper and lower control arms and knuckles are aluminum for low unsprung mass. Manufacturing processes were selected for strength, shape requirements and cost. Castings have historically been least expensive and permit a large degree of flexibility in component shape. Forgings are typically more expensive, provide the highest strength and are best suited for simpler shapes. Alternative manufacturing process trade-off studies were completed for each structural suspension component.

Forging was chosen for the front upper control arm using AA6061-T6 aluminum, due to critical strength and shape requirements. A hybrid cast preform-forging process using A356-T6 aluminum was chosen for the lower control arms, rear upper control arm and knuckles for shape flexibility to minimize mass. This process provides improved surface material properties over castings for improved fatigue strength.

FRONT SUSPENSION

OVERVIEW - Continuing the Corvette tradition, the front suspension is a Short-Long Arm (SLA) configuration, as shown in Figure 4. Similar to the C4, control arms and knuckle are aluminum, and a composite transverse leaf spring and monotube shock absorber are used. New for C5, the lower control arms and steering rack attach to a hard mounted cast aluminum crossmember [5]. The upper control arm attaches directly to the hydroformed frame rail using aluminum bar-pin type bushings. The steering rack features Magnasteer™ II (a variable effort steering system developed by Delphi Saginaw Division of General Motors), is located forward of wheel center, and has cast aluminum outer tire rod ends. The stabilizer bar is packaged forward of wheel center, is mounted to the crossmember with low friction insulators and is attached to the lower control arm with dual ball joint links. Standard shock absorbers are high pressure monotube with digressive valving.

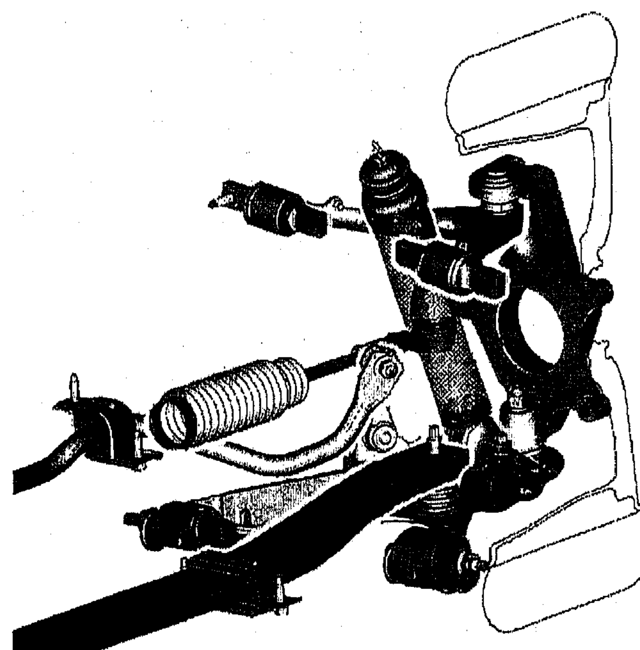

Figure 4. 1997 Chevrolet Corvette Front Suspension.

ALTERNATIVE SELECTION

Lower Control Arm - A strong direction from the Voice of the Customer was the desire for improved ride quality and impact isolation [1]. Extensive design activity focused on reducing fore/aft suspension stiffness to provide improved impact isolation. Comparison cars that use elaborate mechanisms to promote low fore-aft stiffness were benchmarked for performance attributes, packaging efficiency, mass, overall robustness and complexity. These more exotic concepts were evaluated against a conventional aluminum lower control arm. Mass, packaging efficiency, robustness, overall simplicity

and practicality led to the selection of a semi-L shaped aluminum lower control arm that carries the ride spring, shock absorber, and stabilizer bar attachments. Separation of bushing function (stiff handling and soft ride) was maintained to a high degree to decouple suspension fore/aft compliance and lateral stiffness. Subsequent ride and handling development [3] found that bushing tuning was highly flexible, and suitable fore-aft compliance could be achieved without degrading lateral stiffness.

Kingpin Geometry - Two basic kingpin geometry's were considered, differentiated by the upper ball joint and upper control arm location. The configuration chosen placed the upper ball joint inside the wheel and as far outboard as possible to provide a relatively short spindle length [2]. A high arm SLA was also considered. The two concepts were evaluated for characteristics such as steering feel, alignment robustness, fore/aft stiffness and hood height. The high arm SLA was considered unacceptable for reasons that included knuckle compliance and roll center geometry.

A synergy that evolved out of the alternative selection process was applied to the upper ball joint location. The typical placement of the upper ball joint body in the knuckle in a high arm SLA was adopted in the production design. This allows the longest kingpin length possible. Kingpin geometry, spindle length and scrub radius were developed to optimize steering feel and improve mid-range handling, both important customer desires [1,2].

Ride Spring - The first C5 suspension concepts were conventional coil over shock absorber for both front and rear suspension. One proposal utilized a horizontal coil over shock actuated by a bell crank upper control arm, and was evaluated in a mule vehicle.

A composite transverse leaf spring was selected for efficient packaging and low overall mass. Shock towers may be lower and smaller for hood height and less intrusion in the engine compartment. The shock absorber may be placed further outboard on the lower control arm than is possible with a coil over shock unit. The improved shock lever arm ratio provides efficient damping authority and reduced jounce bumper loads (the jounce bumper is integral with the shock absorber).

The gull wing shape of the spring was developed to fit the envelope between the ground line and engine oil pan at the center, and rise up at the tip to rest on the top surface of the lower control arm. An adjustable height insulator at the tip allows custom set of trim height, which is critical to the overall trim height strategy. The insulator is a low shear rate rubber-steel sandwich that reduces the spring contribution to suspension fore-aft rate for improved impact isolation.

Brakes - Opposed piston calipers were considered at one time, but were not pursued because of adverse packaging implications (longer spindle length and excessive positive scrub radius). Floating (single side piston) calipers were chosen to permit better optimization of the kingpin axis, minimized spindle length, and minimized scrub radius.

CASE STUDY: FRONT UPPER CONTROL ARM

The front upper control arm is tightly packaged between the frame rail, road wheel and shock absorber. The C5's longer wheelbase and tighter turn diameter necessitated larger steer angles at full lock, further reducing packaging space. In addition to tight packaging, the front upper control arm is also subjected to high loads under severe events such as a large pothole or panic brake stop. Due to the orientation of the upper ball joint, high bending loads are also present, unlike the C4 front upper control arm.

Extensive shape optimization was conducted with automated finite element analysis to arrive at the final shape. As with any optimization problem, system constraints must be accurately defined to produce a meaningful answer (load environment, package restrictions, and handling-related stiffnesses). The maximum stress level, cross-section envelope and relatively simple V-shape, led to selecting forging as the manufacturing process. The final design that meets all the packaging, stress, and mass criteria is shown in Figure 5.

The upper control arm is attached to the frame rail by means of aluminum bar-pins integral with the pivot bushings. The bar pin design allows a low profile attachment to the hydroformed frame rail, maximizing the cross car length of the upper control arm, and improving front view geometry.

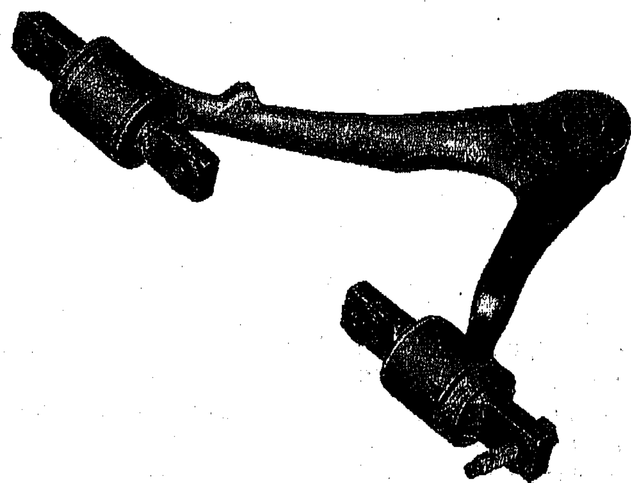

Figure 5. Front Suspension Upper Control Arm.

REAR SUSPENSION

OVERVIEW - The C5 rear suspension is shown in Figure 6. There is strong similarity to the front, with the common knuckle and semi-L shaped lower control arm. The lower control arm and toe link mount to a cast aluminum crossmember [5]. The upper control arm attaches to vertical brackets on the hydroformed frame rail. The knuckle is oriented with zero caster. The shock absorber has a clevis lower mount that mates to the lower control arm. The composite transverse leaf spring is clamped to the crossmember and attached to the lower control arm with rubber isolated tension links. The stabilizer bar is aft of wheel center, clamped to the crossmember (sharing one fastener with the lower control arm rear bushing) and is attached to the lower control arm with dual ball joint links. Steel plunging halfshafts with constant velocity joints deliver torque to the wheels.

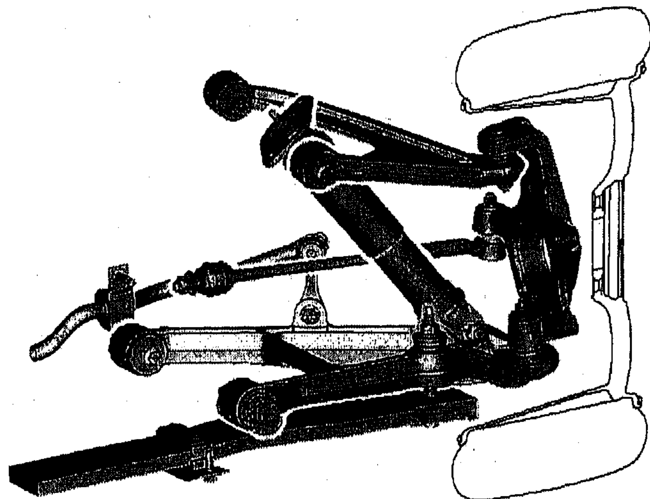

Figure 6. 1997 Chevrolet Corvette Rear Suspension.

C4 PERSPECTIVE - As the C4 matured over the years, it became evident that the rear suspension had reached it's full potential for ride and handling optimization. The fundamental layout dates to 1963, and exhibits very good packaging and unique dual-function use of the half-shaft as a suspension link. With the lateral suspension links attached to the differential, tuning the differential mounts for driveline isolation typically degraded handling, and vice-versa. Dual trailing links controlled the knuckle in the fore-aft and pitch directions. It was difficult to reduce suspension fore-aft stiffness without producing excessive knuckle caster change and ride steer variation. The spring and shock absorber were attached directly to the knuckle a significant distance away from wheel center in side view. The ride spring load added static pre-load to the trailing link bushings. It was difficult to tune the shock absorber because of series compliance and phase lag caused by caster deflection in the knuckle. The half-shaft as the upper control arm of the suspension resulted in a relatively short kingpin axis and sub-optimized roll center geometry. Ride camber geometry and robustness to camber alignment contributed to higher sensitivity to uneven and cambered roads.

ALTERNATIVE SELECTION

Criteria - Numerous packaging and SDF analyses were conducted for each proposal to optimize factors such as packaging, cost, ride and handling performance, interface loads, overall vehicle mass and shock absorber efficiency.

Suspension Type - A survey of all rear suspensions used in high end sports cars today reveals there are a multitude of architecture solutions in use. Some give priority to packaging, others to cost by sharing components with high volume vehicles, and a few to handling performance but typically at the expense of ride.

The top priority of the C5 rear suspension was ride and handling performance. With careful attention to detail, and recognizing that many design features that enable excellent handling also benefit ride, there was full expectation that outstanding ride could be achieved without degrading handling.

The design team concluded that a SLA suspension provided the only acceptable solution for the handling and ride requirements of the C5. A high degree of decoupling between front view and side view geometry, fore-aft and lateral stiffness, camber, caster and toe adjustment, ideal roll center control and robustness to all of the above may be realized in a carefully designed SLA. The C5 rear suspension does not share components with other vehicles, to eliminate any possible performance compromise.

The Corvette driver ranges from the daily commuter to the weekend racer. Toe and camber may be easily adjusted to maximize handling performance without significant impact on other suspension characteristics. Note that virtually every modern, purpose built independent suspension for racing is a SLA because of kinematic decoupling and adjustability.

Control Arms - The L shaped upper control arm design stabilized early. The stiff (handling) pivot bushing is on wheel center, and the soft (ride) pivot bushing is as far aft as could be packaged.

Lower control arm alternatives ranged from a conventional A-arm to a 3-link configuration (trailing link and two lateral links). Correspondingly, knuckle alternatives included sharing with the front or a new design for the 3-link lower arm. New knuckle designs were considered with and without direct attachment of the spring or shock absorber.

Direct attachment to the knuckle in a low profile package requires components to be ahead or behind the drive axle. The resulting fore-aft moment arm for spring or damping transient forces generates caster deflection in the knuckle and unwanted toe change, especially on rough roads. The pitch stiffness of the knuckle becomes a series compliance for the ride spring and shock absorber, degrading tunability.

The concept selected was a semi-L shaped lower control arm that carries the spring, shock absorber and stabilizer bar, mated to a common front/rear knuckle. Commonizing the knuckle eliminated the investment and engineering overhead of another major component. An adjustable, dual ball joint toe link located aft of wheel center simplifies alignment, and provides deflection understeer [2].

Shock Absorber - Following selection of the lower control arm, extensive packaging, load path and SDF analyses were used to locate the shock absorber. Travel ratio, inclination angle, shock tower mass and stiffness were considered. The low profile package was not compatible with a clevis around the drive axle. The shock absorber was attached to the lower control arm as close as possible to the lower ball joint to minimize the series compliance effect and induced loads in the soft ride bushing. Simultaneously, various spring alternatives were evaluated and their influence on shock absorber location.

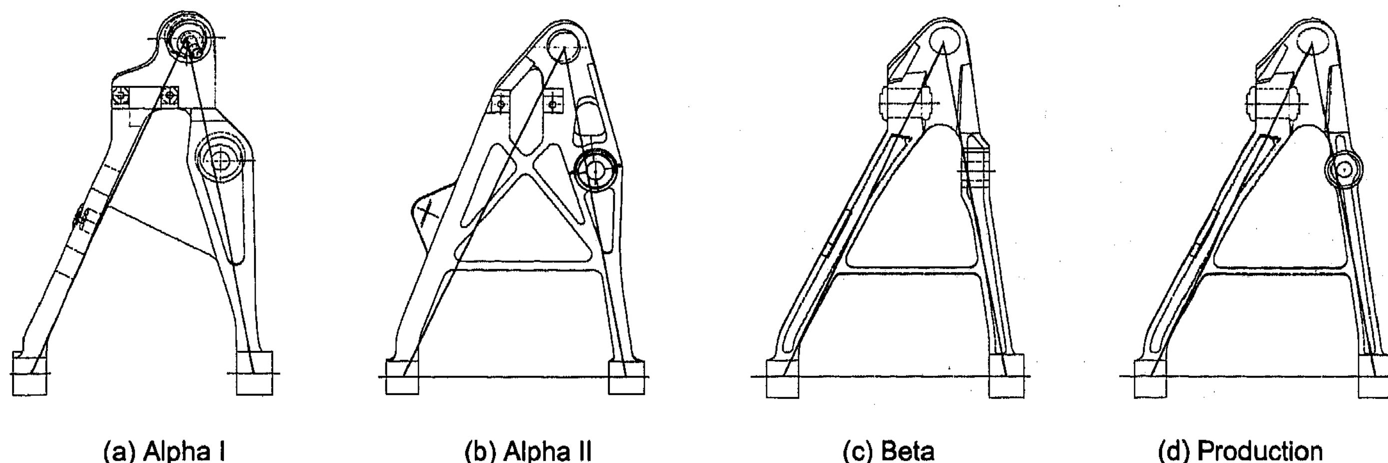
Spring - Three basic spring configurations were considered: transverse leaf, coil over shock, and separate coil. Attachment was considered either to the knuckle or to a lower arm/link. Following the decision to attach the spring and shock absorber to the lower control arm, the composite transverse leaf emerged as the best alternative, permitting the best shock travel ratio, lowest mass and the smallest shock tower which contributed to improved trunk volume.

The transverse leaf spring is suspended below the lower control arm with rubber isolated tension links (Figure 3b). The links decouple the fore-aft stiffness of the spring from the lower control arm, for improved impact isolation and are threaded to allow custom trim set.

CASE STUDY: REAR LOWER CONTROL ARM

The lower control arm underwent extensive shape evolution to accommodate packaging, loads and manufacturability. Finite element models and sand cast prototypes were used to validate the final design.

The rear suspension lower control arm (RLCA) evolved significantly from Alpha to production design. During design development, the only imperative was to maintain the overall topology (pivot point and attachment locations). If the suspension performance parameters specified in the Subsystem Technical Specification [2] were preserved, the macro performance of the RLCA in the suspension would not change. The design team had complete freedom to revise the structural shape and attachments to meet mass, durability and packaging requirements with no risk to suspension performance.



Several load cases were analyzed with FEA, including severe pothole, maximum braking and high cycle fatigue. The Corvette is required to pass the same Proving Ground durability tests as all other passenger cars and light trucks.

ALPHA DESIGN

Structural Shape - Figure 7a shows the Alpha RLCA. Alpha components are intended to prove system functionality and do not reflect any attempt at detailed optimization. Overall package optimization located the pivot points attachments for the shock absorber and spring, which did not change through to the production design.

Initial shape optimization was based on the Alpha design. Figure 7b shows the evolutionary Alpha II design. In plan view, lines of action are shown between the load reaction points (pivot bushings and ball joint). The web between the front and rear legs and the area around the shock absorber attachment was replaced with a truss type structure. The rear leg was revised to distribute material more symmetrically about the ideal load line in plan view. Clearance required for the shock absorber lower mount prevented using a significant amount of material directly on the ideal load line where the highest bending moments occur. Extensive FEA work on the Alpha II design concluded that a reasonable mass reduction could not be achieved.

Shock Absorber Attachment - With the integral jounce bumper, the highest loads applied to the RLCA are at the shock absorber attachment in a severe pothole event. The Alpha lower mount was a commonly used "bowtie" type. To accommodate this fastener configuration, material must migrate away from the ideal line of action. In rear view, the shock absorber is inclined significantly, and jounce loads into the RLCA have a large outboard component. In the Alpha design, two vertical 8 mm fasteners clamped the lower mount to the RLCA. In a severe pothole, the shear load in the interface exceeded the clamping capacity of the 8 mm fasteners. (Observation of an Alpha durability vehicle confirmed this.) To handle the shear load, 14 mm fasteners would have been required. To accommodate 14 mm fasteners, the lower mount would have to increase in size and more material be added to the RLCA away from the ideal line of action.

(a) Alpha I (b) Alpha II (c) Beta (d) Production

Figure 7. Rear Lower Control Arm Evolution.

BETA DESIGN

Criteria - At this time, three factors indicated a major revision to the shape of the RLCA was necessary. First, the desired mass reduction was not being realized in the basic Alpha shape. Second, selection of the cast preform-forging process was not well suited for the Alpha II design. Third, the shock absorber attachment was becoming large and heavy. To address these issues, a very different approach was taken for the Beta RLCA, as shown in Figure 7c.

Shock Absorber Attachment - The lower mount bushing was moved to the RLCA and a clevis added to the bottom of the shock absorber. Placing the bushing in the RLCA was well suited to the optimized section depth at this location. A single 16 mm fastener was used, which provides sufficient clamping force to withstand the severe pothole load. The number of fasteners per side was reduced from four to two, with the potential of reducing to one by using a weld nut on the clevis. In the first Beta design, a clevis attachment for the ride spring was also investigated.

PRODUCTION DESIGN - In the production RLCA shown in Figure 7d, the spring attachment was changed from the clevis concept to a grommet and link bolt. This method of attaching the spring has better articulation in all directions to decouple the fore-aft rate of the spring from the RLCA, and accommodate the lower control arm plan view displacement that occurs with camber adjustment. The stabilizer bar attachment was refined to allow use of the same link as the front suspension. The net mass savings to the vehicle for the production RLCA system was approximately 2 kg, compared to all other alternatives considered.

CONCLUSION

The suspension design of the 1997 Chevrolet Corvette was the product of a dedicated design team that used state-of-the-art computer techniques, prototyping, close cooperation with suppliers, laboratory and mule vehicles while following a logical and comprehensive methodology. The C5 systems engineering process began with the voiced desires of the customer and guided the design and development through to the production designs. The final suspension designs provide ride and handling characteristics that meet or exceed targeted performance. Improvements were made for durability, manufacturability, enhanced alignment and trim height control and low mass. Compared to C4, tolerances were reduced for trim height by 36%, bumper height by 60% and cross-camber and cross-caster by 50%.

The net result of the design effort for the 1997 Chevrolet Corvette suspension systems is an uncompromised balance of ride and handling that re-defines Corvette performance and continues it's unique heritage.

ACKNOWLEDGMENTS

Evolution of the C5 suspension designs were the result of an exceptional team effort by a group of individuals too numerous to recount. The authors would be remiss, however, if they failed to acknowledge the contributions of the following General Motors individuals: Al Bodner, Jerry Ferranti, Kasi Goundan, Cliff Jao, Rich Kowalczyk, Scott Larson, Jim Lloyd, Dave McClain, Mike Neal, Norm Sawaya, Rex Stump, and Dave Wickman.

ABSTRACT

In this paper the criteria and the requirements for the approval of the service strength and the durability of vital car suspension components are treated. The overview of the main influences on the fatigue life is given and the methodology for the design evaluation and a reliable time and cost saving development, including durability approval, are described. These include:

- Description of representative, customer related loading
- Procedure for design evaluation based on customer usage
- Corresponding test programs for durability approval including the requirements for statistical validation and quality assurance of manufacturing.

On two examples - a wheel and a suspension arm - the procedure including individual steps is explained.

INTRODUCTION

Criteria and Requirements for Design and Durability Approval

Trends in vehicle development in recent time are influenced by opposing requirements - on one side, the vehicle should have high efficiency and performance with low impact on environment (low emission, noise, waist at the life end), and on the other side an improved reliability and safety should be realized. Finally, these achievements should be accompanied by low production and possibly also low maintenance (service) costs.

To satisfy all of these requirements a light-weight design is of paramount importance. But for the light-weight design approach it is essential that the required service life is assured under all possible usage conditions, especially for the components for which failure may cause accidents. These are most of the vehicle suspension components like wheels, hubs, spindles, suspension arms etc.

The most important criteria for the design of such vital components are the attainment of the expected **service life** with the required **reliability** and **safety,** whereby applicable standards and regulations must also be observed.

The **service life** depends primarily on the loading conditions in service [1, 2]. Figure 1 shows schematically how the character of service loads will influence the service life. In this figure the fatigue life *L* curves are presented in relation to the stress amplitude S_a for different stress (loading) spectra, as a typical S-N-diagram, whereby the stress amplitude $S_{a,l}$ is based on the components' endurance limit for which the value is $S_a = 1$. It can be seen that for a maximum stress amplitude $\bar{S}_{a,o}$ of the load-time history resulting in a spectrum, called also cumulative frequency distribution [3, 4, 5] of type *A* (constant amplitude loading) the fatigue life will be, for example, 200 times lower compared to the varying amplitudes with the spectrum *B* or 2000 times lower compared to the spectrum of the type *C*. For the design spectrum of the type *D*, consisting of two individual spectra that are valid for specific loading conditions, like cornering and straight driving for wheels [6] the fatigue life will be about 10^4 times higher than in the case of spectrum *A*.

If the comparison is made for an allowable stress in the case of a design life L_o (corresponding to e.g. 300 000 km for passenger cars which lead to about $2 \cdot 10^8$ cycles as shown in Fig. 1), which is related to the endurance limit ($S_{a,A} = 1$ being allowable stress for spectrum *A*) the values will be

$\bar{S}_{a,B} = 1.3$ means the allowable stress for spectrum *B* will be 30 per cent higher than the endurance limit,

$\bar{S}_{a,C} = 1{,}7$ the allowable stress for spectrum *C* is 70 per cent higher than the endurance limit, or even

$\bar{S}_{a,D} = 2.1$ the allowable stress for spectrum *D* is 110 per cent higher than the endurance limit.

These relations depend besides on operational loading also on material properties [2, 7] and design data (stress distribution, stress state). But for an optimum light-weight design the loading spectrum related to usage conditions is of paramount importance.

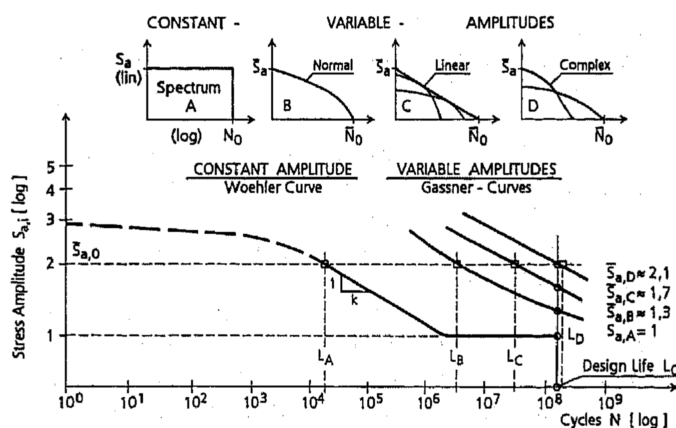

Fig. 1: *Influence of the Load (Stress) Spectra on the Fatigue Life and on the AllowableStress*

It must be regarded that for a reliable evaluation of the service fatigue life the probability of occurrence of the design spectrum must be defined [2]. The scatter in service loading is relatively high. This is influenced by the vehicle usage, driver habits and capability and operational conditions. Some vehicles are used predominantly for long distance driving on highways and good roads achieving several hundred thousand of kilometers (spectrum *a* in Fig. 2); others are used mainly on country roads with a high amount of bad road sections and bends, and finally some only in cities with a high number of braking and accelerating operations (spectrum *b* and *c* in Fig. 2).

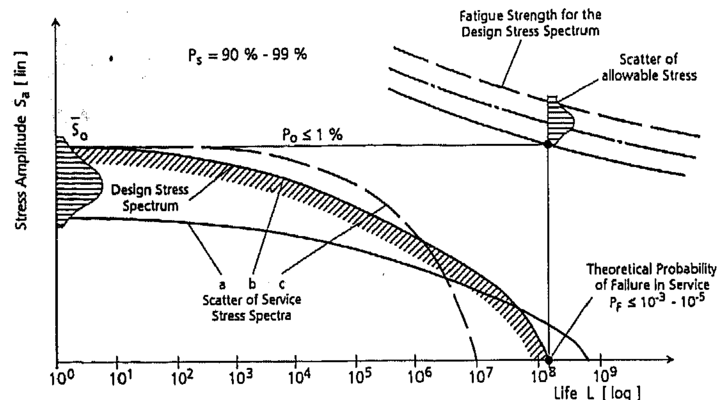

Fig. 2: *Scatter of Service Spectra and the Definition of the Design Spectra*

For reliability analysis a design spectrum must take into account both scatters. This should be done assuming a **design life L_o** and a **standardized spectrum** (e.g. spectrum *b*), whereby the scatter is determined by recalculation of the loading intensity (damage) of individual service usage spectra using the damage accumulation procedure (Fig. 4). For vital suspension components it is absolutely necessary to use a "hard" design spectrum, which has a very low probability of occurrence (*P_o < 1 %*) and which includes maximum values of operational loads $\hat{S}_a$ for each individual loading case; this is shown schematically on Fig. 2.

Based on the probability of occurrence P_o and the scatter of components fatigue strength, the **probability of failure P_F** in service could be determined by an adequate statistical evaluation:

If, based on the scatter of the fatigue strength, a fatigue life curve with a probability of survival *P_s = 90 per cent* (failure criterion: an initial crack of the component with additional fatigue life in crack propagation before total fracture) or *P_s = 99 per cent* (failure criterion: fracture of the component) is used, the resulting **theoretical** probability of failure for the component will be *$P_F < 10^{-3}$ to 10^{-5}*.

This approach assures that the component under consideration will not fail during the expected service life in a way that may cause an accident [2]. By this procedure also the maximum operational loads of normal usage are included in the design evaluation and test programs, being of importance with respect to the structural yield point and possible global plastic deformations of investigated components.

Additional to the design spectrum it is necessary for some vehicle component to take into account some specific overloads generated by special events or even accident-like loading. These loads are predominantly impact loading and do not influence directly the fatigue behavior; their influence must be separately controlled, as it is the case in regulations for cast aluminum wheels [6, 8].

To fulfill the requirements concerning the required durability life it is important that the failure criteria is adequately determined. A definition that "no fatigue cracks" should occur under the usage is not possible for an up to date design, due to technical and economical reasons. As shown on Fig. 3, for a representative load spectrum the durability life is determined based on a certain failure criterion, called technical crack, detectable with simple means like dye check or even by the naked eye.

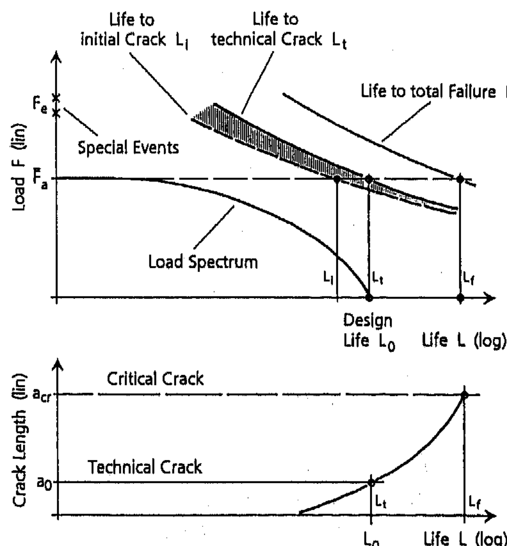

Fig. 3: Failure Criterion and Durability Life

The **safety**, an important criterion, is largely determined by the components ability to cope with unexpected over loads F_e without catastrophic failures. It is of decisive importance for the safety components that under overloading total fracture doesn't occur. This overloading, occurring outside the normal usage mission, is often defined as a **misuse**, and therefore assumed that it could be neglected by the design. This could be a great risk from the legal point of view if this concerns a vital, safety component. Generally, these high impact loadings, which occur e.g. by driving with higher than allowable speed over speed bumps or if a vehicle hits a curb in a bend, is defined as "a special event loading" and must be covered by the design and the material selection, nevertheless they do not influence the fatigue damage and are therefore not included in the design spectrum and durability approval.

For the criteria concerning the allowable technical crack in durability tests it should be kept in mind that, beside the requirement that such a crack should have a low crack propagation rate, it should also not lead to a component's total fracture if loaded by a **special event loading.** The requirements concerning the **special event loading** differ at individual vehicle companies and it will be beyond the scope of this paper to treat them.

Because the existing procedures for fatigue life estimation are of limited accuracy, the final durability approval must be carried out experimentally. This is done as well by driving with vehicles over proving grounds as by tests in laboratory. To decrease the development time and to achieve a light-weight design already in a very early stage, tests under simulated operational loading are necessary.

To carry out such tests an appropriate test facility, in which the **generated component's deformations correspond to that under operational loading** and a **reliable test program,** must be available.

A vehicle prototype for service measurements to derive a drive signal for testing is usually not available at this stage of development. Using standardized test programs [2, 6, 8 to 13] the preliminary durability approval can be carried out. Such programs are adapted to individual vehicles adjusting "basic program" by factors which depend on vehicle data and its representative usage.

When a vehicle prototype for road measurements is available, the assumed loads for durability tests can be controlled by simple short-time measurements with wheel load sensors [14] and the test data verified. If the used and measured data differ, it is possible in most cases by recalculation of achieved results, to estimate the expected fatigue life for the measured loads.

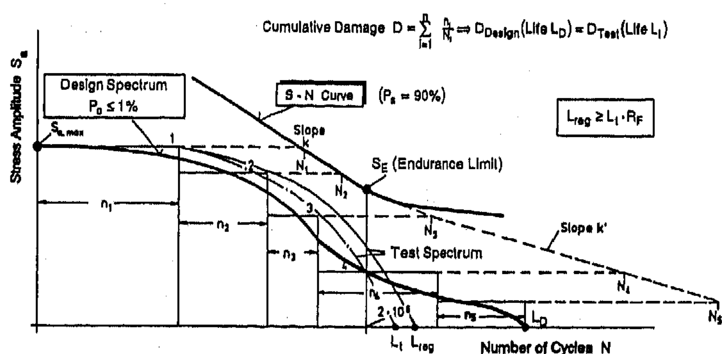

Fig. 4: Damage Fatigue Life Validation for Design and Test Spectrum by Modified Palmgren-Miner Damage Accumulation Calculation

To carry out the durability approval the damage accumulated in the test must be accelerated in relation to service [13]. The fatigue damage under accelerated test must correspond to the damage under customer usage. This means that the fatigue damage of the design and test spectrum must be equal, what could be verified by a relative fatigue damage calculation, as shown in Fig. 4. To take into account all possible damage influences, e.g. fretting corrosion, the test acceleration must be limited to a certain number of cycles, which should be achieved in tests to prove the durability life. For suspension components the required number of cycles should be not lower than $2 \cdot 10^6$ *to* $7 \cdot 10^6$ depending on the individual case [11 to 13].

Generally, the test acceleration should be based on the adjustment of the load spectrum in medium and high load levels and on omission of non-damaging low intensity loads, having high frequency of occurrence and predominantly originating from operational conditions during driving over smooth roads. The test acceleration by increasing maximum operational loads should be avoided, because it could change the fatigue damage development due to possible plastic deformation not occurring in service.
To meet the reliability requirements several durability tests should be carried out. Using a risk factor, based on the statistical approach [13] the required test life should be determined:

$$L_{req} \geq L_t \cdot R_F$$

L_t = Fatigue life under the test spectrum generating the damage equal to that under design spectrum

R_F = Risk factor, which takes into account possible misjudgment due to low number of tests and scatter of the components fatigue strength

Usually for durability life approval of vital suspension components at least three tests should be carried out, whereby a risk factor of $R_F = 1.4$ *to* 1.5 should be used [13, 16].

METHODOLOGY

The design evaluation and durability approval must include all parameters decisive for the service strength. An effective development must be a part of simultaneous engineering in the development, which includes a **design** and a **testing phase**. In the design phase, besides the stress analysis, the material selection including corresponding manufacturing procedure are also included. In the testing phase the approval of the design including the influence of the manufacturing on the components fatigue strength is carried out (Fig. 5).

This procedure guarantees a time saving, reliable design evaluation and durability approval including manufacturing influences.

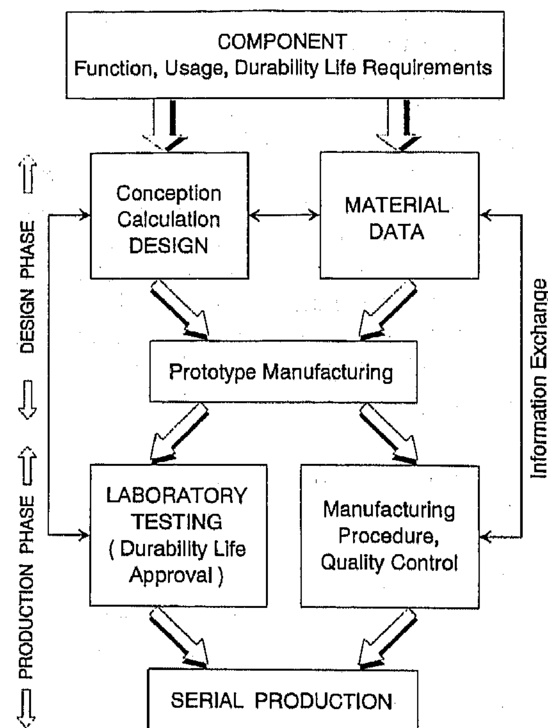

Fig. 5: *Procedure for an Effective Components Development*

To determine the durability life and to achieve an optimum design it must be known:

- the **operational loading** of the suspension under individual driving conditions
- the **allowable stresses**, which depend on material, manufacturing, design, and stress spectra.

OPERATIONAL LOADING -The main influences on the load spectra are: the **usage,** the **operational conditions** and the **dynamic behavior** of the vehicle including suspension. Decisive for the **usage** are vehicle utilization and driver, for the **dynamic behavior** it is vehicle design and tire properties, and for the **operational conditions** it is quality and type of roads.

If the data about usage and operational conditions are known, then, to determine the load spectra of a new vehicle, it is mainly necessary only to adapt the loads related to the vehicle data; the most important vehicle data are: dimensions, rated wheel loads, driving characteristics and vibratory behavior.

In service the suspension is subjected to variable loads, which originate from the road roughness and maneuvers like braking, steering or accelerating a vehicle (Fig. 6). The distinction between these sources is important for the derivation of the design or test spectra and for the design evaluation. The operational loads could be determined either by calculation based on the vehicle data or experimentally using a sensorized suspension or a measuring wheel (Fig. 6), whereas for a reliable load determination the experimental approach is often necessary.

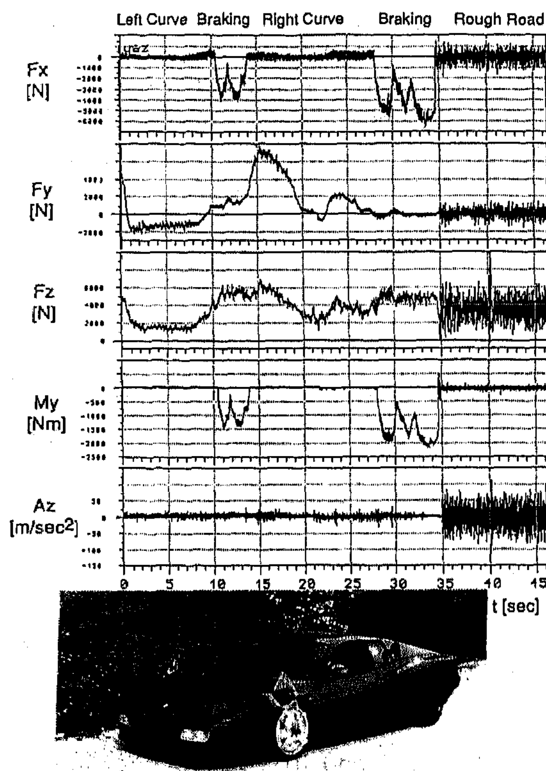

Fig. 6: *Operational Wheel Loads Sensed by Measuring Wheel VELOS 8 J x 18*

For the design evaluation the load-time histories, as shown on Fig. 6, must be transferred to the stresses generated on individual points of components. The stress-time history on a component depends both on the external loads and the responses of individual components to these loads. Basically, we have different response of the suspension rotating and non-rotating components as it can be seen on Fig. 7. For the rotating components the stress-time history is influenced by the cycles generated through rotation (these stress cycles are generated even at driving on ideal flat road surface at which condition non-rotating suspension components are stressed only by a possible prestress due to the payload) and superimposed stresses due to the variable operational loads. Also the mean stress of the rotating components doesn't change in maneuvers like cornering while this could be significantly changed on the non-rotating components, as it can be seen on Fig. 7.

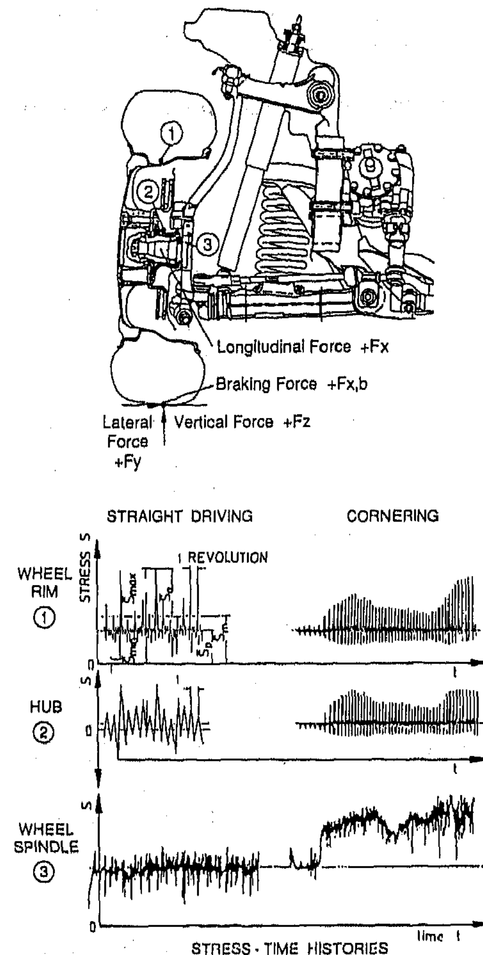

Fig. 7: *Stress-Time Histories on Individual Suspension Components*

Because the operational stresses vary at random, their evaluation is based on statistical counting methods [3 to 5]. The counting methods being of importance for the fatigue life evaluation and presentation of operational spectra are range pair ("rain flow counting") and level crossing counting, by which the ranges can be derived. It would be beyond this paper to treat the counting methods, used for fatigue life evaluation, in detail. It could be summarized that for the fatigue evaluation of suspension components, achieving more than 10^8 cycles during required operational life, a spectrum based on amplitude distribution (Fig. 8) fulfills the conditions for a reliable fatigue evaluation. This spectrum shows how often (value N) the stresses (stress amplitude $S_{a,i}$) have been reached or exceeded so that the analyzed stress-time history are classified only according to magnitude and number of occurrences. For the stress-

time histories with the mean value shift, like that shown for wheel spindle in the cornering (Fig. 7), the amplitude spectra of the range pair and the level crossing counting will differ, so that for the fatigue life evaluation (damage calculation) the mean value of both spectra should be used.

In Fig. 8 the main parameters of such a spectrum are presented.

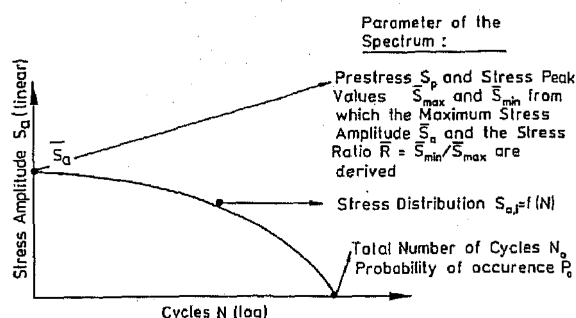

Fig. 8: Design Spectrum

The extensive research including the measurements and the evaluation of failures (damage, initial cracks, fractures) under proving ground tests, public road approval and customer usage was carried out to derive a representative design spectrum for wheels and hubs [2, 6, 8, 10].
On Fig. 9 the basic data necessary to derive the design spectra for **wheels and hubs** under the mission profile for West-European roads are presented. The operational stresses on wheels and hubs are mainly the result of the vertical wheel forces F_z and the lateral wheel forces F_y [6, 10]; longitudinal wheel forces F_x doesn't generate fatigue relevant stresses and should be considered only for the wheels with spokes.

	Loads		Spectrum Parameters			
Condition	F_z	F_y	N	N_β	N_e	Distribution
Straight Driving :	$F_{z,s}$	$\pm F_{y,s}$	$0{,}96 N_t$	$0{,}48 N_t$	$05 \cdot 10^{-6} N$	Linear
Cornering :	$F_{z,c,a}$	$F_{y,c,a}$	$0{,}04 N_t$	$0{,}02 N_t$	$12{,}5 \cdot 10^{-6} N$	Normal

Total Frequency $N_t = \frac{10^3}{2 \cdot r_{dyn} \cdot \pi} \cdot z \cdot L$

L = Design Life in km
r_{dyn} = dynamic tire radius in m
z = Number of cycles for a wheel revolution
N_β = Frequency of the basic stresses $S_{a,stat}$ under rated wheel load $F_{z,stat}$
N_e = Frequency of Maximum Values

Fig. 9: Basic Data for the Derivation of Stress Spectra on Wheels and Hubs

The decisive load cases for the fatigue life of wheels and hubs are **straight driving** and **cornering** [6]. The loads which determine the stress at **straight driving** $S_{a,s}$ are maximum vertical load $F_{z,s}$ and in-phase lateral loads, directed inside ($+F_{y,s}$) and outside ($-F_{y,s}$) the vehicle; in **cornering** of importance are only the maximum vertical ($F_{z,c,a}$) and lateral ($+F_{y,c,a}$) load acting on the wheel positioned on the bend outer side by which the maximum cornering stress $S_{a,c}$ is generated.
The operational stresses of wheels and hubs correspond to the oscillation of the basic stress amplitude $S_{a,stat}$ due to the wheel rolling under its static vertical load $F_{z,stat}$ (the rated wheel load) and by superimposed stresses generated through variable service loads acting in straight driving and cornering.
Figure 10 shows in generalized form the spectra derived by the data given in Fig. 9.

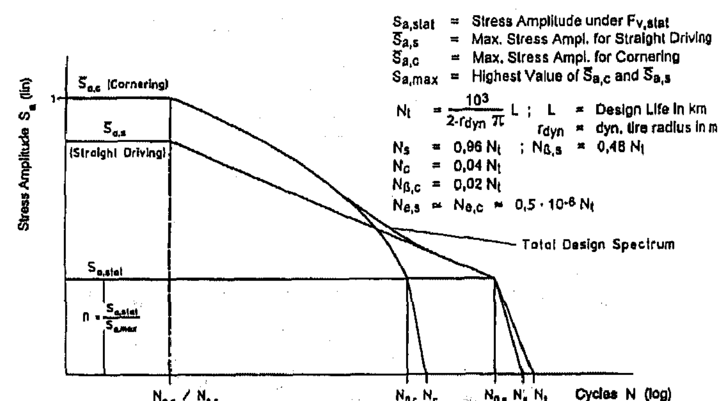

Fig. 10: Generalized Description of Wheel and Hub Design Spectra

The data on Figs. 9 and 10 cover the existing recommendations for the durability approval of wheels and hubs from SAE, JASU, TÜV [6, 8, 10], so far in using test facilities a service-like deformation in critical areas is achieved, which for rotating bending test facilities is seldom the case. Also the known requirements for durability approval on proving grounds or public roads by individual vehicle companies in most cases are covered too.

As the state-of-the-art for **non-rotating suspension components**, for the preliminary design evaluation and the durability approval by tests, the data in Fig. 11, based on existing data and experience [11, 12, 15 to 17], can be used. The decisive load cases for the fatigue life of these components are: **straight driving, cornering** and **braking / accelerating** is by experience of importance only in the case of driven axles. The decisive **straight driving** loading conditions to be taken into account are: simultaneously acting maximum vertical force ($F_{z,s}$) and lateral load

directed inside ($+F_{y,s}$) or outside ($-F_{y,s}$) of vehicle or longitudinal load acting toward vehicle ($F_{x,s}$). The maximum stress amplitude for straight driving $S_{a,s}$ is derived from the maximum and minimum stress, whereby $S_{min,s} \leq 0$.
For **cornering** the loading conditions on the wheel at the outer side of a bend (loads $F_{z,c,a}$ and $+F_{y,c,a}$) and on the inner side (loads $F_{z,c,i}$ and $-F_{y,c,i}$) must be taken into account.
For **braking and accelerating** only the loads acting at maneuvers in straight driving are decisive, so that only a simultaneous combination of vertical loads ($F_{z,b}$) and the longitudinal loads ($F_{x,b}$) are of importance.

The number of cycles for individual spectra N and for maximum values N_e are given as values related to the total number of cycles N_t. The total number of cycles vary depending on dynamic behavior, but for fatigue evaluation, as a mean value for cars 500 cycles per km can be used.

	Loads				Spectrum Parameters		
Condition	F_z	F_y	F_x	$F_{x,b}$	N	N_e	Distribution
Straight Driving :	$F_{z,s}$ $F_{z,s}$	$\pm F_{y,s}$ –	– $F_{x,s}$	–	$0,96 \cdot N_t$	$N \cdot 10^{-6}$	Linear
Cornering : outer side inner side	$F_{z,c,a}$ $F_{z,c,i}$	$F_{y,c,a}$ $F_{y,c,i}$	– –	– –	$\frac{0,04 \cdot N_t}{20}$	50	Normal
Braking :	$F_{z,b}$	–	–	$F_{x,b}$	$3 \cdot 10^5$	$3 \cdot 10^2$	Normal

with Total Frequency $N_t = L \cdot l$
N = Frequency of individual spectrum, N_e = Frequency of extreme values
L = Design Life
l = Number of cycles per km

Fig. 11: *Basic Data for the Derivation of Stress Spectra for Suspension Components of Cars*

It is still in validation how well this data covers the durability test requirements on proving grounds and the public roads used for durability approval by individual companies, but it covers the known laboratory test requirements of certain individual companies as well for the case of the multiaxial loads as for uni-axial load testing.

The graphical presentation corresponds to the form given in Fig. 10 for wheels and hubs, where in the periodic stress amplitude $S_{a,stat}$, generated by the rolling wheel with the frequency of occurrence N_β, is to be dismissed. The spectra in a log (life, cycles) - linear (stress or load) diagram between the cycles N_e for maximum values and the total number of cycles N are described by a linear distribution for straight driving and a normal distribution for cornering and braking/ accelerating maneuvers.

ALLOWABLE STRESSES - The allowable stresses depend on **operational loading** and on **material properties, manufacturing procedure** and **design details**. Therefore, for a reliable design evaluation before any durability approval is made, a good knowledge about individual influences is necessary. Due to the manufacturing procedure the hardness distribution, the grain size, the surface roughness, and the residual stresses can be decisively changed and thus the fatigue strength. It is known that through surface treatment an increase of the fatigue strength up to 300 per cent could be achieved, depending on material properties, stress distribution, type and level of stress-time history.
The design details can influence the stress concentration (notch factor K_t), the stress distribution in the components crack propagation section and the stress state (bending, tension, multiaxial stress state), which all have effect on the fatigue strength too. Generally, it should be regarded that the increase of the material ultimate (static) strength doesn't improve the fatigue strength proportionally and depends decisively on the design details as well as on the manufacturing process.

As an example the fatigue strength data for the cast aluminum wheels (Al Si7 Mg, T6) are summarized by Fig. 12. The fatigue strength for different wheel areas differ due to influence of prestress ($R = 0.2$ for rim and $R = -1$ for disc areas), stress distribution and the damage mechanism.

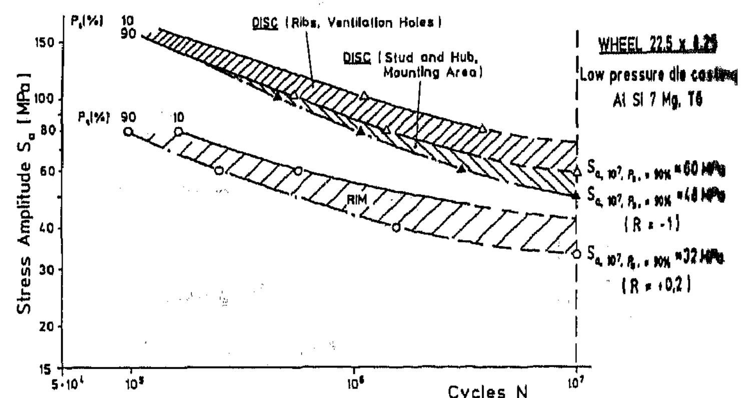

Fig. 12: *Fatigue Strength Data for Different Wheel Areas of Low-Pressure Die Casting Al Si7 Mg, T6*

More data and details concerning the fatigue strength of materials and suspension components including influences and procedures to improve the fatigue strength can be found in corresponding literature and data banks.

As a general comment it must be understood that a fatigue evaluation of a design, based merely on material fatigue properties determined under strain controlled cyclic loading, can't deliver reliable results, if additional influences on components fatigue strength are not taken into account.
It must be emphasized that a good design is of paramount importance. We have to keep in mind that due to the exponential relation between fatigue life and the stress

$$N_x = N_o \cdot \overline{S}_{a,x}^{-k} \text{ (see Fig. 13)}$$

a decrease of the stress by 10 per cent can increases the fatigue life roughly by 100 per cent. It means that a small change in design shape or dimensions can satisfy the requirements for an increase of the fatigue life. The relation between the fatigue life and the dimensions depend, on the stress distribution in the critical components section and is described by the equation:

$$t_o = t_x \, (N_o \, / \, N_x)^{\frac{1}{k \cdot n}},$$

where:
- N_o = required fatigue life
- N_x = achieved fatigue life
- t_o = required thickness to reach N_o
- t_x = existing thickness
- k = slope of the fatigue life curve (usually between $k = 4$ to $k = 7$)
- n = ratio of the stress change through thickness ($n = 2$ for pure bending and $n = 1$ for pure tension/compression stress).

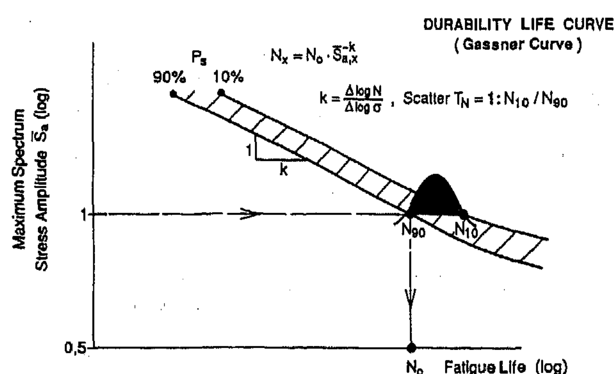

Fig. 13: Relation between Operational Stress and Fatigue Life

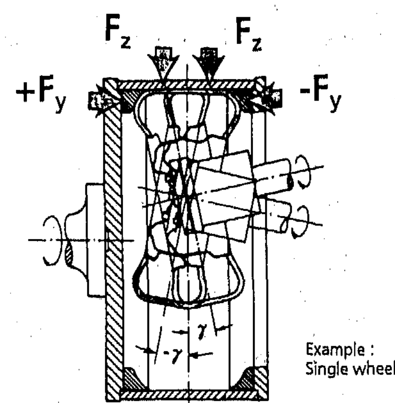
Finally it should be mentioned that for a state-of-the-art fatigue life scatter in the production of suspension components [2], depending on the production technology, a value $T_N = 1 : 3 \text{ to } 1 : 4$ (see Fig. 13) should be achieved. This data should be used as a basis to determine the requirements (risk factor R_F) for the durability approval of the suspension components.

DURABILITY APPROVAL

Because the existing procedures don't satisfy the requirements for a reliable fatigue life prediction the durability approval of vital suspension components generally is made experimentally by tests in laboratory as well as on roads (proving grounds). To guarantee a time and cost effective development the experimental tests on components should be made in an early development stage. To carry out such tests appropriate test facilities including load programs [8 to 12, 15 to 18] must be available. A general approach to the durability approval of rotating components (wheels, hubs) and non-rotating suspension components will be presented.

PROCEDURE FOR DURABILITY APPROVAL OF THE ROTATING SUSPENSION COMPONENTS (WHEELS, HUBS) - To assure a service-like durability approval of rotating suspension components the tests are carried out in a wheel/hub multiaxial load test facility. This test facility, which is increasingly used at vehicle and wheel producer companies, allows an effective and reliable durability approval, whereby a wheel with mounted tire runs inside a drum and simulated loads are generated by servohydraulic cylinders.

There exist basically three different variations of this facility, which all have in common the same basic loading principle, shown on Fig. 14a; more details can be found in the literature [16].
The time history of the loading program used in such a test facility, which takes into account the mission profile for the West-European loading and usage conditions and the generated strain in a point of the wheel disc are presented in Fig. 14b.



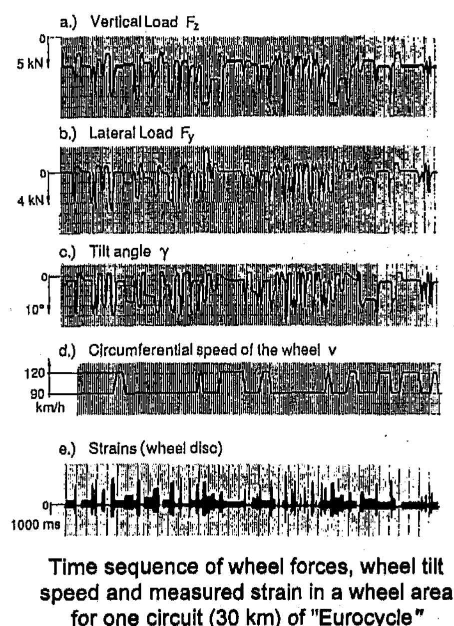


Fig. 14a: Loading Principle for the Testing of Rotating Suspension Components

Time sequence of wheel forces, wheel tilt speed and measured strain in a wheel area for one circuit (30 km) of "Eurocycle"

***Fig. 14b:** Standardized Load Program for Rotating Suspension Components*

In Fig. 15 the design spectrum derived by the data on Fig. 9 and the test spectrum for the generated stress in the wheel disc are presented. The requirement is that the fatigue damage induced by test program D_T has the same value as the damage of the design spectrum D_D ($D_D = D_S + D_C$, whereby D_S represents the damage at straight driving and D_C at cornering):

$$D_T = D_D.$$

This is realized by the standardized test spectrum, called "Eurocycle", whereby a test distance of 10,000 km is needed for aluminum wheels, taking into account that three tests are carried out for each wheel type and a corresponding safety factor R_F, as discussed in Chapter 1.

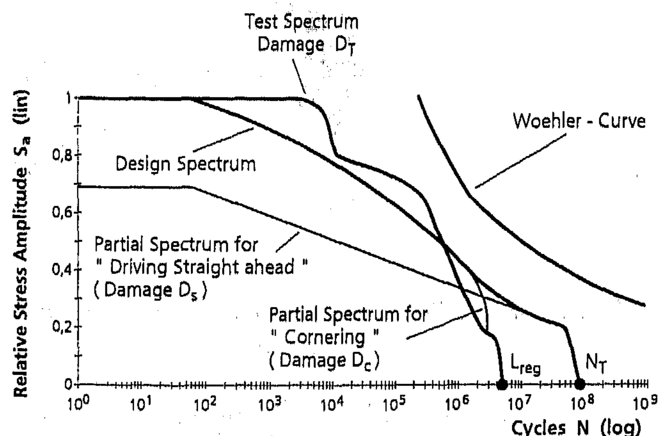

***Fig. 15:** Design (300 000 km) and Test (10 000 km) Spectrum for Light Metal Car Wheels*

As an example the results of a durability approval on a cast aluminium wheel 6 J x 14 are presented. The wheel has as a result of its design relatively high local stresses in the connection area between disc and rim on the cooling hole (spot A1, Fig. 16), whereby the nominal stress in that section is relatively low being primarily bending. At Area *B* the local surface stress on the inner side is about 30 % lower compared to spot A1 (Fig. 17), but the nominal stress level is higher because in this section primarily tensile or compressive stresses occur during wheel rolling. These stress conditions result in the following failure mode development (Fig. 17):

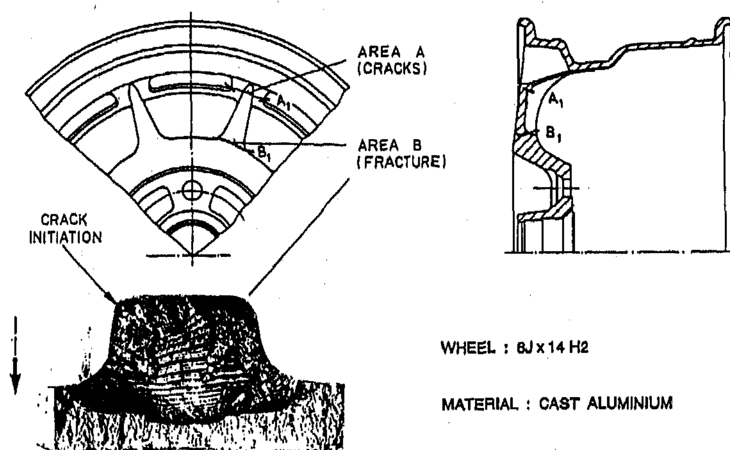

***Fig. 16:** Fracture under Durability Tests in the Biaxial Wheel Test Facility*

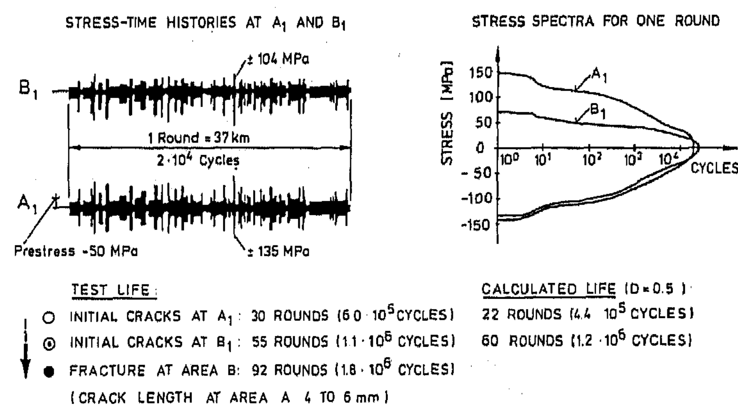

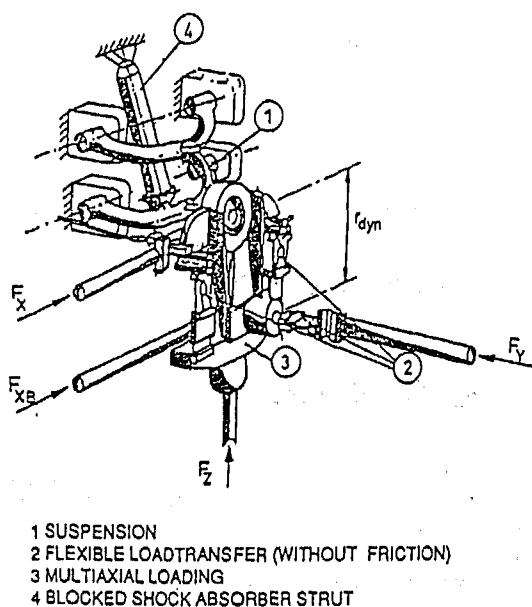

***Fig. 17:** Stress-Time Histories, their Spectra and Fatigue Life*

Initial cracks of approximately 1 mm are registered after about 1/3 for the total test life in the Area *A*. After 2/3 of the total test life the cracks occur also in Area *B*. The cracks propagate in this area quickly while in Area *A* very slowly.
Finally, the tests are finished because of the global deformation of the wheel due to very deep cracks in Area *B* (see Fig. 16), while the cracks in Area *A* are almost stopped after achieving a length of 4 to maximum 6 mm. So the improvement and redesign of the wheel is more important in Area *B* than in Area *A*, nevertheless, the local stress in this area is about 30 % higher.

PROCEDURE FOR DURABILITY APPROVAL OF THE NON-ROTATING SUSPENSION COMPONENTS - A schematic layout of the test facility for the durability approval of the non-rotating suspension components, from the spindle up to the shock absorber and a standardized load program are presented on Fig. 18a and Fig. 18b. The suspension components at this test are assembled to a "half axle". The four relevant loads, acting at the wheel, are generated by servohydraulic actuators. These loads are transferred through rods, joints and a wheel adapter to the wheel base (vertical, lateral and braking loads) or to the wheel centre (longitudinal loads generated by rough road and acceleration) and further transferred to the suspension components which have to be tested. The excitation of the servohydraulic actuators are made to be load controlled.

Fig. 18a: *Layout of the Test Facility for Durability Approval of Suspesnion Components*

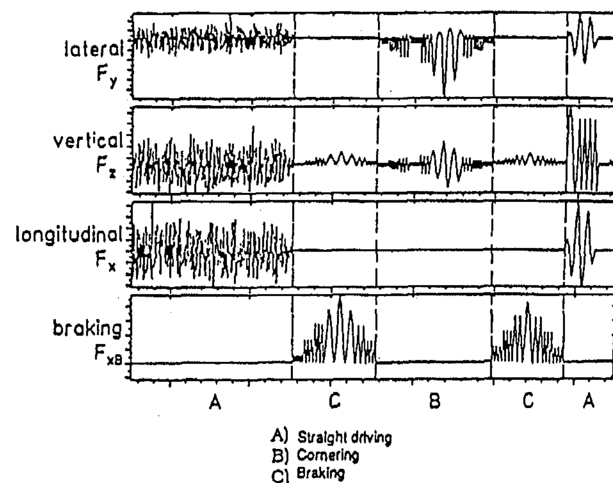

Fig. 18b: *Standardized Load Program for Durability Approval of Suspension Components*

The procedure for the design evaluation and durability approval will be presented on an example. On Fig. 19 a front suspension lower arm, manufactured by welding of steel sheet parts is shown. Based on vehicle data the loads for individual conditions - straight driving, cornering, braking - were determined and used as well for calculation of stresses in individual areas as for the adaptation of the drive signals (test program).

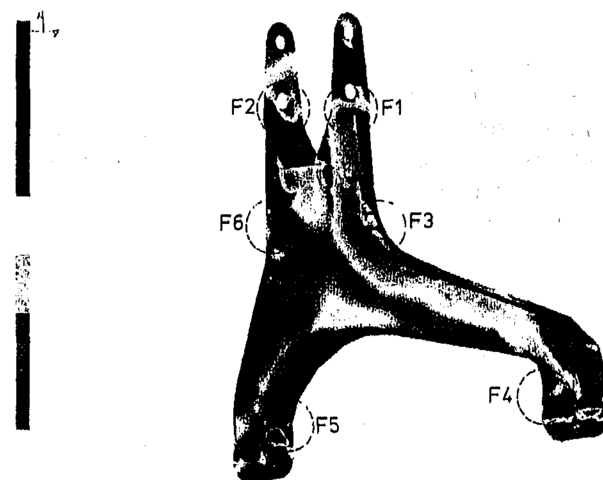

Fig. 19: *Front Suspension Lower Arm and Possibly Critical Area F1 to F6*

Based on preliminary theoretical design evaluation the prototypes were manufactured and experimentally investigated. In individual areas *F1 to F6* strain gages

were positioned and stresses analyzed under individual load case and compared with the stresses during durability tests.
An excerpt of the measured stresses in areas *F3*, *F5* and *F6*, superimposed to the pre-stresses, induced by static suspension load, are reproduced in Fig. 20. It can be seen from this recordings that the highest stresses in the areas *F3* and *F6* are generated by braking, being mainly bending stress at the sections *F3* to *F6*, while in the area *F5* the higher stress, being generally much lower than in areas *F3/F6*, are induced through straight driving.

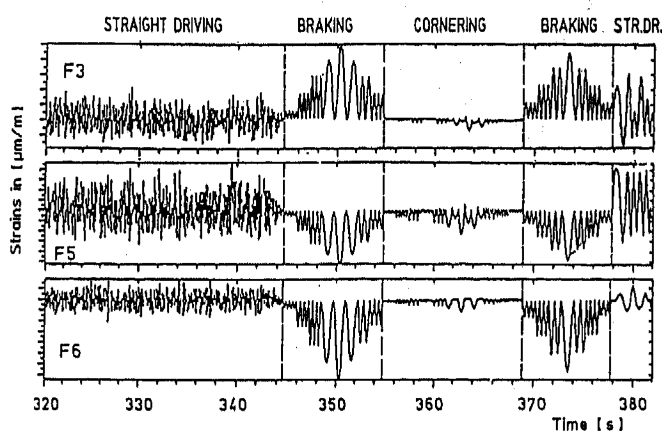

Fig. 20: *Measured Strains in Areas F3, F5 and F6 at Durability Test*

Based on the data in Fig. 11 the stress spectra for individual load cases are derived and compared with the test stress spectra; the results obtained for area *F3* and *F5* are shown on Fig. 21 and Fig. 22.

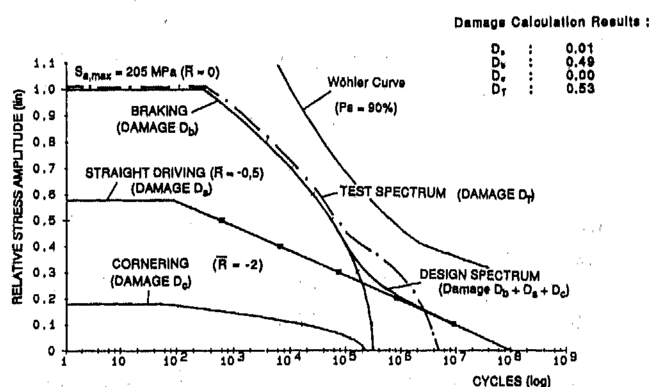

Fig. 21: *Comparison of the Design (300 000 km) and the Test Spectrum - Area F3*

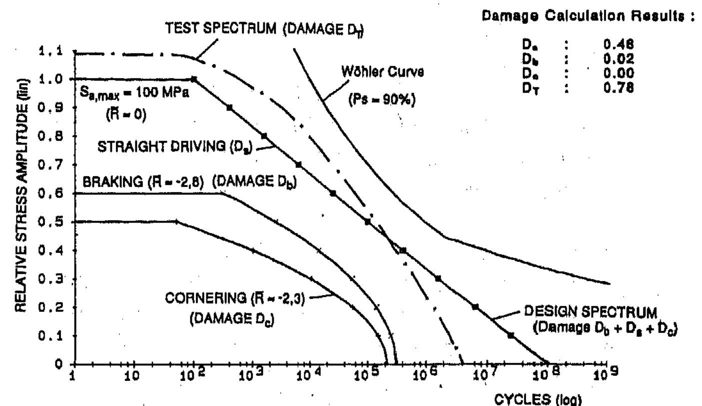

Fig. 22: *Comparison of the Design (300 000 km) and the Test Spectrum - Area F5*

For the design evaluation also the analysis of the fatigue damage induced by individual loading were carried out simultaneously. These analysis delivered the following results:

Area F 3:

The fatigue damage in this area is influenced almost only by braking (partial damage of braking spectrum $D_b \approx 0.49$, damage at straight driving $D_s = 0.01$ and cornering $D_c \approx 0.00$). This means that if a redesign should be necessary, it should be concentrated mainly to decrease the stresses due to the longitudinal forces.
To achieve the required fatigue life based on an allowable total damage $D \leq 0.5$ an endurance limit of $S_e \geq 0.42 \cdot S_{a,max}$ taking into account a slope $k = 4$ *to* 6 valid for welded steel sheet components. For the maximum stress amplitude $\overline{S}_{a,max} = S_{a,b} = 205$ *MPa* an endurance limit $S_e \geq 86$ *MPa* is needed in this area, what could be realized by good manufacturing for welded steel sheet components.
Based on the damage calculation the damage in the durability test corresponds quite well the damage for the design spectrum ($D_D \approx 0.5$ and $D_T = 0.53$). Similar results are obtained for areas *F2* and *F6.*

Area F 5:

The damage in this area is mainly influenced by straight driving $D_s = 0.48$; the damage due to the braking is about $D_b \approx 0.02$, while in cornering the value is very low $D_c \approx 0.00$. Based on an allowable total damage $D = D_s + D_b + D_c \leq 0.5$ an endurance limit (under same conditions as for area *F3*) of $S_e \geq 0.43$ $S_{a,max}$ should be realized;

for the value of $S_{a,max} = S_{a,s} = 100\ MPa$ an endurance limit of $S_e \geq 43\ MPa$ is necessary, which could be easily achieved.
The damage of the test spectrum in this area is $D_T \approx 0.78$ being higher than the damage of the design spectrum ($D_D \approx 0.5$), but due to low stress level without influence on the validation of durability life.

The result of durability tests show that the required fatigue strength in individual areas and corresponding durability satisfy the demand, whereby initial fatigue cracks appeared after achieving the required test life in areas F1, F3 and F6. On Fig. 23 an example of the typical failures during durability tests are shown. The cracks occurred in the areas F3 and F6, near the stabilizer fixture, and F1 at the weld toe. The achieved results verify that the test requirements based on load assumptions are satisfied.

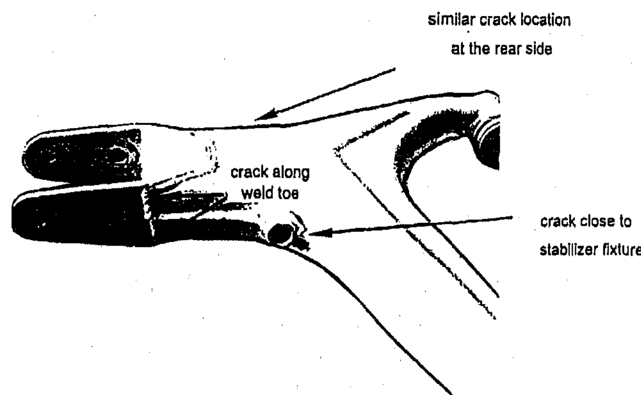

Fig. 23: Damage Locations at Durability Approval

To verify these results the measurements concerning expected operational loads (as shown on Fig. 6) and the stresses were carried out with the prototype vehicle; the stress measurements were carried out with the suspension arm used for stress analysis in the test facility.
The results of these measurements have shown that the assumed loads for individual conditions generally correspond to the measured loads with cornering and braking slightly lower than calculated. The achieved stresses in individual areas correspond also generally to the simulated stresses, whereby related to fatigue damage non-significant differences between measured and simulated stresses in individual areas were found.

CONCLUSION

For a reliable approval of vital suspension components the following conditions must be fulfilled:

1. **The representative loading, which include the maximum values, frequency of occurrence distribution and the total number (called load spectrum) for the specific mission profile (customer usage) must be defined.**
The load data should be a part of the specification to be used for the design evaluation and the durability approval. The load data must take into account all possible loading conditions, which maximum values during a customer usage would be seldom achieved; this is of decisive importance for the suspension safety components.

2. **The test programs for the durability approval should assure that the fatigue damage under operational loading is adequately verified.** To fulfill this requirement it is not recommended [13] to accelerate the durability approval by increasing the maximum test loads in relation to operational loads, but the acceleration is achieved by the omission of low intensity loading occurring predominantly at straight driving and by increasing the frequency of occurrence of the medium loads. Nevertheless, the total frequency of the test cycles should be not lower than $3 \cdot 10^6$ to $7 \cdot 10^6$ to simulate all fatigue damage phenomena, being of importance for suspension components.

3. **The design and durability approval should be a part of the simultaneous engineering process, in which the evaluation of material behavior and manufacturing procedures as well as design selection for prototypes to be proved, is carried out.**
For suspension safety components all influences on the strength and the fatigue life, especially for the light weight design, like material behavior under operational conditions, influence of the manufacturing process and components behavior under special event loading must be taken into account. It must be known that the most expensive failures, if a component doesn't meet the requirements, are made during design and approval stage

4. **The requirements for the quality assurance and control should be fixed based on results of design evaluation and durability tests.**
These requirements should guarantee a reliable service strength and durability.

Finally it must be emphasized that the future requirements for optimal light-weight design and improved reliability and safety will increase the demands on procedures being used to determine the service strength of suspension components. Therefore, the

further development is expected regarding standardized test procedures at which computer assisted design evaluation will be simultaneously carried out. This will allow an effective, time and cost saving control of the new designs and developments and yield also the data which may be important, should there be a question of product liability.

ACKNOWLEDGMENTS

This paper includes individual results of the project »Design and Dimensioning of Highly Stressed Welded Light Alloy Suspension Components«, supported by the European Community Project No. BE5249 (Contract No. BRE2-CT92-0181) and co-operating industrial partners AUDI-Ingolstadt, FERRARI-Maranello, and SPEEDLINE-Tabina di Caltana. We express our thanks to all of them.

Design and Operation of a New Vehicle Suspension Kinematics and Compliance Facility

ABSTRACT

A Kinematics and Compliance (K&C) facility is a test rig which undertakes quasi-static testing of vehicles to measure the K&C characteristics of the suspension and steering systems.

This paper describes a new K&C test facility which is a four wheel station machine designed to accommodate automobiles and light trucks. It is electro-mechanically operated, fully automated and computer controlled, and will complete a full suite of measurements in hours rather than days.

The first installation, at MIRA England, was commissioned in January 1996. Since then it has been in almost continuous use and a variety of vehicles have been tested; typical results are presented.

A second machine is now installed at the facilities of Goodyear Tire & Rubber Company in Akron, Ohio, USA.

INTRODUCTION

Kinematics is defined as the study of motion without reference to mass or force. Compliance is the deflection resulting from the application of force (ie the inverse of stiffness). These two words are particularly apt in describing a machine which measures kinematic characteristics due to suspension and steering system geometries and compliances due to springs, anti-roll bars, elastometric bushes and component deformations.

The study of suspension kinematics and compliances is not new. However, measurement rigs have improved over the years, not only because of improved technology, but also because of the increasing importance placed by the vehicle manufacturers on the need for complete and high-quality measurements.

With the increased thrust to reduce time from concept to production of a new vehicle, more and more use is being made of computer analysis and prediction techniques. Initial design parameters may be based on experience but, increasingly, use is being made of measurements on previous models and on competitor "target" vehicles. Suspensions are refined with the aid of computer ride and handling models for which measured data is essential; also managers need to ensure that development work is carried out only on vehicles that are known to be built to specification. All this can be achieved only by making the relevant measurements.

The test facility described here is a machine that measures the wheel displacements, and the forces and moments occurring at the tyre to road interface, caused by bounce, roll and pitch of the vehicle body and also by the application of simulated cornering, braking and traction forces.

The essence of the machine is that it subjects the vehicle suspension and steering system to a variety of forces and displacements applied slowly, so as not to excite any inertia forces from accelerating masses or any damping from shock absorbers or elastomers, whilst recording all the relevant deflections and loads.

BACKGROUND

Various systems for measuring suspension kinematic and compliance characteristics have been designed and installed around the world, some in vehicle manufacturing companies, some in component manufacturers and universities. Many are in-house designed and built and therefore each is often unique to its own institution.

However, to the authors' knowledge, there are three main threads to the development of a more widely adopted solution.

The advent of the radial ply tyre in France in the late 1940's created a requirement for more precise control of suspension kinematics, and early work in this area was done by Citroen in close collaboration with Michelin. The need to introduce longitudinal compliance whilst retaining good wheel control saw Peugeot collaborate with Michelin during the next decade.

As the popularity of the radial tyre grew worldwide, Michelin extended its "Suspension Static Test Facilities" first into the UK and later into the USA. Traditionally these rigs have moved the body of the car against a fixed ground plane, with the wheels supported on air bearings to allow free changes of track, wheelbase and steer.

Probably the most well known machine is the Chevrolet VHF (Vehicle Handling Facility) designed and built by General Motors in the USA [1]. This became operational in the early 1970's. Subsequently a number of machines have been based on the design of this facility. In this design the body is held stationary and the wheel platforms are moved in the vertical direction. In the plane of the ground the wheel platforms are servo controlled to provide forces or moments if desired, or to provide zero forces and moments to allow unrestrained track, wheelbase and steer changes.

The third line of development with the title SPMD (Suspension Parameter Measuring Device) started in the 1960's at Cranfield Institute of Technology in England under the direction of Professor J R Ellis [2]. In 1983 the National Highway and Traffic Safety Administration (NHTSA) of the US Federal Department of Transport sponsored an SPMD which was installed at the NHTSA operation in East Liberty, Ohio [3]. The design was further developed for an SPMD which was purchased by Goodyear Tire and Rubber Company and installed at its site in Akron, Ohio [4]. In this version, the SPMD moves the vehicle body against a fixed ground plane and uses servo controlled wheel pads in the ground plane to provide forces and moments.

CHOOSING A FACILITY FOR MIRA

Initially MIRA considered the feasibility of producing a facility from an in-house design. This would have drawn inspiration from previous experience of MIRA staff and the then-current methods of K&C testing. However, it was realised that this would have involved a degree of "re-inventing the wheel", and consequently a lengthy and expensive development process.

A commercially available solution was sought, but none (with service support in Europe) was found in a fully developed and production ready state. The survey included visits to the SPMD facility of the Goodyear Tire & Rubber Company in Akron, Ohio. This facility impressed the MIRA engineers because:

- The SPMD design had been under development for 30 years.
- At the time of the decision, the SPMD facility had been in successful operation for the previous four years.
- The SPMD is highly automated and can produce a complete map of suspension characteristics within a day or two (vehicle attachment or non-routine testing may increase this time).
- The SPMD produces data at the end of each individual test sequence so that results may be viewed as the test programme progresses.
- A number of US vehicle manufacturers have found the Goodyear facility useful and competent.
- Although retaining high accuracy and ease of use, the measurement system is simple in concept.
- The SPMD concept is based on the use of commercially available actuators and transducers, and the software control and analysis routines are constructed around commercially available packages.

SUPPLIER OF THE FACILITY - The then-current SPMD was a two wheel station device that required the test vehicle to be measured one axle at a time. From the outset it was envisaged that the MIRA K&C rig would be a four wheel station machine enabling two-axle operation and, hence, a further reduction in test time from that available on the SPMD facility. It was also envisaged that the rig would be capable of accommodating all vehicles from the smallest passenger cars to the largest light trucks.

These changes, and the consequent changes in test control requirements, demanded a radical re-think of the design. Goodyear had also been thinking of upgrading to a new generation machine along similar lines. With this in mind, it was decided to seek a designer and builder for the machine. The essential criteria for selection were that the supplier should have experience in designing, developing and marketing test equipment, and experience in design and development of vehicle suspension systems. The company chosen was Anthony Best Dynamics Limited (ABD).

THE DESIGN PHILOSOPHY BEHIND THE NEW SUSPENSION PARAMETER MEASURING MACHINE (SPMM)

In the concept stage there were three guiding requirements:

1) The design should be cost effective, simple and compact.
2) In use, the machine should be efficient, requiring the minimum number of operators and the minimum of maintenance.
3) MIRA was insistent that the machine should test both axles simultaneously.

There was a fundamental question to be answered: should the machine move the vehicle body or move the road? There are two arguments which favour moving the vehicle body:

- To apply the correct tyre loads, with the centre of pressure in the correct position for a vehicle running on a level road, the relationship between the tyre and ground should be correctly simulated. The simulated road surface beneath all wheels should lie in one plane whatever the position of the body in roll or pitch. If the body is held stationary and the suspension is exercised by vertical actuators effectively moving the road, then each of the wheel pads has to tilt both about a roll axis and a pitch axis and be controlled to lie in a plane. Conversely, if the body is moved, then the simulated road surface beneath each wheel does not have to be moved in the vertical direction, and all the surfaces will remain in one plane.

- Tyre characteristics such as camber are quoted relative to the ground plane. Therefore camber and steer angles should be quoted relative to the ground plane. This is more easily achieved by keeping the ground plane and the measuring transducers stationary.

Having decided to move the body against a stationary ground plane the question remained: how to do it?

This test philosophy implies that the machine must be able to move the vehicle body in pitch. The SPMD, which only moves the body in roll and bounce, uses a fixed pivot about which the roll and bounce frame is rotated. Extending this concept to add a pitch pivot proved very unattractive. To design any gimballed arrangement that would have sufficient stiffness to restrain the body satisfactorily, was difficult, and mechanically the concept seemed complex.

A number of alternative solutions were considered. The most mechanically attractive was to eschew the idea of fixed pivots and allow the table the full six degrees of freedom whilst ensuring that the table was properly constrained by six separate actuators. This meant that even for a pure vertical bounce movement all six actuators would have to be moved and the precise deflections for each actuator would have to be computed. However, today, appropriate computing power is available.

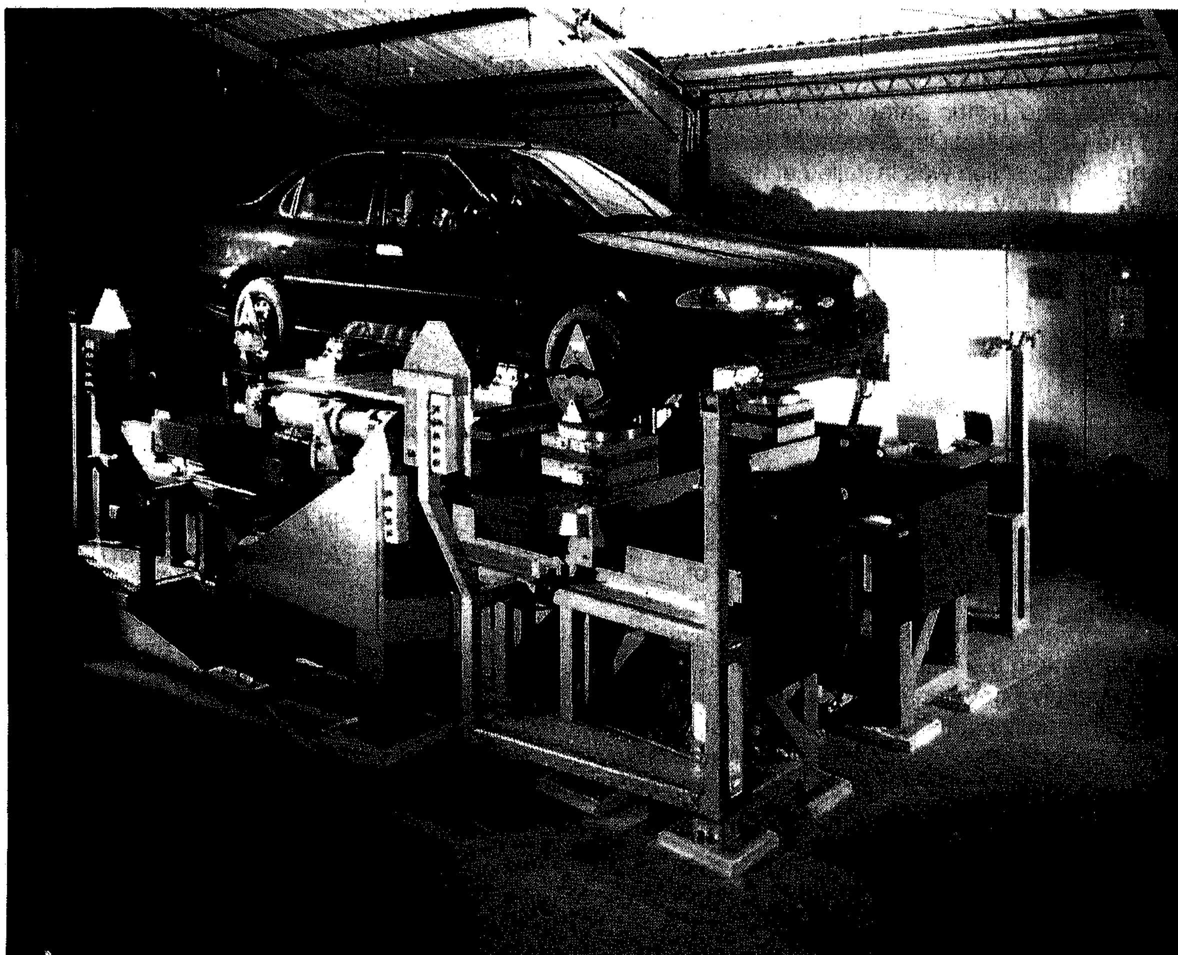

Figure 1 - SUSPENSION PARAMETER MEASURING MACHINE (SPMM)

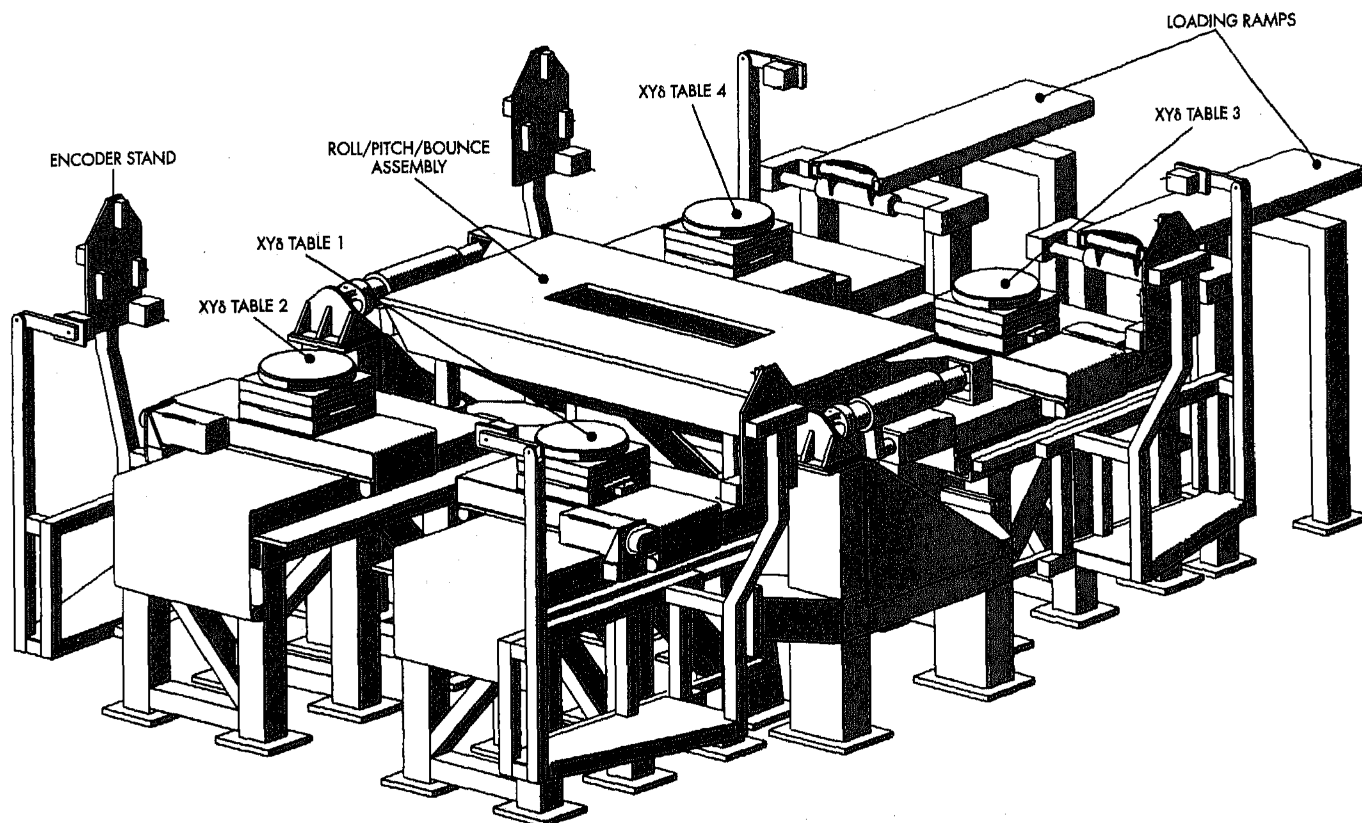

Figure 2 - SPMM GENERAL ARRANGEMENT

DESCRIPTION OF THE SPMM

OVERVIEW - The main structure of the machine consists of three different sub-assemblies: the Roll/Pitch/Bounce assembly, the XYδ tables and the loading ramps. Each XYδ table is bolted to the roll/pitch/bounce table, two in front and two behind. The loading ramps are attached behind the two rear XYδ tables. The arrangement is shown in Figures 1 and 2.

ROLL/PITCH/BOUNCE ASSEMBLY - The heart of the machine is the roll/pitch/bounce assembly (Figure 3) which controls the motion of the body of the vehicle under test. It comprises two rigid steel frames, the base frame (which is bolted to the floor and to the XYδ tables), and the moving frame, which is connected to the base frame by six "Rolaram®" linear actuators. The Rolarams® are connected to the base frame by special high rigidity universal joints, which allow them to pivot in any direction, but prevent rotation about their axes, and are connected to the moving frame via spherical joints. Three of the Rolarams® are oriented so that they act principally in the vertical direction, two so they act principally in the fore and aft direction, and one laterally. Accurate motion of the assembly is achieved by synchronised movement of all six actuators.

The Rolaram® actuators are commercially available units, driven by brushless DC brake-motors, which convert rotary motion to linear motion by means of a roller-screw assembly. This is intrinsically more accurate and rigid than re-circulating ball screws.

XYδ TABLES - Each of the four XYδ tables has a turntable upon which the test vehicle's wheel rests (see Figure 4). The turntable assemblies can be driven in the fore and aft (X) and lateral (Y) directions, and can be driven about their central vertical axis (δ). These motions enable horizontal forces or aligning torques (steer torques) to be applied to the wheel. In addition, the X and Y motions provide rapid computer-controlled adjustment to accommodate different vehicle wheelbases and tracks.

The X and Y axes are driven by brushless - DC motors via recirculating ball screws, and are mounted on pre-loaded rolling linear bearings, for maximum rigidity and minimum friction. The δ axis is driven, via a clutch, by a "pancake" DC motor and a Harmonic Drive gearbox, which provides a high reduction ratio with high stiffness and zero backlash.

Force measurement - Integral to each XYδ table is the transducer system for measuring the forces acting on the wheel. This eight channel piezo-electric system, manufactured by Kistler, enables the three orthogonal forces and moments about the pad centre to be determined. From these outputs, the location of the line of action of the resultant force, and the pure steer torque on the wheel are also determined.

The piezo-electric transducer system was chosen in favour of a strain gauge system for its high accuracy and low inherent crosstalk characteristics, its stability and proven reliability, its ability to provide both high loads and high resolution, and for its compact

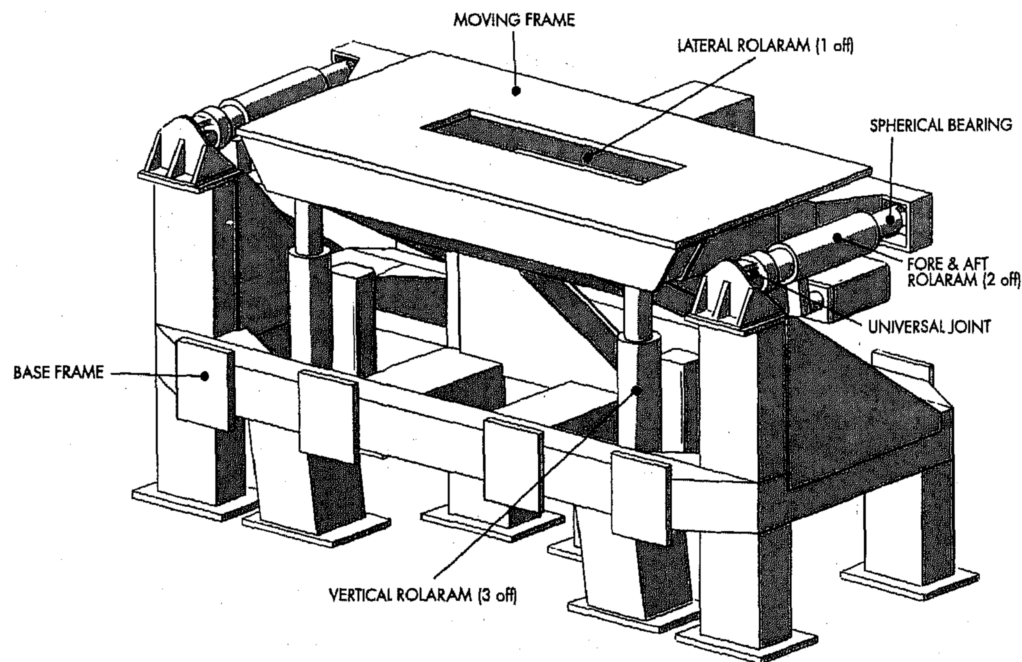

Figure 3 - THE ROLL/PITCH/BOUNCE ASSEMBLY

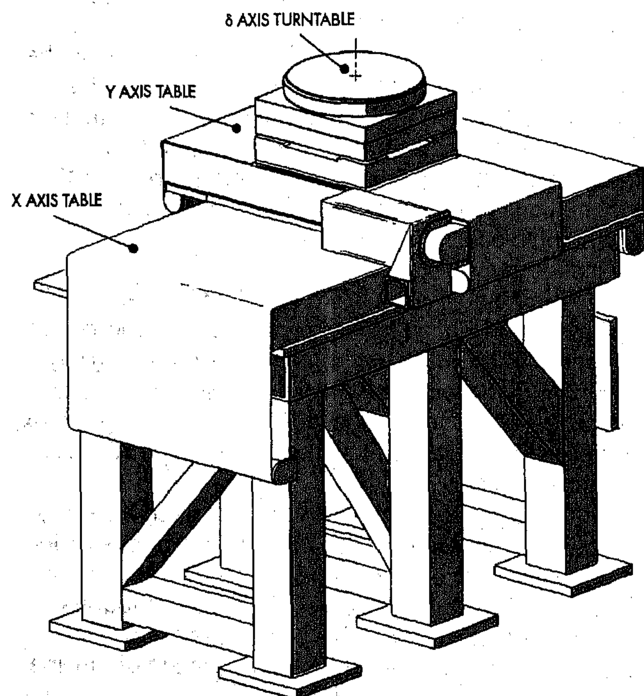

Figure 4 - THE XYδ TABLE ASSEMBLY

design. These advantages far outweigh the well known DC drift difficulties. The drift in a typical test period was predicted to be insignificant and this has now been proved in use

Wheel Position Measurement - The deflections of the wheels are measured by an array of optical "string" encoders which are mounted on a stand beside each XYδ table (see Figure 2). The encoder stands can be moved in the fore and aft direction on linear bearings to allow adjustment for different wheelbases.

Each encoder consists of a fine stainless steel cable, which is wound around a spring-loaded precision spool. As the cable is extended, the spool rotates an optical encoder which provides a digital position signal. The cables are hooked-up to a plate which is attached to the vehicle wheel in a known position. The plate is free to rotate about the axle line, and is weighted to hang vertically like a pendulum. As the wheel moves, each encoder of the array also moves. The encoder outputs are processed by the computer to determine the X, Y, Z, steer and camber deflections of the wheel. The castor change of the suspension is measured by a separate inclinometer which must be attached to the wheel carrier.

The wheel deflection measurement system has proved to be accurate and reliable. The system is easy to fit to the vehicle and is easy to understand and troubleshoot.

LOADING RAMPS - The ground plane of the rig stands approximately 1.5 metres above the floor, allowing easy inspection of the vehicle whilst under test. A standard garage lift is used to raise the vehicle to enable it to be loaded onto the rig. The two ramp

assemblies, attached to the rear XYδ tables, bridge the gap between the machine and the lift. The ramps are telescopic, and are pulled out and attached to the rear turntable assembly for loading and unloading the vehicle. This process is a computer co-ordinated automatic sequence, which enables vehicles to be loaded and ready for testing in less than one hour, and unloaded in about half an hour. During testing, the ramps are disconnected from the turntable assemblies and retracted (the positions shown in Figure 2)

STEERING WHEEL MOTOR - The characteristics of a vehicle's steering system can be investigated by testing with a drive-motor assembly attached to the steering wheel. This assembly uses a DC pancake motor and harmonic drive gearbox to provide motion, and has an integral transducer to measure the steering torques. The unit is designed to allow for eccentric steering column motion without distortion of the torque output, and reacts the torque onto the doors of the test vehicle.

CONTROL SYSTEM - A sophisticated machine-tool / robotic controller system (PMAC®) is used to synchronise the motions of the rig. The PMAC® system is designed to be interfaced with PC's, and consists of a number of plug-in boards which are installed within the PC. These boards control the feedback system for the SPMM's motors and capture all data from the measurement transducers.

The SPMM has 19 servo-controlled axes of motion, enabling it to subject a vehicle to a wide range of motions and forces. Up to 128 channels of data-capture measure simultaneously the forces on, and deflections of, the wheels, the body and the suspension.

SOFTWARE SYSTEM - The kernel of the SPMM software is its database, written in MAGIC®, which provides the principal user interface. The database stores all the set-up information for each vehicle tested, as well as all instrumentation data. It manages the processes of loading and unloading vehicles, performing tests and carrying out calibration routines, and monitors the status of the rig at all times. The database also catalogues the tests which have been performed for each vehicle, and interfaces with the post-processing software.

An individual test is defined by a single screen of numeric data, which specifies the motions and force limits for each axis of the machine. Tests are built up into sequences of one or more tests, which are run consecutively. A sequence of tests can be run fully automatically, or set to pause between tests to enable the results to be examined before continuing with the next test. Utilities provided in the system allow new sequences to be built up by copying from standard "templates", which define a particular type of test, or by copying sequences of tests from previous vehicles. The database will allow up to 26 sequences of tests, each containing up to 99 individual tests, to be defined for each vehicle, and will allow each of these to be run up to 99 times!

The standard post-processing supplied with the machine uses the commercially available plotting and mathematics package DIA®. This is used in two modes, interactive and batch. The interactive mode is used for examining and plotting test results on the computer screen, and can be used immediately a test is complete. It allows any measured channel, as well as a large number of derived data channels, to be plotted against any other channel, by means of an easy-to-use menu system. Multiple plots can also be overlaid. The batch mode can be used when a sequence of tests has been completed, to automatically perform standard post-processing and plotting for each test in the sequence.

Test results are stored in a standard binary format and can be transferred to other post-processing packages if required.

TESTING STRATEGY - In the current testing strategy, all tests are cyclic, with the cycle time being specified by the user (typically between 45 and 120 seconds per cycle).

Each axis of the rig can move independently from each other axis, and each axis has both displacement and force limits defined for it in the test definition. All axes can be set to "displacement" control, and all axes, except body roll, can also be set to "force" control. Axes under displacement control are cycled at a constant velocity between the displacement limits specified, with their motions synchronised. Motions can be either in-phase or in anti-phase. Axes under force control are programmed to maintain a constant force (or torque) level throughout the test cycle.

The system allows up to five consecutive cycles to be performed during a single test, and captures 256 points of data for each channel, each cycle. This produces a results file of approximately 1 Mb. The results for each cycle can be plotted independently, or all the cycles averaged. However, the normal testing method is to perform two cycles for each test and to plot the results of the second cycle (the first cycle being a "break - in" cycle). This gives data files of about 400 kb in size.

The SPMM has been designed to allow testing to be carried out with steel wheel substitutes fitted, although, for most tests, it is considered preferable to test with the normal road wheels and tyres fitted. The turntables of the wheelstations have high-friction surfaces which enable nearly 1 'g' to be generated in horizontal compliance tests. However, in these circumstances, there is often some tyre slip which results in there being residual horizontal forces at the end of the test cycle. The SPMM overcomes this by automatically performing a "lift cycle" to reset the vehicle between each test. In this cycle, the vehicle is lifted clear of the XY turnables, which are then moved to the correct positions to allow the vehicle to be lowered back to its datum ride height. As the vehicle is lowered, the XY turnables are servo-controlled to maintain zero horizontal force and to ensure that the tyres are correctly centred on the tables.

During steady-state cornering, an unrestrained vehicle rolls about its roll axis, maintaining the total vertical load at each "axle" constant. To replicate this behaviour during a roll test, and to obtain correct roll stiffness and lateral weight transfer information, the SPMM moves the vehicle simultaneously in roll, pitch and heave.

RANGE OF MEASUREMENTS

The SPMM offers a wide range of standardised and customised measurement possibilities.

The standard range of measurements includes the following:

- Roadwheel angular and rectilinear movements due to suspension system kinematics and compliances.
- Wheel vertical rates, tyre radial rates, suspension roll stiffness distribution and suspension horizontal compliances.
- Roll centre heights and anti-dive and anti-lift tangents.
- Steering ratio, steering system stiffness, Ackermann curves, kingpin offset, scrub radius and mechanical trail.

More detailed information is given in Appendix A.

SOME EXPERIENCES OF USING THE SPMM

At the time of writing, MIRA had been operating the SPMM for seven months, during which nearly fifty vehicles had their kinematic and compliance characteristics measured. Having gained a reasonable amount of experience in using the SPMM the following notes have been formulated.

PURPOSE OF MEASUREMENT - The SPMM provides the engineer with an important data set relating to vehicle ride and handling performance. The purposes of obtaining this data set can be broadly classified as follows:

Benchmarking - quantification of a competitor/class leading vehicle's kinematic and compliance characteristics in order to obtain a better understanding of its performance, or measurement of a prototype/production vehicle to verify its characteristics against the design intent.

Modelling support - verification of suspension system models against vehicle characteristics measured on the SPMM and modelling of whole vehicle dynamic behaviour using suspension derivatives from actual vehicle measurements.

Vehicle development - correlation of track based objective and subjective data with vehicle kinematic and compliance characteristics gives the development engineer a greater understanding of the influence of suspension system behaviour on the whole vehicle ride and handling performance. In particular the sensitivity of whole vehicle characteristics to variations in different suspension parameters can be explored, thus defining both the "ideal" characteristics and a tolerance bandwidth.

TEST CONFIGURATIONS - An initial examination of the test configurations listed in Appendix A may give the impression that a typical programme of kinematic and compliance measurements is reasonably short and concise. However, the SPMM is extremely flexible in allowing the user to drive any of its axes either singly or in parallel with each other whilst imposing displacement or force offsets on one or more axes. Hence, for example, a series of lateral force tests could be performed with the vehicle at different fixed roll angles and with the force input at a series of different trail values. Add to this the possibility of varying the force inputs in terms of amplitude and phasing in an attempt to simulate a "real" driving condition, and the test programme can quickly grow to a size where the volumes of data produced are large, unwieldy and of limited utility. The real value of the SPMM is that it allows the engineer to separate and identify the different suspension system kinematic and compliance parameters, and the test configurations should be structured to reflect this.

TURNAROUND TIMES - An original requirement specified by MIRA was a total turnaround time from the commencement of loading, through testing, to completion of unloading of not more than two days. This allowed for a test programme consisting of eight to ten tests assembled from those listed in Appendix A. In practice the SPMM has exceeded this requirement by a large margin with test programmes of around twenty five tests routinely completed within six to eight hours. One engineer with occasional technician help during the loading and unloading cycles can achieve this throughput.

CORRELATION - During and since commissioning of the K&C rig, correlation exercises have been successfully completed against the facilities of a number of vehicle mnanufacturers.

TEST RESULTS

As Appendix A indicates, a suite of tests on one car yields a large quantity of results, and it is beyond the scope of this paper to present more than a sample of the results available.

The authors have concentrated on presenting a small number of results which demonstrate interesting phenomena or trends.

Table 1 lists a selection of current European market sedans, giving vehicle type, drive configuration and principal dimensions.

Table 2 provides a comparison of some suspension stiffness and hysteresis characteristics associated with these vehicles, of all classes, and highlights some interesting phenomena.

Given that all the vehicles possess relatively "normal" weight distributions, there are fairly significant

differences in the ratios of front to rear vertical stiffness and, hence, in suspension frequencies.

Excessive wheelrate hysteresis is often detrimental to smooth road ride performance. In MIRA's experience, a target of 200 N or less is beneficial in this respect. It was surprising therefore to discover that many of the vehicles exhibited hysteresis values significantly larger than this. In general, those vehicles with "simple" suspension systems possessed the lowest values. One of the MacPherson strut derived systems displayed the lowest value for the front suspensions, although others of this type were considerably inferior. This indicates, perhaps, that spring offsets are incorrect or compromised by working space or roadwheel interference considerations. At the rear a twistbeam-derived suspension has the least hysteresis of the vehicles shown. The performance of the more "sophisticated" multilink types vary between 130N and 290N.

There is a large variation in rear suspension toe stiffness with respect to the lateral force, probably reflecting the decision of the designer either to hold the wheel rigidly or to employ some form of passive steer control.

Roadwheel longitudinal compliance is a significant contributor to impact isolation. Some of the vehicles in the "luxury" class possess an indifferent performance in comparison to the "cheaper" cars in this respect. Indeed the lowest stiffness/highest compliance is exhibited by a MacPherson strut type suspension system fitted to Car 3, a medium saloon.

From the roll test, one of the results produced is of the "Static Roll Weight Transfer Coefficient" or SRWTC. The SRWTC is calculated as:

$$SRWTC = \frac{2.dZf}{Zf} - \frac{2.dZr}{Zr}$$

Where Zf = front "axle" weight

Zr = rear "axle" weight

dZr = weight transfer across front "axle"

dZr = weight transfer across rear "axle"

The SRWTC is plotted against roll angle, and the graph produced can be interesting from two points of view. Firstly the gradient of the characteristic gives an immediate visual indication of which way the suspension roll stiffness is biased compared to the static weight distribution of the vehicle.

For example, a positive gradient indicates that the front "axle" reacts proportionately more lateral weight transfer during roll than it bears in static load; this is normally regarded as an understeering trend. A negative gradient would normally indicate an oversteering trend. Rear wheel drive cars tend to produce SRWTC graphs with positive gradients, whereas front wheel drive cars tend to produce SRWTC graphs with small negative gradients. In practice, the roll stiffness distribution may vary with roll angle and, again, the SRWTC graph gives a visual indication of this by showing a gradient which changes with roll angle.

The roll stiffness distribution can be calculated from the SRWTC gradient and from knowledge of the total roll stiffness of the vehicle (also measured during the roll test). This may be done to obtain an overall figure using average gradient and stiffness values, or to obtain a point figure using gradient and stiffness values at a particular roll angle.

The roll stiffness distribution may be calculated as follows:

$$\frac{Sf}{S} = \frac{t.Zf.Zr}{2Z} \times \frac{dSRWTC/d\theta}{dM/d\theta} + \frac{Zf}{Z}$$

Where Sf = front suspension roll stiffness

S = vehicle total roll stiffness

t = wheel track

Z = vehicle total weight

θ = roll angle

dSRWTC/dθ = gradient of SRWTC versus roll angle graph

dM/dθ (=S) = gradient of rolling moment versus roll angle graph

The second aspect for which SRWTC plotted against roll angle provides a very sensitive indication is an effect of friction in the suspension system. The introduction of friction turns a line graph into a hysteresis loop. Large disparity between the amounts of friction in the front and rear suspensions, combined with a low SRWTC gradient, tends to produce large hysteresis. The effect of this is to make the roll stiffness distribution indeterminate during transient handling manoeuvres involving roll angles within the hysteresis loop. For such vehicles in such manoeuvres, the understeer/oversteer effects of roll stiffness distribution may be unpredictable.

Table 1. Vehicles Subjected to Kinematic Compliance Test

	Vehicle Type	Drive Configuration	Wheelbase, m	Track, m Front	Track, m Rear	Test Weight, kg Front	Test Weight, kg Rear

Notes: 1. W/C = Wheel Centre
2. SRWTC = Static Roll Weight Transfer Coefficient (see text)

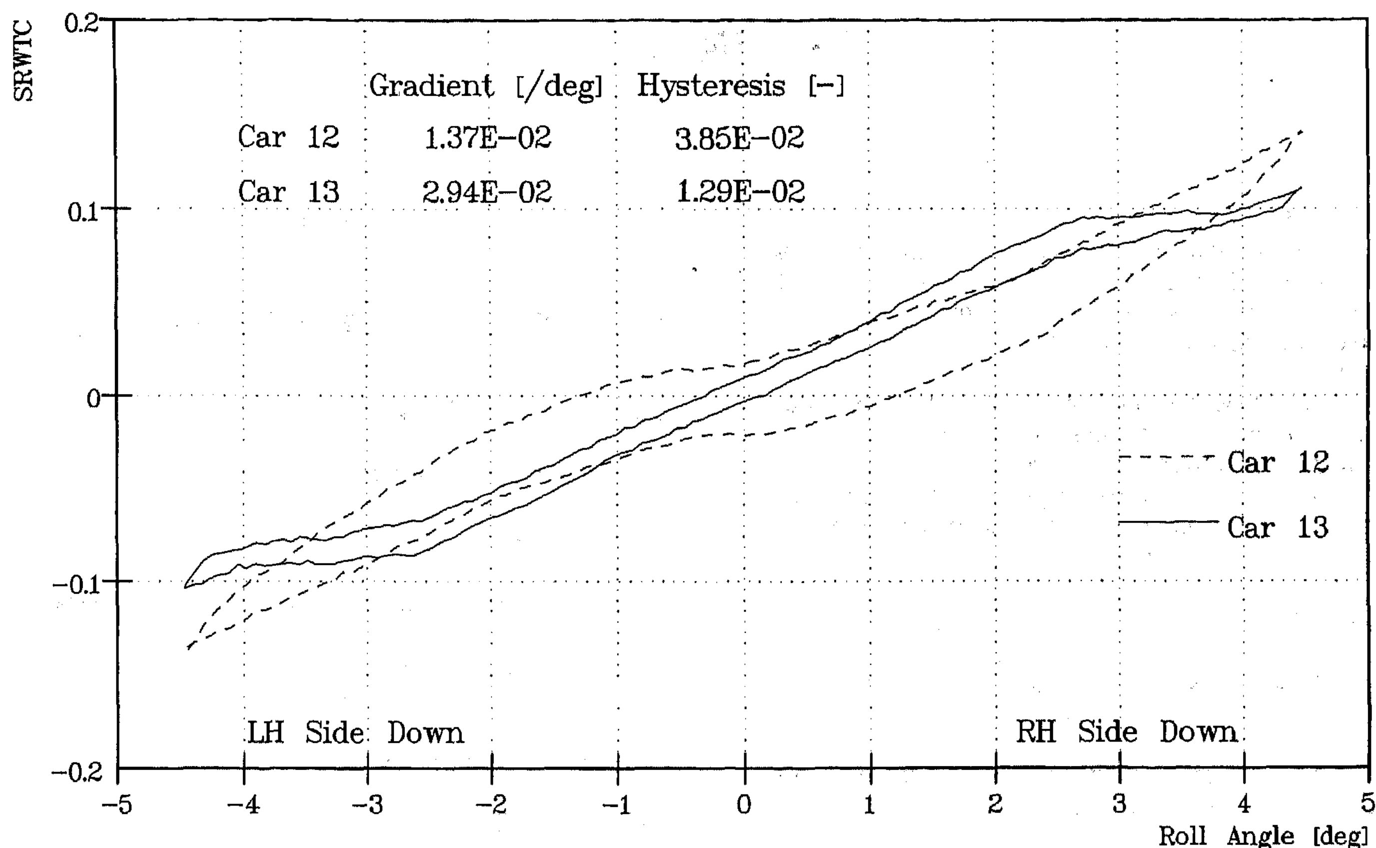

Figure 5 - STATIC ROLL WEIGHT TRANSFER CO-EFFICIENT v ROLL ANGLE

Figure 5 presents SRWTC plotted against roll angle for Cars 12 and 13 (reference Tables 1 and 2). For Car 12, the SRWTC hysteresis is high at 0.038. The ratio, front to rear, of suspension hysteresis is 2:1, and the SRWTC gradient over the central, low roll angle, region is low at 0.013. By contrast, the SRWTC hysteresis for Car 13 is only one third that of Car 12. Although Car 13 has greater suspension hysteresis, the ratio front to rear is 1.2:1 and the SRWTC gradient over the central region is much higher, at 0.03. Figure 5 also shows characteristics of distinctly different shapes for these two cars. For Car 12 the gradient increases with increasing roll angle, indicating an increasing bias of the roll stiffness distribution towards the front with increasing roll angle. For Car 13, the SRWTC curve shows the opposite trend.

CONCLUSIONS

In seeking to enhance its suspension design and development services, MIRA saw the need for an efficient, state-of-the-art kinematics and compliance measurement facility. After surveying the market, the decision was taken to order a new machine. Although it would have some similarities with earlier machines it should represent a significant advance.

MIRA collaborated with Anthony Best Dynamics (ABD), on the specification of the new machine. The Suspension Parameter Measurement Machine (SPMM) maximises the use of commercially available hardware and software. The use of commercially available components minimises both the initial and the maintenance costs.

Since entering service, the SPMM has more tha fulfilled expectations, particularly in ease and speed of use and in quality of output. K&C tests typically have taken two weeks to complete. The new machine enables most cars to be tested in one or two days, depending upon difficulty of vehicle attachment.

APPENDIX A

LIST OF RESULTS

The format for presentation of results is specified by the operator. Results are available at the end of each test sequence on PC screen display. Printed results are available immediately upon completion of a test programme.

The following is a list of the "standard" package of tests and results parameters, although it is acknowledged that many clients will have custom requirements, particularly with regard to presentation of results. The facility and service operation is flexible to cater for these requirements.

Vertical Test

- Wheel Vertical Rate (contact patch vertical force versus wheel centre vertical displacement).
- Tyre Radial Rate (contact patch vertical force versus vertical compression displacement).
- Bump Steer (roadwheel steer change versus wheel centre vertical displacement).
- Bump Camber (roadwheel camber change versus wheel centre vertical displacement).
- Bump Castor (roadwheel castor rotation versus wheel centre vertical displacement).
- Track Change (contact patch lateral displacement versus wheel centre vertical displacement).
- Wheelbase Change (contact patch longitudinal displacement versus wheel centre vertical displacement).
- Kinematic Roll centre height for each "axle"
- Kinematic Anti-lift or Anti-drive tangent for each "axle"

Roll Test

- Roll Stiffness (roll moment versus roll angle).
- Wheel loads (roadwheel vertical loads versus roll angle).
- Roll Stiffness Distribution (ratio of individual axle roll stiffness to total vehicle roll stiffness).
- Roll Steer (roadwheel steer change versus roll angle).
- Axle Steer (steer change of beam axle versus roll angle).

Steering System Tests

- Roadwheel Steer versus Hardwheel Steer.
- Ackermann curves.
- King Pin offset, scrub radius and mechanical trail.
- Handwheel Steer versus Handwheel Torque for various control strategies of Roadwheel Steer.
- Steering System stiffness.

Lateral Compliance Tests

- Lateral Compliance (roadwheel centre lateral displacement versus contact patch lateral force).
- Lateral Compliance Steer (roadwheel steer change versus contact patch lateral force); this may be a family of curves with different effective longitudinal moment arms acting in the contact patch.
- Camber Lateral Compliance (roadwheel camber angle change versus contact patch lateral force).
- Roll force centre height for each "axle".

Longitudinal Compliance Tests

- Longitudinal Compliance (roadwheel centre longitudinal displacement versus contact patch longitudinal force).
- Longitudinal Compliance Steer (roadwheel steer change versus contact patch longitudinal force).
- Castor Longitudinal Compliance (roadwheel castor angle change versus contact patch longitudinal force).
- Force derived Anti-lift or Anti-dive tangent for each "axle".

Synthesis of Chassis Parameters for Ride and Handling on the 1997 Chevrolet Corvette

Steven P. Fuja, Henry A. Schmid, and Joseph P. Ryan
General Motors Corp.

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

This paper describes the performance attributes of the all-new front and rear SLA (short-long arm) suspensions, steering system, and tires of the 1997 Corvette. The process by which these subsystem attributes flowed down from vehicle-level requirements for ride and handling performance is briefly described. Additionally, where applicable, specific subsystem attributes are rationalized back to a corresponding vehicle-level performance requirement. Suspension kinematic and compliance characteristics are described and contrasted to those of the previous generation (1984 to 1996 Model Year) Corvette. Both synthesis/analysis activities as well as mule-level vehicle development work are cited for their roles in mapping out specific subsystem attributes and related vehicle performance.

INTRODUCTION

The all-new 1997 Chevrolet Corvette has been internally dubbed "C5", shorthand for 5th Generation Corvette. Likewise, the previous generation Corvette (1984 to 1996 Model Year) is referred to as C4 (4th Generation Corvette). These terms will be used throughout.

This paper is one of a set of four SAE papers which discuss the evolution of the C5 Corvette's ride and handling characteristics. Reference [1] is sequentially the first of the four, and describes how vehicle level targets for vehicle dynamics performance were defined. The paper you are now reading is second in the series, and describes how these vehicle targets resulted in specific subsystem attributes for suspensions, tires, and steering system. The third paper in the series (Ref. [2]) describes the execution of the front and rear suspensions in production hardware. The last paper (Ref. [3]) deals with the final development tuning of those suspensions, as well as that of the tires and steering system. Together, the four papers describe the derivation of the C5's vehicle dynamics attributes, from the broadest expression of customer desires and preferences to the specific design details of the final product to be delivered to those customers.

SUBSYSTEM ATTRIBUTES

ROLLDOWN PROCESS - The C5's suspension/steering system design and functionality are the result of a structured flowdown process dictated by General Motors' 4-Phase Vehicle Development Process. This process may be summarized as one in which Voice of the Customer (VOC) inputs flow down to Vehicle Technical Specification (VTS) requirements, which in turn flow down to Subsystem Technical Specification (STS) requirements. See Figure 1. This process is a systems engineering-based method which captures customer inputs and then translates these desires into measurable engineering metrics. Competitive vehicles are benchmarked for these engineering metrics, and the measured results form one set of inputs to the negotiated vehicle-level targets which ultimately become the VTS. (Other inputs to the VTS may include such items as relevant C4 historical data, technology rollout considerations, etc.) These vehicle-level specifications are then rolled down to subsystem and component-level specifications which must be satisfied to enable the vehicle level goals to be met.

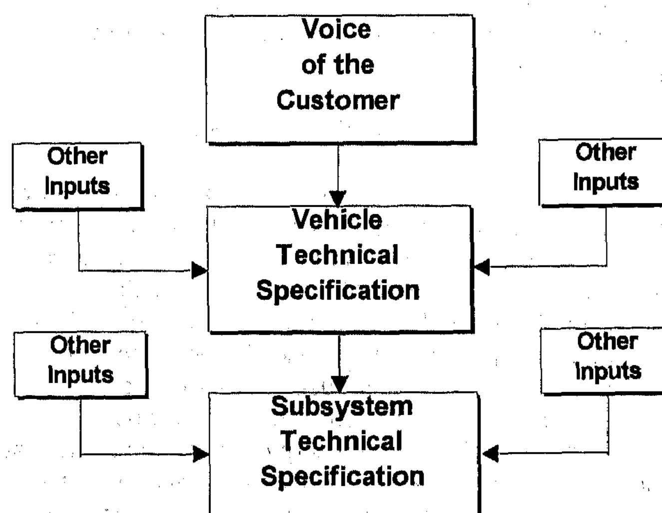

FIG. 1: Requirements Flowdown

In the case of the C5 suspensions and steering system, this rolldown of vehicle-level requirements to specific suspension/steering system attributes was accomplished by a variety of methods, including extensive computer simulation, actual hardware builds (mules, alpha, and beta vehicles), and knowledge by recognized experts in the field (both inside and outside of General Motors).

In systems engineering, equally important to the rolldown process is the process of confirming that subsystem and component goals are met, then re-assembling those validated subsystems back into an overall vehicle, and finally checking the performance of the vehicle against the original goals. Again, the C5 team used both analytical models of subsystems as well as subsystem hardware tests to demonstrate capability, then assembled these subsystems into more complex vehicle models or actual vehicles. Objective vehicle testing against VTS metrics completed the systems engineering process. The result is a requirements-driven vehicle system design enabling world-class ride and handling capability.

SUSPENSION STATIC DESIGN FACTORS - Necessary to understanding a suspension's influence on overall vehicle dynamics is a system of describing that suspension's kinematic and compliance characteristics. At GM, these suspension attributes are known as Static Design Factors (SDFs). Over 60 SDFs are defined and are monitored analytically as well as (in some cases) experimentally as a suspension design evolves. As is the case with any complex system, modifications meant to improve one particular suspension attribute may cause degradation in another area. Packaging changes and other considerations will also drive changes which must be quantified, evaluated, and balanced in terms of impact to overall suspension and vehicle performance. This continuous, proactive modeling, measuring, and balancing of suspension SDFs is key to arriving at a vehicle which delivers capable, pleasible dynamic performance.

FRONT SUSPENSION AND STEERING

TOPOLOGY - Figure 2 shows an isometric view of the C5 front suspension. In the tradition of the earlier generation Corvette, the upper and lower control arms and knuckle are all cast or forged from lightweight aluminum to enable low unsprung mass for good wheel control and impact isolation. Also similar in concept to the previous Corvette is the use of a composite transverse leaf spring and monotube shock absorber. The lower control arms and steering rack mount to a cast aluminum crossmember, which in turn is hard mounted to the frame rails. The crossmember, with its machined interfaces, serves as a precision locating surface for the suspension/steering system components. The upper control arm attaches directly to the hydroformed frame rail. The steering rack, which features Magnasteer™ II (a variable effort steering system developed by GM's Delphi Saginaw Division), is located forward of wheel center. It should be noted that Magnasteer™ was considered part of vehicle program content from the very beginning, and that the front suspension was designed accordingly to complement the Magnasteer™ II system.

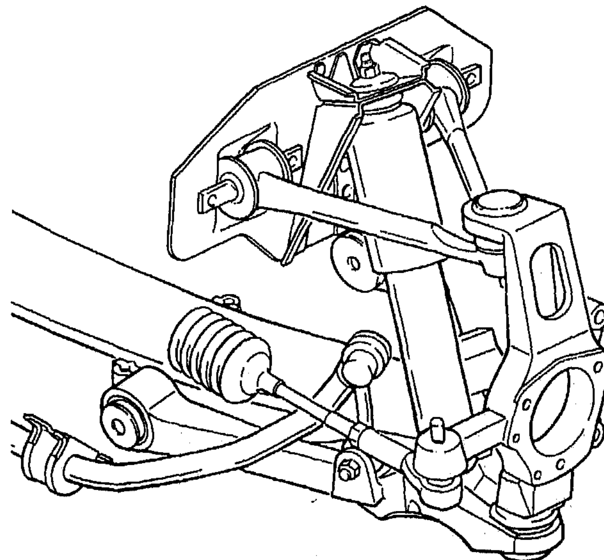

FIG. 2: C5 Front Suspension (Alpha Build)

KINGPIN GEOMETRY - C5's front-view kingpin geometry is set up to enhance steering system performance, with the aim of satisfying vehicle-level requirements for improved steering feel and better mid-range handling. C5 features a relatively short spindle length of 63mm (vs. 93mm in C4), and a relatively upright kingpin (8.8 degrees for C5 vs. 16.0 degrees for C4). Since the spindle length acts as a moment arm for both Fore/Aft and Vertical road input, reduction of this length results in lower kingpin moments due to rough road events, thereby reducing the resulting steering system transient forces and enabling better rough road handling. Reduced spindle length also results in a lower camber moment to be reacted by the upper and lower ball joints; these resulting reduced ball joint lateral forces act to reduce kingpin friction and hysteresis, which may further improve steering feel.

In the side view, C5 features 6.5 degrees of caster angle and 36mm of caster trail. By contrast, the C4 design features 5.9 degrees of caster angle and 45mm of trail, with a 12mm side view spindle offset. The reduction in caster trail was aimed at reduced front cornering compliance to enable a vehicle-level goal of improved yaw damping and better midrange handling. An additional input parameter to the determination of caster geometry, however, was the vehicle-level goal of good steering wheel road feel, with a desire for relatively high handwheel torque gradients (steering wheel effort as a function of lateral acceleration). Since the caster trail is the moment arm for steering system loads resulting from lateral acceleration, this desire for high torque gradients is in conflict with reduction in caster trail desired for improved yaw damping. The need for

balance between these two conflicting goals was recognized early on, and drove extensive computer modeling to explore the relationship among front cornering compliance needs, torque gradient needs, and the interaction of the suspension with steering system tuning.

Even the earliest C5 computer simulations and front suspension mules focused on upright kingpin geometry and carefully balanced caster geometry as an enabler of good steering feel. Competitive vehicles were measured for their kingpin geometric features and were also quantified at a vehicle level for their steering feel performance attributes. Specific steering attributes of some of these competitive cars were eventually factored into C5's VTS.

CAMBER GEOMETRY - C5's camber geometry is shown relative to that of C4 in Figure 3. C5 has a static negative camber setting to allow enhanced cornering power under maximum lateral acceleration. The slope of the camber curve around the layout design position is less aggressive than that of C4, providing less camber change and tread change for low lateral acceleration road disturbances, improving rough road handling and tracking. Roll center height and roll center height migration as a function of ride travel are similar to the C4 design. See Figure 4. Roll stiffness of the new car is somewhat lower than that of C4; accordingly, roll steer is likewise reduced.

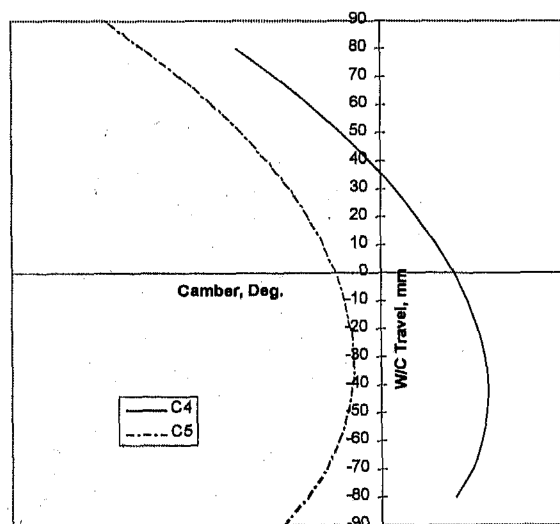

FIG. 3: Front Suspension Camber

Reduction in roll stiffness is part of an overall vehicle level strategy of allowing somewhat more compliance and higher gains, but with greater levels of damping. This approach works to the benefit of both ride and handling by better managing tire normal load variations due to road inputs. The occupants' perception of higher gain may be minimal because they are less sensitive to absolute gain (controlled by stiffness) than they are to rate of change (controlled by damping).

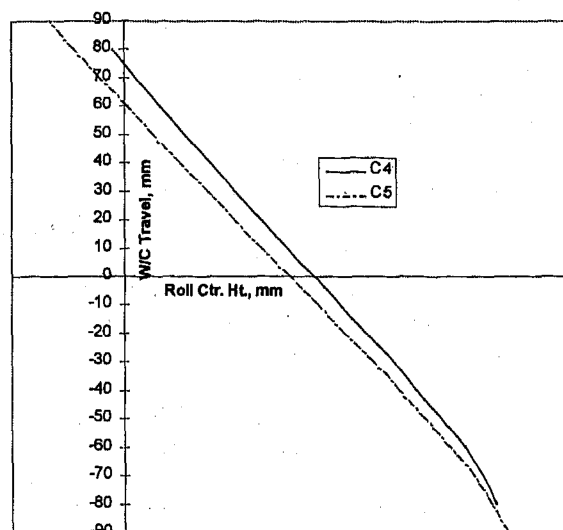

FIG. 4: Front Suspension Roll Center Height

Early suspension mules experimented with different camber curve slopes around zero wheel center travel. These cars, with their adjustable levels of roll camber, were subjectively evaluated for such difficult to quantify attributes as rough road wheel kick. Computer simulations both preceded the hardware development as well as tracked it through development-led changes. The resulting camber geometry and roll gain offers good down the road midrange handling without intrusive wheel kick, yet enables the high maximum lateral acceleration capability necessary in a Corvette.

RIDE QUALITY FEATURES - One message which came through very strongly from the Voice of the Customer was the desire for improved ride quality, particularly in the area of impact isolation. Several suspension features were aimed at satisfying this requirement without sacrificing the handling capability necessary in a high-end sports car.

The lower control arm is set up as a modified L-shaped arm, rather than an A-arm, featuring a stiff bushing close to wheel center for good lateral stiffness, and a soft "ride" bushing aft of wheel center for reduced fore/aft stiffness. These bushing locations and compliances are carefully matched to enable good isolation, yet result in minimal toe change under transient road inputs, to the benefit of rough road handling.

Another ride "enabler" is the transverse fiberglass leaf spring. The packaging efficiency of this springing medium allows the shock absorber to be placed further outboard laterally than could be achieved with a conventional coil spring over shock absorber arrangement; the result is a better shock lever arm ratio (1.34:1), which enables better wheel damping authority for both isolation and roadholding.

A key vehicle-level feature which enables good ride performance out of the suspension is the exceptional rigidity of the C5's unique body structure.

Body stiffness unparalleled in an open roof production car provides a firm reaction surface so that springs, dampers, and bushings in the suspension can function properly without excessive series compliance.

Early mule work also focused on suspension enablers for improved ride quality. Different variants of the leaf spring were tried, as were other springing systems (including a bell crank system with horizontal coil springs over shocks!). Impact harshness considerations were developed in hardware by use of an early mule which had adjustable fore/aft stiffness down to very low levels, as well as adjustable side view geometry; this vehicle was the hardware realization of extensive lumped parameter simulation work which focused on the same attributes.

BRAKE STEER CHARACTERISTICS - Front suspension braking performance characteristics were dictated by a philosophy of making the vehicle insensitive or neutral to acceleration/deceleration events. As such, brake steer characteristics for both symmetric and asymmetric events were kept to a minimum by matching carefully balanced control arm bushing compliances with plan view tie rod angle. These neutral steer characteristics, combined with a wheelbase increase of over 200mm and a slightly positive scrub radius (10mm), provide a significantly greater envelope of vehicle capability under braking.

Brake performance sensitivity to scrub radius was evaluated in hardware by the use of suspension mules using tire/wheel combinations with several different wheel offsets. The wheel offsets used allowed evaluation of changes to both direction and magnitude of scrub radius. This sensitivity work was augmented and enhanced by computer simulation provided by GM's NAO Brake and Bearing Systems group.

STEERING SYSTEM INTERACTIONS - A strong message from the Voice of the Customer was the desire for improved steering feel. As such, the C5 steering system and how it interacts with suspension parameters and tire characteristics was the subject of extensive computer simulation before hardware was ever built. The GM NAO Vehicle Handling Lab has developed sophisticated vehicle models capable of simulating the complex nonlinear functions of the steering system. Steering system characteristics such as hydraulic boost, friction, lash, etc. may be modeled based on physical tests at a subsystem and component level. These analytical tools may be used to simulate full vehicle tests which are statistically correlated to customer preferences. Thus, given good vehicle level targets of steering performance, the team could use these analytical tools to synthesize a design capable of meeting these goals before hardware is built. Subsequent hardware build approximates the desired capability, and is available for development engineers to tune to final configuration using both objective and subjective evaluation.

C5's Magnasteer™ II system is capable of varying handwheel efforts with both vehicle speed and lateral acceleration, enabling a wide tuning range of effort characteristics for varying vehicle regimes (parking lot vs. highway vs. aggressive high lateral acceleration events). This capability was first simulated in the aforementioned steering vehicle models to assess the bandwidth of their effect on customer-perceived attributes; subsequent vehicle development in hardware focused on mapping out performance requirements within this bandwidth to result in a subjectively pleasing package for the customer.

The earliest Magnasteer™ development work in hardware was actually performed in C4 vehicles. Because C5 has different kingpin and steering geometry as well as different tire requirements, the C4 Magnasteer™ experience was not directly applicable to C5. Accordingly, simulation work significantly preceded hardware development work on C5 steering performance. Simulation first focused on modeling and understanding the C4 system to serve as a hardware correlation point. A C5 model was then developed, and this model was used to set subsystem performance attribute targets which were needed to enable vehicle steering goals as defined in the VTS. When actual C5 hardware arrived later in the vehicle program, the C5 models were benchmarked against measured vehicle performance, with the result being exceptionally good correlation.

REAR SUSPENSION

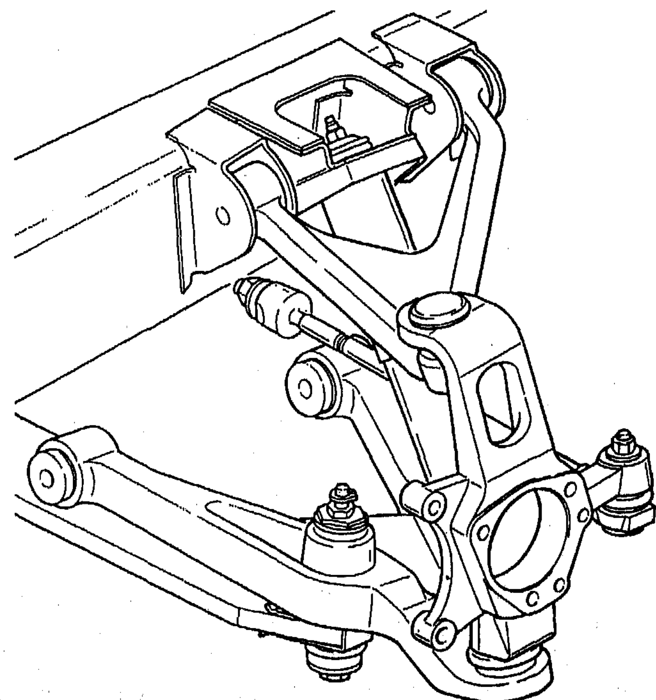

FIG. 5: C5 Rear Suspension (Alpha Build)

TOPOLOGY - Conceptually, the C5 rear suspension resembles the C5 front suspension and is a significant departure from the C4 rear suspension. Like

the C5 front, the C5 rear is a true SLA suspension with a modified L-shaped lower control arm for decoupled lateral and fore/aft compliance. It uses cast aluminum components and features a transverse fiberglass leaf spring and monotube shock absorbers. See Figure 5. Steel plunging halfshafts with constant velocity joints deliver torque to the 18" tire/wheel combination. As in the case of the C5 front suspension (and in contrast to the C4 rear suspension), the lower control arms and tie rods mount to a cast aluminum crossmember with machined interfaces. The upper control arms attach to the hydroformed frame rail. The C5 rear suspension's kingpin geometry is conceptually similar to that of the front due to the fact that knuckle castings are identical, front to rear; angular orientation differences enable front to rear caster and kingpin angle differences. By contrast, the C4 rear relies upon a non-plunging halfshaft to act as the upper control arm; as such, the outer Cardan joint of this halfshaft acts as an effective upper ball joint. The C5 geometry, with separate components (plunging halfshaft and true upper control arm) providing separate functions (torque delivery and suspension control, respectively) enables the reduced scrub radius and spindle length summarized in Table 1.

SDF	C4	C5
Caster Angle (degrees)	1.2	0.2
Kingpin Inclin. (degrees)	-7.1	9.2
Scrub Radius (mm)	162.3	1.0
Spindle Length (mm)	123.0	50.7

TABLE 1: Rear Suspension Kingpin Geometry

CAMBER GEOMETRY - C5's separate upper control arm also allows a more optimal tuning of its camber geometry. See Figure 6. Note also negative static camber setting for improved maximum lateral cornering power. C5's reduction in camber change as a function of ride travel around zero wheel center travel and reduction in tread deviation with ride travel is considered to be directionally correct for improving rough road handling and minimizing truck groove wander. An additional benefit of C5's improved camber geometry is a reduction in roll center height, and an improvement of roll center height change as a function of ride travel; the lower roll center height will result in less jacking during cornering, and the improved slope will result in the roll center height being fixed to the vehicle during ride/roll events, enabling more predictable roll performance. See Figure 7.

Even the earliest mules were SLA architecture, with a separate upper control arm to enable the desired camber geometry. Various levels of roll camber were subjectively evaluated for rough road and truck groove performance. Other factors such as tire size, alignment settings, etc. also influence wander behavior, so these considerations had to be kept in mind when making these evaluations. The resulting combination of camber geometry and roll gain represent the necessary balance between good down the road performance on less than optimal pavement and the necessary high-g cornering power required.

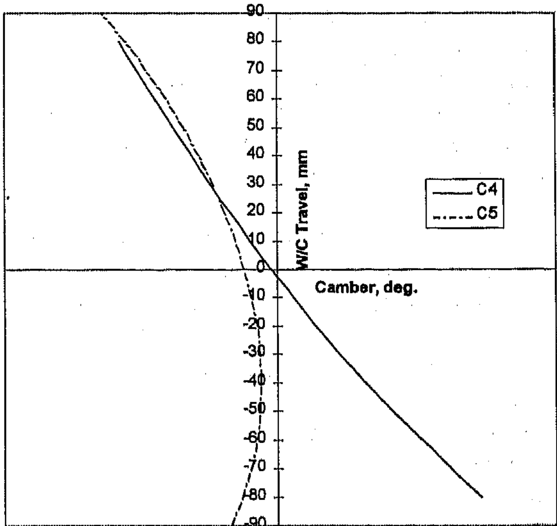

FIG. 6: Rear Suspension Camber

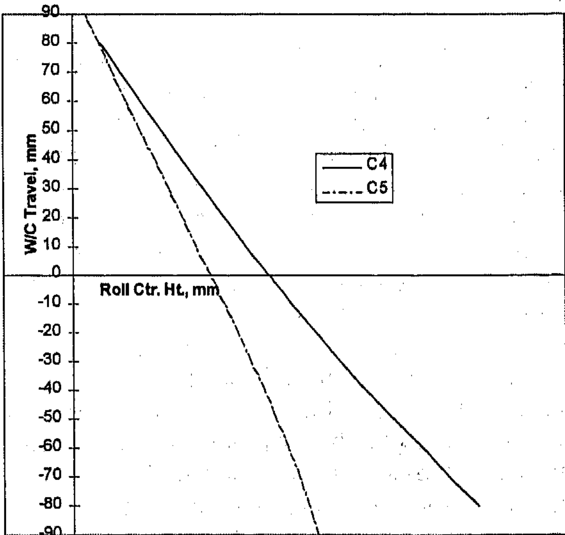

FIG. 7: Rear Suspension Roll Center Height

TOE CHANGE UNDER ACCEL./DECEL. EVENTS - A further benefit of the C5's upper control arm and the resulting reduced spindle length and scrub radius is their influence on the tractive and braking steer

performance of the car. A large reduction in spindle length and scrub radius results in corresponding reductions in kingpin moments due to acceleration/deceleration events. These reduced kingpin moments are then reacted through control arm bushings and a tie rod plan view angle carefully matched to minimize toe change during these events. This is in keeping with the previously stated vehicle-level philosophy of neutral steer characteristics under fore/aft inputs. These suspension features, combined with C5's wheelbase increase, result in clearly superior performance under drop-throttle events.

Toe change under accel./decel. conditions was the focus of considerable early mule work. Early analytical work had focused on minimizing these toe changes as a key enabler of achieving the neutral character desired in the car. Early hardware execution, however, pointed out the importance of such subtleties as body and component series compliance, as well as bushing non-linearities. Each of these additional compliances were tracked down in turn and were either minimized or managed through complementary hardware and simulation work. Resulting toe change under free-rolling conditions was then predicted analytically as well as measured experimentally on suspension compliance measurement systems such as GM's Vehicle Handling Facility and a similar facility at Goodyear's Akron Technical Center. The resulting toe change under fore/aft inputs is exceptionally low, resulting in the desired vehicle level performance under accel./decel. events.

This careful management of toe change under fore/aft road inputs is also a key enabler of ride isolation improvement. Because steer characteristics are so well controlled, greater compliance can be allowed without sacrificing handling precision, to the benefit of impact harshness.

LATERAL FORCE STEER CHARACTERISTICS - C5's use of a rear-mounted, stiff tie rod (toe link) allows it to toe in slightly under the application of a cornering load. This lateral force steer is in the understeer direction, and thereby reduces rear cornering compliance. This in turn enhances lateral acceleration response time and thereby addresses Voice of the Customer inputs which demand responsiveness in midrange handling events.

C5's lateral force understeer is enabled by virtue of the body-side toe link attachment to a rigid crossmember, rather than to a rubber isolated differential (as is the case with the C4 rear suspension). The direction of toe change under the application of lateral load was the focus of considerable debate, test, and simulation work by experts both within and outside of GM during the early phases of the C5 vehicle program. All sides agreed that very small, controlled levels of lateral force steer were appropriate for the C5, with the difference of opinion arising in regard to the sign of that toe change (toe in or toe out). Tuning philosophy, subjective preferences, and development heritage played a strong role in the determination of opinions on this topic. In the end, the very small amounts of toe-in exhibited by C5 were considered appropriate as an enabler of mid-range responsiveness, as well as being subjectively pleasing to the driver.

SIDE-VIEW GEOMETRY - C5 features a relatively long side-view swing arm (2.1 meters) and a somewhat reduced side-view swing arm angle (5.2 degrees for C5 vs. 7.8 degrees for C4). This results in the reduced levels of Percent Anti-Squat (PAS) and Percent Anti-Lift (PAL) shown in Figures 8 and 9. Long side-view swing arms with relatively low angle changes as a function of ride travel result from C5's SLA architecture; trailing link suspensions such as C4 usually result in shorter side-view swing arms with more angle change with ride travel.

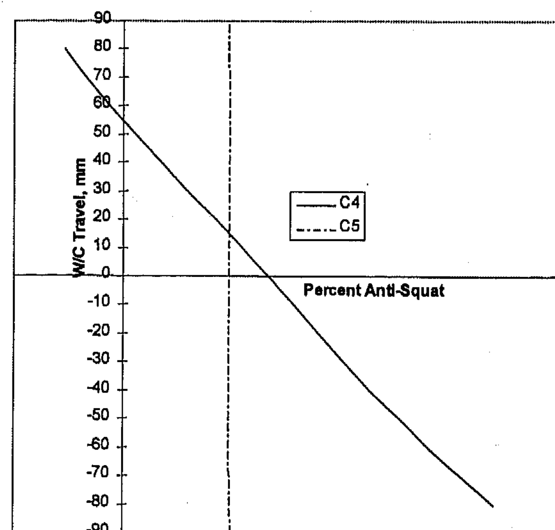

FIG. 8: Rear Suspension Percent Anti-Squat

C5 is able to reduce PAS and PAL and still retain good pitch control because of its increased wheelbase. Equally important to absolute pitch gain is the driver's perception of pitch under accel./decel. events. In a two-seat car such as the Corvette, the occupants sit closer to the rear axle than would be the case on a car which has a back seat; rear suspension anti features may therefore be more perceptible to occupants than would be the case on other types of vehicles.

Earliest mule work focused on very low levels of anti features, with the mule also incorporating the C5's extended wheelbase. Since this earliest mule was deemed too "pitchy" under acceleration, subsequent development work focused on a mule with adjustable anti features. This vehicle was used to more precisely map out driver preferences with respect to pitch control. Obviously, spring rate and shock authority also contribute to pitch perception, so tuning considerations had to be kept in mind when making these evaluations.

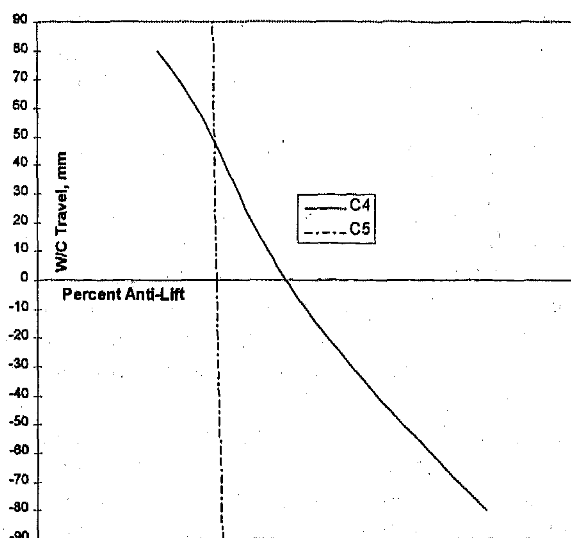

FIG. 9: Rear Suspension Percent Anti-Lift

SPRING AND SHOCK CONSIDERATIONS - The rear leaf spring is packaged beneath the lower control arm, suspended by rubber isolated tension links. These links serve to decouple the leaf from the lower control arm in the fore/aft direction, preventing the leaf spring from contributing to fore/aft suspension stiffness, and thereby reducing impact harshness.

The choice of a leaf spring for the C5 rear suspension was influenced by needs of packaging efficiency. Benefits offered include increased trunk volume as well as enhanced shock lever arm ratio. The decision to mount the spring and shock to the lower control arm (as opposed to mounting directly to the knuckle) was a conscious tradeoff of what would have offered an even greater potential improvement in shock lever arm ratio. Mounting these elements to the lower control arm results in a knuckle which is decoupled from the shock and spring transient forces which might result in undesirable toe changes, particularly under rough road events.

Additionally, mounting the shock to the lower control arm provides benefit by decoupling fore/aft stiffness from the shock absorber's load path. This reduces series compliance to the damper and thereby enhances shock authority. In suspensions which mount the shock directly to the knuckle, a "bell crank" mechanism can result, whereby reducing the fore/aft stiffness to improve impact harshness can result in more effective compliance acting in series with the shock absorber. This in turn results in diminished capability for wheel control. An early C5 candidate rear suspension which featured a multi-link lower control arm exhibited this undesirable coupling in analytical modeling.

TIRE CONSIDERATIONS

EXTENDED MOBILITY TIRES - Standard on the C5 is the use of Goodyear Eagle F1 GS Extended Mobility Tires (EMT), otherwise known as "run-flat" tires. These tires offer the capability of driving with zero air pressure; this capability, combined with C5's Tire Pressure Monitor system, obviates the need for a spare tire, benefiting the customer both in terms of increased trunk space and reduced overall vehicle mass.

While EMTs offer obvious benefits to the customer, they also present unique challenges to the suspension design. EMT construction which allows run-flat capability also generally results in higher vertical tire spring rates and increased unsprung mass. Both of these characteristics tend to work against good impact isolation and good wheel control. Fortunately, C5's suspensions were designed with EMTs considered standard equipment from the very beginning, so these tire attributes were recognized and comprehended early in the suspension design. Additionally, C5 benefited from lessons learned on the C4 Corvette, which offered an earlier version of EMT tires with one suspension option package. Accordingly, the C5 suspensions were designed to provide relatively low fore/aft stiffness (with corresponding neutral steer characteristics) to minimize impact harshness. Additionally, C5's exceptional body stiffness at local shock/spring/bushing attachment points allow optimal isolator and damper performance to the benefit of both isolation and wheel control.

Early suspension mules relied upon C4 EMT tires. Since these earlier variants of EMT technology are somewhat stiffer and more massive than those which ultimately were developed for C5, they served to provide a worst case scenario for considerations such as impact harshness, wheel control, and peak jounce bumper loads. Continuously during the course of the vehicle program, development engineers from both GM and Goodyear worked suspension compliances, shock and spring combinations, and tire characteristics in a complementary fashion to arrive at the resulting total C5 package.

LATERAL REQUIREMENTS - Tire characteristics form the basis of front and rear cornering compliances and thereby vehicle yaw plane behavior; suspension attributes serve to modulate those tire characteristics. Accordingly, proper specification of tire handling characteristics such as cornering coefficient, aligning torque coefficient, camber stiffness, weight transfer sensitivity, etc. is critical. Targets for these parameters were rolled down very early in the program via the use of coarse, lumped parameter vehicle models. These targets were then monitored and modified as appropriate as the design continued to evolve and mature. The C5's differential tire sizes front-to-rear are critical to enable proper front and rear cornering coefficients for desired yaw plane behavior; the C5 front

tires are P245/45ZR17, and the rear tires are P275/40ZR18. Goodyear was identified early on as a potential source for C5 tires and their representatives were ongoing participants in the C5 Ride and Handling Product Development Integration Team.

In addition to their role at the highest level of vehicle yaw plane dynamics, tire lateral characteristics also play a key role in steering system performance and feel. Likewise, tire asymmetries and suspension alignment also influence customer perception of steering feel. As the C5 design matured, the influences of such parameters on steering performance were comprehended in detailed vehicle models.

SUSPENSION INTERFACE STIFFNESS REQUIREMENTS

GLOBAL STIFFNESS REQUIREMENTS - The C5 is unprecedented in terms of overall global stiffness in an open roof production car. First body bending and torsional natural frequencies are in the range more commonly associated with those of good fixed roof coupes and sedans. The development of C5's unique body structure was the result of extensive up-front specification, benchmarking, and simulation work and is documented in Ref. [4].

This up-front focus on exceptional global body stiffness works to the benefit of both ride and handling performance. It also serves to illustrate one of the many interfaces between the chassis/suspension activity and simultaneous work in other areas of the car. Each of these interfaces had to be carefully mapped out and managed, with each of the interfacing disciplines imposing requirements upon its interface counterpart. In the case of the body/chassis interface with respect to vehicle modal performance, it meant that each of the suspension modes (hop, tramp, and fore/aft) was assigned a frequency "slot", into which it had to fall. This allowed suspension modes to be decoupled from body and powertrain modes to enable good noise and vibration performance. As an example, consider suspension wheel hop frequency. In a high end sports car, this typically falls in the range of 12-15 Hz. Unfortunately, typical open roof vehicles usually have body torsional modes in that same frequency band. This can result in coupling between suspension and body modes and poor vibration performance. In the case of C5, however, this assigned slot of 12-15 Hz for suspension hop is far below the C5's body torsional mode, allowing decoupled modal performance with good isolation. This pro-active modeling and managing of modal requirements is another key contributor to C5's significant improvement in ride quality and isolation performance.

LOCAL STIFFNESS REQUIREMENTS - Equally important to global stiffness, however, is local stiffness requirements at suspension interfaces. In the case of C5, some of these interfaces are upper control arm to frame rail, shock absorber to shock tower, and lower control arm to the cast aluminum crossmember. Additional interfaces are steering rack to (front) crossmember, and rear suspension tie rod to (rear) crossmember. The suspension/tire local stiffness interface is through the bearing and wheel stiffness. Targets for each of these local stiffnesses were assigned, tracked, and managed through the course of C5 development.

Defining interface stiffness results in several obvious benefits as well as some more subtle. One obvious benefit is the suspension tuning flexibility afforded by stiff suspension interfaces. Isolation elements such as bushings are able to function to their maximum capability if unwanted series compliance effects are minimized. Likewise, shock authority is not limited by series compliance effects in the shock tower.

Another obvious advantage of stiff suspension interfaces is the beneficial effect on road noise. Early analytical work identified important noise paths, then local stiffness targets were assigned to allow the isolator to provide an appropriate input mobility mismatch across the interface.

A more subtle benefit, not always recognized, is the fact that good stiffness at suspension interfaces allows up-front synthesis/analysis to be more accurate and effective. Early in a vehicle program, analytical models are of necessity more coarse in order to quickly evaluate numerous design alternatives without the benefit of large amounts of design data. Some types of suspension models used in this phase are rigid body models, without structural compliance effects explicitly modeled. If suspension interfaces are eventually managed to be appropriately stiff, these early approximations of rigid behavior are much closer to the mark than would be the case if significant series compliance effects resulted. Obviously, as a vehicle program progresses, series compliances can be tracked, modeled, and managed, but if those contributions are kept to a minimum, the resulting vehicle design will perform much closer to those early predictions.

CONCLUSION

An exhaustive team effort over the course of several years led to C5's ride and handling chassis systems as they are now defined. Early vehicle level specification work set the stage with extensive customer input as well as that of recognized experts. A critical program enabler was clear management direction at an early juncture that the C5 would be allowed all-new suspension designs, to be shared with no other GM vehicle. Computer simulations of vehicle performance as well as those of the subsystems which enable that performance led to design solution requirements; that effort was augmented by mule vehicle level development work. The use of premium and innovative materials and components allowed design solutions to be executed in hardware. Development engineers then tuned the whole package into a pleasible, capable vehicle for the customer. The result is a no-compromises balance of

ride and handling which extends and expands upon the Corvette's unique heritage.

ACKNOWLEDGMENTS

The evolution of the C5 ride and handling chassis systems was the result of an exceptional team effort by a group of individuals too numerous to recount. The authors would be remiss, however, if they failed to acknowledge the contributions of the following individuals: Al Bodnar, Dave Wickman, Jim Lloyd, Dick Topping, Rich Kowalczyk, Mary Dona, Scott Allman, Rex Stump and Mike Neal.

ABSTRACT

This paper describes the ride and handling development process used for the 1997 Corvette. Three levels of suspension are available for the 1997 Corvette: base (FE1), sport (FE3) and RTD or Real Time Damping (F45) suspensions. All suspensions will be discussed in this paper. A review of the development and vehicle integration tradeoffs for each of the specific chassis components is included. Control arm bushings, springs, jounce bumpers, anti-roll bars and insulators, tires, shock mounts, shock absorber valving, real-time damping, steering development, alignment and measurements are discussed.

INTRODUCTION

OVERVIEW - The fifth generation Chevrolet Corvette introduced in 1997 (C5) is a completely new vehicle, featuring significant design changes in areas compared to the fourth generation Chevrolet Corvette of 1984-96 (C4).

Four papers have been written that summarize the Systems Engineering approach to the suspension design of the 1997 Chevrolet Corvette. The first paper [Ref. 1] reviews the customer research, Engineering Direction, human factors and analytical evaluation that established the objective Ride and Handling targets for the vehicle. The second paper [Ref. 2] describes the "roll down" of the vehicle level performance targets to specific subsystem attributes and parameters for the suspension, steering, and tires. The third paper [Ref. 3] reviews the hardware that complies with the specifications established in the previous two steps. This paper summarizes the final development tuning of the suspension, steering and tires. Careful execution of the procedures and techniques discussed in this series of papers was critical in producing the highly optimized suspension of the 1997 Chevrolet Corvette and for assurance of high customer satisfaction for ride and handling performance.

DEVELOPMENT PROCESS - C5 ride and handling goals specified significantly improved ride, but not at the expense of handling. In fact, handling should be improved as well. To achieve both meant that suspension compliances had to be present for enhanced ride quality, but needed to be managed for nimble and predictable handling. The chassis development process optimized the suspension components to obtain the specified linear and non-linear range handling characteristics while achieving exceptional ride quality. Enablers for this process were an exceptionally stiff structure (450% stiffer in torsion than C4) to mount the springs, shocks and bushings, and a new optimized suspension geometry specifically designed to manage kinematics and compliances and allow each component to function properly.

CHASSIS INTERFACE

STRUCTURAL FOUNDATION - The C5 structure was a clean sheet of paper design [Ref. 4]. The new structure enabled the suspension to be tuned for improved ride and handling by decoupling the structure and suspension dynamically. Control arm bushings, shocks, springs and anti-roll bars were tuned independent of structural interaction, unlike C4, which had to account for structural interaction. C5 structure had four primary design specifications to decouple structure and suspension, as shown in Table 1.

Table 1. Body Structure Specifications.

Mode	Freq Range (Hz)	Supports	Specification
Static Stiffness	0-5	Handling	720 N-mm/deg (>10X roll couple distribution)
1st Torsional	5-50	Structural	23 Hz (separation from suspension tramp mode)
		Vibration	Nodal Lines @ front edge of seat, vehicle centerline
1st Bending	5-50	Structural	21 Hz (separation from suspension hop mode)
		Vibration	Nodal lines @ front and rear shock towers
Input Mobility	50-800	Noise	20 dB separation from mount

STATIC STIFFNESS - The static stiffness specification insured that the torsional stiffness of the structure did not interact with the roll stiffness distribution of the front and rear suspensions. Thus, anti-roll bars and ride springs were very efficient, and did not require oversizing to compensate for torsional deflection of the structure.

STRUCTURAL 1st TORSIONAL MODE - The 1st torsional mode of the structure was decoupled from the suspension by frequency and mode shape. The 23 Hz frequency provided adequate separation from suspension tramp (16 Hz), so tramp mode vibrations were not amplified by the structure. By placing the 1st torsional mode nodal line at the front edge of the seat and center line of the vehicle, perception of shake was minimized at the seat track and steering wheel. Shock tuning could focus primarily on wheel control without compromise to control structural shake.

STRUCTURAL 1st BENDING MODE - Similar to the 1st torsional mode of the structure, the 1st bending mode was decoupled from the suspension by frequency and mode shape. The 21 Hz frequency provided adequate separation from suspension hop (15 Hz), so hop mode vibrations were not amplified by the structure. By placing the 1st bending mode nodal lines at the front and rear shock towers, the structural bending mode was further isolated from road induced excitation. The primary excitation by the suspension for stuctural bending vibrations occurs at the least sensitive area of the structure. As with structural 1st torsion, shock tuning could focus on wheel control without compromises to control structural shake.

INPUT MOBILITY - Specifying 20 dB separation between the suspension isolation components and the attaching structure enabled interior road noise specifications. The mobility specifications insured the effectiveness of each isolator by forcing each to be the weak link in the system.

Due largely in part to the comprehensive specifications created for each major subsystem at the beginning of the program, chassis development was able to achieve all the targets for ride, handling, vibration, and noise. Only predetermined tuning elements were adjusted, no suspension or structure revisions or patches were required (for all three levels of suspension).

CHASSIS COMPONENT DEVELOPMENT

This section describes the development process for optimizing the individual chassis components of the FE1, FE3, and F45 suspension packages.

A minimum amount of effort was required to tune springs and anti-roll bars. Their development was straightforward, and once established, did not have to be revisited at a later date to "fix" subsequent issues.

Emphasis was placed on control arm bushing development because of their key role in achieving the C5 ride and handling goals. Jounce bumper development was a major subset of chassis development, because of it's role in managing the highest suspension and structure loads.

DEVELOPMENT TIME LINE - The ride and handling process was very iterative and was active over the entire C5 program. Different types of vehicles were used to prove different objectives during that time.

Mule vehicles built from C4s were used initially to prove suspension concepts and help set goals and specifications for the C5.

Pre-Alpha vehicles were the first chassis built from the ground up and closely represented design intent at that time, except styling. These vehicles were used to prove out structural design and suspension isolation capabilities and helped establish the Alpha and Beta tuning libraries for chassis components.

Alpha vehicles were the first completely new vehicles built from the ground up that represented 100% mainstream design. They included functionally correct components in all areas. These vehicles and the previously established tuning libraries were used to establish the preliminary chassis tuning of the complete, design intent vehicle.

Figure 1. Chassis Development Timeline.

Beta vehicles were also built from the ground up, with the first production intent components, and were used for the majority of chassis tuning.

Prototype vehicles were built with production parts and were used to refine and finalize the tuning process. The timeline in Figure 1 shows the development sequence and the iterative nature of the development of the C5 suspension.

CONTROL ARM BUSHINGS - Due to the robustness of the suspension design, only one control arm bushing package was necessary for all suspension levels. The assembly plant was willing to proliferate, but the suspension design did not require it.

The C5 uses Short-Long Arm (SLA) suspensions front and rear, as shown in Figures 2 and 3. The control arms were designed as close to an "L" shape as possible, with a stiff "handling" bushing near wheel center and soft "ride" bushing aft of wheel center. The front upper control arm is a symmetric A-arm, due to packaging constraints of the front suspension during full lock steering. The "separation of function" concept for the control arm bushings worked very well in hardware execution.

Except for the front upper control arm (which was subject to very tight package constraints), all other control arm bushings were sized sufficiently to accommodate the anticipated rate of each, using a conventional rubber/elastomer bushing. Bushing durability, linear and non-linear rate characteristics, contribution to ride rate, and other factors were considered. Higher cost bushing alternatives (i.e. lubricated journals, voided or non-symmetric, cross-axis ball joints) were considered, but determined to not be necessary with the C5 suspension designs.

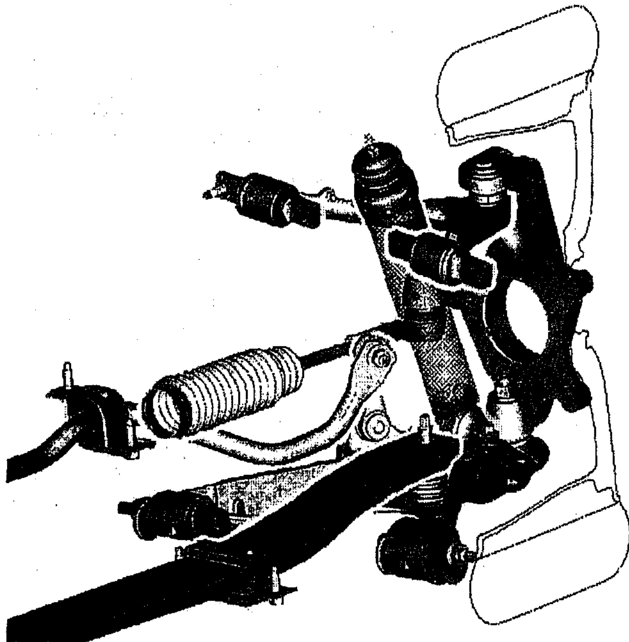

Figure 2. 1997 Chevrolet Corvette Front Suspension.

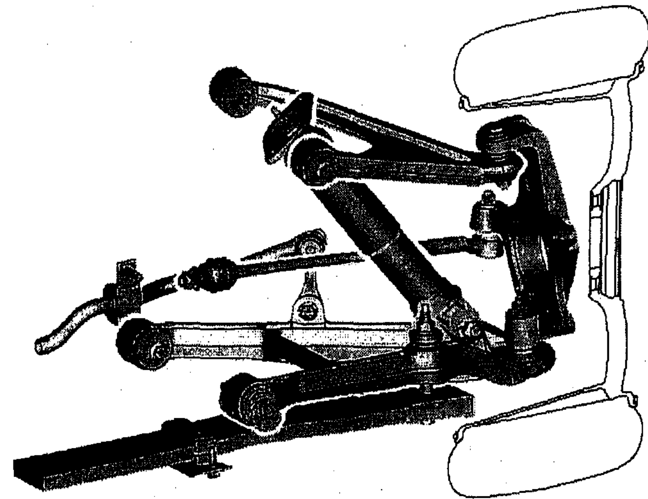

Figure 3. 1997 Chevrolet Corvette Rear Suspension.

Ride Bushings - Reducing the rate of any ride bushing improved impact hardness or reduced interior noise but not have a significant impact on handling. The suspension kinematics were robust to normal changes in bushing rates, compliance SDFs were somewhat decoupled, and primarily, unwanted toe change was non-existent. The suspension elasto-kinematics were designed for near-zero toe change with fore-aft displacement. Development experience with the ride bushings confirmed that large reductions in rate still did not introduce unwanted toe change. Handling modes such as rough roads, split-coefficient braking, braking-in-a-turn, accelerating in a turn, and dropped throttle were not significantly affected, a tremendous advantage for tuning suspension fore-aft compliance.

If the ride bushings were stiffened, there was a negligible improvement in handling, and always a significant degradation to ride quality and interior noise. There was little to be gained from specific bushing packages for each suspension option. Only one control arm bushing configuration was required to obtain the desired handling characteristics plus refined ride for all three suspension levels.

Handling Bushings - Increasing the rate of any handling bushing would improve multiple areas of handling but not significantly degrade impact hardness or increase interior noise. Handling bushings were extremely stiff, typically 3 to 6 times higher rate than ride bushings.

Analysis Support - A system to objectively quantify the kinematic and compliance characteristics of a suspension is necessary to understand, measure and simulate a suspension's influence on overall vehicle dynamics. At General Motors, these suspension attributes are known as Static Design Factors (SDFs). Over 60 SDFs were defined in analytical models, many are used in handling models and are monitored on the vehicles. As may be the case with any complex system,

modifications that improve one suspension attribute may degrade another [Ref 2].

Chassis Analysis synthesized a set of nominal bushing rates to meet the suspension SDF targets that in turn were synthesized to achieve the handling requirements. Using the nominal bushing rates as a basis, a tuning library of 20% softer and 15% stiffer bushing rates was obtained and subjectively evaluated by Chassis Development.

To assist the development process, a bushing rate sensitivity study was run which examined the effect on handling of varying each bushing rate individually or several simultaneously. Eighty-one combinations of nominal, soft, and stiff bushing rates were analyzed for the front and rear suspensions. Seventeen compliance related SDFs were tracked.

An example of the analysis is shown in Figure 4, where 1 of the 17 SDFs (Lateral Force Compliance Steer) is shown for 11 of the 81 bushing combinations.

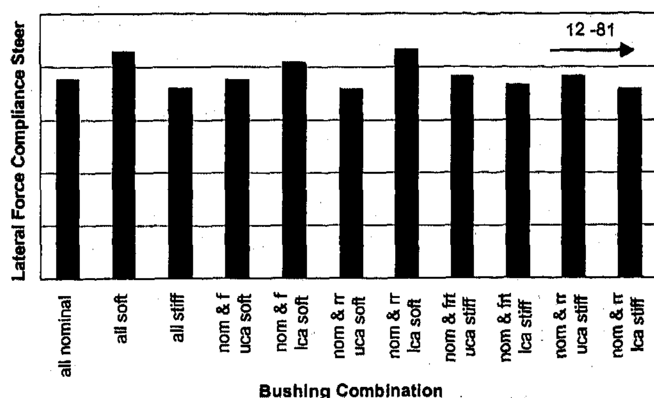

Figure 4. Sensitivity of Lateral Force Compliance Steer to Various Bushing Rate Combinations

The SDFs found to be most sensitive to bushing rate changes in the front suspension were: Lateral Force Compliance Steer, Stiffness at Wheel Center (Lateral, Fore-aft, and Pitch) and Brake Steer. The rear suspension showed the same sensitivities as the front, plus Tractive Force Steer.

The magnitudes of the steer SDFs were in all cases very small (again, a key feature designed into the C5 suspension). For example, in the final tuning of the rear suspension, Tractive Force Steer was reduced 65% over C4, while simultaneously reducing Wheel Center Fore-aft Stiffness by 10%.

Results of the bushing rate sensitivity study were used to reduce the number of bushing configurations to be subjectively evaluated. Combinations were evaluated for handling, impact hardness, structure borne road noise, on-center handling, lane change and recovery, braking in a turn, braking on split coefficient surfaces, any many more.

Using information from the analytical studies and subjective evaluation, Development rapidly arrived at a final control arm bushing tuning for the C5.

Figure 5 show the relative magnitude of each bushing rate for the initial synthesized values and the final developed values. The rate difference between the ride and handling bushings of the L shaped arms (all except front upper) may be seen. For the lower control arms, the handling bushings got stiffer and the ride bushings got softer. All the upper control arm bushings got softer.

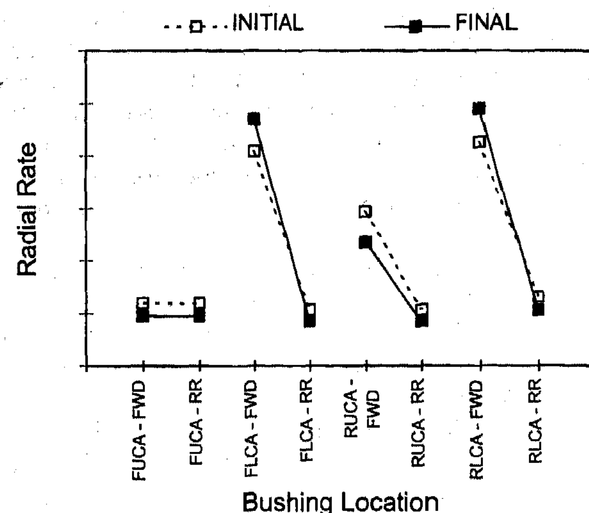

Figure 5. Control Arm Bushing Rates - Initial and Final.

Lower Control Arm Bushings - Bushing development of both the front suspension and rear suspension lower control arms followed nearly identical sequences.

Stiff (Handling) Bushings - The forward bushing of each arm was considered the "handling" bushing (closest to wheel center in plan view). For each lower control arm, the handling bushing was approximately 5 times stiffer than the ride bushing. From the library of bushings available, the rates selected by Chassis Development were each 15% stiffer than the original synthesized values. There were improvements in all areas of handling, particularly on-center. The control arms pivot about the handling bushing in plan view, and there was minimal degradation in impact hardness. There also was minimal increase in structure borne noise transmission, due primarily to the high impedance and damping of the crossmembers [Ref. 5].

Soft (Ride) Bushings - The aft bushing of each arm was the "ride" bushing, which absorbs the fore-aft input of a road disturbance. The rates selected by Chassis Developmentdeveloped rates were each 20% lower than the original synthesized values, which yielded a significant reduction in impact hardness. Very low fore-aft suspension rates were achieved, yet did not create additional toe change under fore-aft disturbances, braking, or acceleration, due to the carefully managed

elasto-kinematics of the suspension [Ref. 2]. C5 is significantly better than C4 for dropped throttle characteristics in a corner.

Upper Control Arm Bushings - The front upper control arm was a symmetrical design due to packaging constraints [Ref. 3] and was not able to separate bushing function. Both forward and aft bushing rates were the same. The rear upper control arm was a true L shape, with the forward bushing directly on wheel center. The rate of the handling (forward) bushing was approximately 3 times higher than the aft bushing.

For all upper control arm bushings, the developed rates were 20% lower than the original synthecrease in road noise. The upper control arms are attached to the side of the main frame rails (one piece hydroformed tube). The frame rails, being large cross-section and continuous tube, can potentially carry road noise to the occupants if the source is not properly isolated. Softer bushings for the upper control arms improved the impedance mis-match across each noise path.

There were no significant changes in handling. There was no impact to on-center performance, because of the low friction ball joints that were specified by early steering system synthesis and verified by development (see steering section). Control arm bushings can contribute to steering compliance if high steering forces are required to overcome high (rotating) ball joint friction. There was no effect on handling or impact hardness, fore-aft loads are relatively small in the upper arms. The control arm bushings were developed in Alpha vehicles. There was sufficient lead time to redesign the upper control arms to accommodate a larger outer diameter for the lower radial rates.

SPRINGS - With continuation of the composite transverse leaf spring for C5, there was a 15 year history to draw upon. FE and F45 share the same rates, and the FE (sport suspension) had higher rates, as shown in Table 2. Ride frequencies were developed to meet subjective requirements for controlling rigid body motions of the sprung mass, primarily flat ride. Required spring rates were then determined from the ride frequency targets.

Table 2. Spring Rates and Ride Frequencies.

	Front Suspension		Rear Suspension		
Suspension Option	Spring Rate (N/mm)	Ride Frequency (Hz)	Spring Rate (N/mm)	Ride Frequency (Hz)	Ride Frequency Ratio
FE1 & F45	77	1.15	103	1.36	1.18
FE3	93	1.20	113	1.45	1.21

Ride motion flatness was defined as a minimum pitch motion as the vehicle settled from cresting a swell. The front and rear spring rate balance was developed without shocks or jounce bumpers on the vehicle, since damping and jounce bumpers also affect ride motion flatness. This enabled the front and rear spring rate balance to be optimized for ride motion flatness ensuring that shocks and jounce bumpers weren't compromised by doing unnecessary work to control ride flatness motion.

The FE1 and F45 rear spring rate and ride frequency were increased beyond synthesis predicted values to control rear ride motions. The front ride frequency was then selected by evaluating ride motion flatness. The front spring rate increased 15% over the synthesis prediction, due to the lower torsional contribution of the developed control arm bushings.

The FE3 rear spring rate was selected from the synthesis prediction of rear ride frequency. The front rate was selected by evaluating ride motion flatness as in the FE1 and F45 suspensions. The developed front spring rate was 14% greater than the synthesis prediction.

JOUNCE BUMPERS - C5 jounce bumpers are integral with the shock absorbers, and must comprehend the load multiplication effect of the shock travel ratios. Jounce bumpers were developed for subjective ride entry feel, ride motion flatness and managing shock tower loads for a severe pothole event that is part of standard Proving Ground vehicle durability testing. The Corvette must pass the same Proving Ground durability tests as all other General Motors passenger cars and light trucks.

C5 had higher shock tower loads to manage than the C4 due in part to the stiffer body structure. The C5 rear suspension also had the added challenge of having a higher wheel/shock travel ratio (1.43), as compared to the C5 front suspension (1.34), which was a multiplication factor for the loads into the jounce bumper.

Keeping shock tower loads below the target levels led to an in depth study of jounce bumper energy absorption capabilities. Analytical modeling identified that shock tower loads management depended on a system of free travel, shock valving, and jounce bumper configuration. A jounce bumper configuration was characterized as a force-displacement curve. Assuming shock valving and free travel remained constant, a proposed jounce bumper configuration for loads management could be rapidly determined.

Coordinated Test, Analysis, and Development - A physical jounce bumper test was developed for evaluation of different configurations. In th bench test, a mass was dropped onto the jouce bumper configuration and drop height adjusted until the peak load correlated with the measured vehicle load. The same drop height and mass combination was then used to assess all subsequent jounce bumper configurations.

The bench test was a repeatable and fast method of quantifying each jounce bumper configuration's ability to absorb the amount of energy present in a severe pothole event. The jounce bumper configurations included variations in height, diameter, shapes, containment, and materials. An example of a

force-displacement curve for two typical jounce bumper configurations is shown in Figure 6. The measured force-displacement curve from the bench test as well as free travel and shock damping curves were then used in analytical models to predict and guide jounce bumper selection for loads management.

From initial analytical predictions, it was determined that the lowest peak loads could be obtained from a tall, uncontained jounce bumper. This jounce bumper configuration had good entry feel but ride motion flatness was unacceptable. The tall bumper decreased free travel and interfered too much in ride motion and wheel control development work. This required the shock damping to be revised for spring rate plus jounce bumper rate instead of spring rate only.

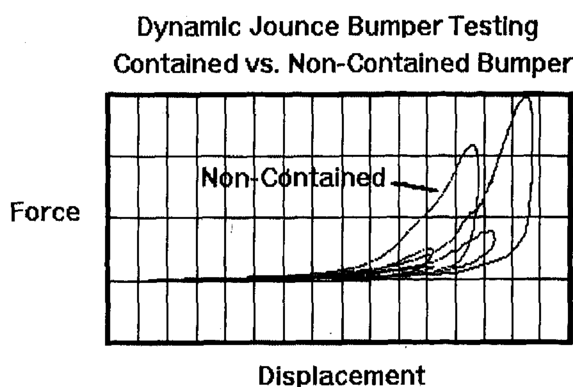

Figure 6. Jounce Bumper Force-Displacement Comparison.

The high shock travel ratio caused rear jounce bumper contact during roll at approximately 0.5 g lateral acceleration. This increased rear roll rate and upset the Tire Lateral Load Transfer Distribution (TLLTD). The nonlinear range understeer balance of the vehicle changed during limit handling maneuvers. To alleviate this phenomenon, a smaller rear anti-roll bar with 15% less vehicle roll stiffness was necessary to balance the vehicle.

To remedy the compromises in the shock damping and anti-roll bars caused by the long jounce bumper, a shorter jounce bumper coupled with a slight trim height change was developed which kept the suspension from contacting the jounce bumper during limit handling maneuvers. Jounce bumper configurations and revised shock damping recommended by Chassis Development were bench tested and checked in the analytical model to ensure shock tower loads were maintained below the target values. When a suitable jounce bumper configuration was found, the original rear anti-roll bar was installed and the handling characteristics were noticeably more linear (roll stiffness now relied on the linear rate elements versus the nonlinear rate of the jounce bumper).

Shock damping curves were then tuned to provide better wheel control over chatter bumps, improved impact isolation and flatter motion over swells The revised shock damping was included in the analytical model, and shock tower loads were further improved. Final changes to the jounce bumper configuration included redesigning the shock dust tubes to allow the largest jounce bumper diameter that could be packaged. To increase durability of the jounce bumper, some containment was found to be necessary. This increased impact hardness and bumper entry feel. A five percent less dense bumper material regained previous impact feel.

The final jounce bumper package was bench tested, and the rate curve combined with the final shock valving and free travel to predict shock tower loads, which were confirmed to be acceptable. Final validation was done by installing the new components on the loads measurement vehicle and checking shock tower load for the severe pothole, which was confirmed to be below the target value.

ANTI-ROLL BARS AND INSULATORS - Anti-roll bars were selected to achieve the target vehicle roll gain and TLLTD. TLLTD influences the nonlinear range understeer balance, which on C5 was more constant and predictable than most comparison vehicles because of the careful synthesis and design efforts to maintain SDF linearity [Ref. 2].

Rear Anti-Roll Bar - The original nominal tuning of the rear anti-roll bar was used during early tire construction development. During jounce bumper tuning the size was decreased to balance the vehicle for limit handling maneuvers. After the jounce bumper tuning was completed, the original size was re-instated. This size was used for the majority of shock valving and tire construction development. The production supplier was selected and available tube sizes identified.

Final nonlinear range understeer balance was developed by evaluating production available bar sizes with different durometer insulators.

Front Anti-Roll Bar - The front anti-roll bar did not change during the chassis development sequence, except to accommodate tube sizes available for production. This is just one of many examples that reflect the accuracy of the target setting and synthesis processes used on C5. On-center performance was enhanced with relatively stiff front bar insulators.

TIRES - Extended Mobility Tires (EMT) were adopted very early for the C5. A spare tire is neither needed nor available, and there are no optional tires. The tire mold shape, tread pattern, construction and compound were developed specifically for the C5. The result was the Goodyear Eagle F1 GS tire.

Tire specifications that were addressed in design and development included targets for cornering coefficient, aligning torque, wet and dry traction, mass,

rolling resistance, uniformity, durability, air borne noise, and many others.

Development of the tire's handling characteristics included subjective evaluations of transient and steady state handling characteristics such as: linearity, recovery, cornering power, on-center feel, steering sensitivity and many others. Evaluation rides were made in both dry and controlled wet environments at the Goodyear San Angelo Proving Ground. Subjective ride evaluations were made for ride characteristics such as impact isolation, impact noise, damping and tread noise at the GM Proving Ground.

The development process typically evaluated several tire submissions at one time on a C5 development vehicle. The evaluation information from the subjective rides was sent back to the Goodyear engineers to aid in designing the next round of tire submissions. In-between submissions, the best tire from each round was retained by the C5 development team for further suspension development work. This iterative development process for the tires was critical in the final optimization of the C5 suspension.

SHOCK ABSORBER MOUNTS - Upper and lower shock absorber mounts (bushings) were identical for the FE1 and FE3 suspensions, and unique for the F45 shocks (a different design and supplier). The series spring rate of both the upper and the lower shock mounts affect wheel control. A relatively high radial rate for the lower bushing was developed. The lower bushing conical rate was minimized to reduce bending loads in the shock during fore-aft suspension recession. This allowed the axial rate of the upper mount to be kept low for good coarse road isolation without sacrificing wheel control. As with the lower bushing, the conical rate had to be managed to minimize shock bending loads.

SHOCK ABSORBER VALVING - Each of the three suspension levels has unique shock absorber design and valving. This section describes the FE1 and FE3 suspensions.

The FE1 suspension uses a monotube design with a 36 mm piston. The FE3 suspension also uses a monotube design with a 45 mm piston. Both FE1 and FE3 shock absorber valvings were developed concurrently. Early valving iterations were unrefined but of adequate control to make the vehicle useful for other development work. Once the jounce bumper development was finalized, shock valving began in earnest.

Force-velocity curves were measured from the 1996 C4 FE1 and FE3 shock absorbers. The curves were adjusted for differences in wheel/shock travel ratio, to yield similar body and wheel control as C4. Different valvings were measured on a shock dynamometer until the target damping curves were matched. Shock valving development was based primarily on subjective rides that totaled over 175 for both FE1 and FE3.

Particular attention was paid to reducing quiick abrupt motions and developing them into controlled, fluid body motions. This not only improved the ride qualities but also made the vehicle handle better on the race track by more progressively managing normal tire loads when encountering bump disturbances such as apex curbing and when cornering through elevation changes. Keeping the rear tires "hooked up" when accelerating out of corners was also enhanced. A sufficient level of compression damping was developed to force the very stiff sidewalls of the EMT tires to envelop bumps. Digressive valving was utilized to keep from being over-controlled in high velocity events. Force-velocity curves comparing FE1 and FE3 damping are shown in Figure 7.

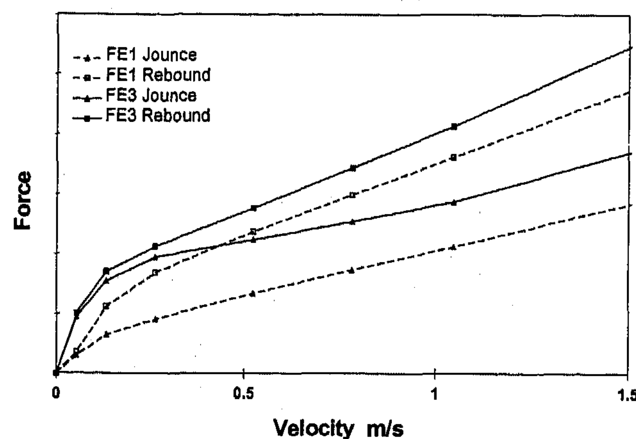

Figure 7. Typical FE1 and FE3 Shock Absorber Damping Characteristics.

REAL TIME DAMPING - An optional suspension for the C5 is the F45 or Real Time Damping (RTD - a system developed by Delphi Chassis of General Motors). RTD measures body and wheel motions, vehicle speed, lateral acceleration, steering wheel angle and velocity and electronically adjusts a continuously variable valve that changes the damping in each shock absorber independently. The system is extremely fast and is capable of controlling quick events such as chatter bumps.

The system will adjust several times during a single event. For instance: the body motion algorithm adjusts the damping to reduce or eliminate vertical motion of the sprung mass while driving through a negative swell. It does this by releasing rebound shock damping as the wheel falls into the swell so that the body will not be tugged down. The system then stiffens compression damping to hold the body up while the wheel travels the bottom of the swell. As the wheel rises up out of the swell, compression damping is released so that the body will not be pitched up. Finally, both rebound and compression valving are moderately stiffened to damp any further relative motion between the sprung and unsprung masses. This algorithm tightly controls heave, pitch and roll body motions. There are also algorithms that monitor lateral and fore-aft acceleration. Some of these anticipate body motions for

various road induced or driver commanded events (i.e. a severe lane change) and adjust damping accordingly.

The system also has a three position driver input switch with "Touring"," "Sport" and "Performance" modes. The "Touring" mode was developed to isolate the body from road contours as discussed in the previous paragraph. The "Performance" mode was developed to follow road contours as with highly damped passive shocks. A compromise middle ground was developed for the "Sport" mode.

Refining RTD involved traditional valving development, plus calibrating the many algorithms that control all the various ride and handling events.

STEERING - A single steering system is used for all suspension levels. C5 was designed from the beginning to use the Magnasteer ™ II variable effort power steering system (a product of Delphi Saginaw of General Motors).

This system was selected because it provided smooth, continuous tuning flexibility. It had the widest effort range of any variable effort system evaluated. It also provided tuning capability with vehicle lateral acceleration.

Reducing steering system friction was very important to meeting the steering system performance goals. This was accomplished two ways. First, the suspension was designed to minimize the ball joint loads and as a result minimize friction. Ball joint loads were minimized by reducing kingpin inclination, scrub radius, and spindle length [Ref 2]. Second, component friction was managed by setting friction specifications for all moving elements of the complete steering system, including ball joints, steering gear and steering column.

Steering ratio was determined by the Steering Sensitivity specification [Ref. 1], fore-aft rack packaging and steer arm length.

Several power steering valve profiles and torsion bar sizes were synthesized from the Steering Torque Gradient and Parking Effort requirements. The valve profiles were subjectively evaluated for on-center performance including linearity. During development, the valve profile was optimized first without the enhancements from Magnasteer™ II. This was followed by calibration of the variable assist curves.

Magnasteer™ II is an enhancement of Magnasteer™ I, but also calculates lateral acceleration from steering wheel angle and vehicle speed to adjust effort as a function of lateral acceleration. (Magnasteer™ I uses an electromagnet to manipulate the torsional rate of the power steering spool valve, and adjusts steering effort as a function of vehicle speed.) Magnasteer™ II allows the vehicle to be tuned for extremely smooth and linear steering feel with increasing lateral acceleration. The steer effort versus vehicle speed and lateral acceleration curves are shown in Figures 8 and 9.

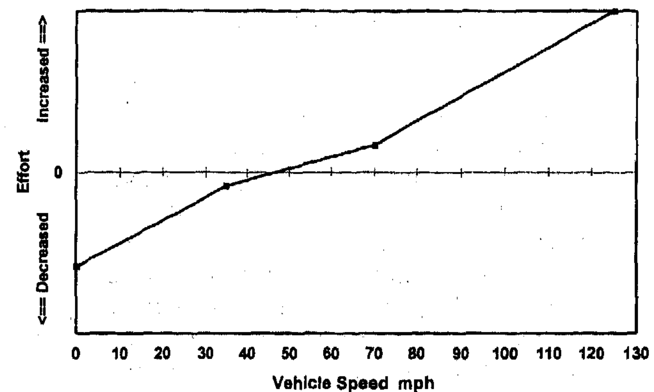

Figure 8. Magnasteer™ II Steer Effort Contribution vs. Vehicle Speed

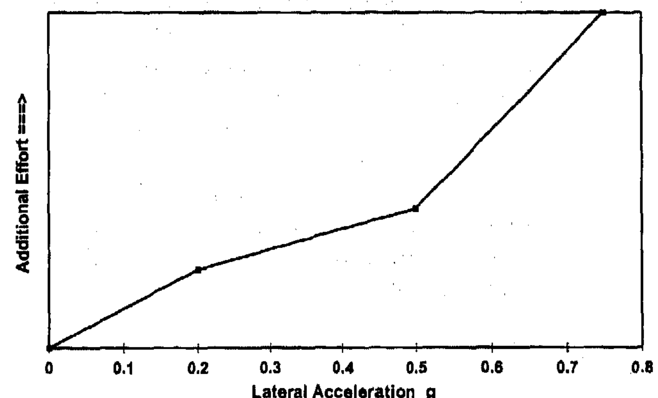

Figure 9. Magnasteer™ II Steer Effort Contribution vs. Lateral Acceleration.

ALIGNMENT - The C5 suspension geometry was uses more static negative camber and more positive caster than C4. The static alignment was evaluated at several points during the development process. It was finalized after the tire construction was fully developed, front camber, caster and toe and rear camber and toe were optimized for on-center steering performance, responsiveness, linearity, cornering power, tread wear etc. Consideration was made for negative camber adjustment capability for race track and gymkhana handling set-ups.

MEASUREMENTS - Two types of measurements were taken periodically to verify the design and to aid in the development process. Suspension kinematics, ride and roll rates, lateral and fore-aft compliances were measured at GM's Vehicle Handling Facility. Test results were compared to the target SDFs and used to validate the design [Ref. 2] and provide guidance for chassis development.

Total vehicle handling characteristics such as Steering Sensitivity, Lateral Acceleration Response Time, Yaw Velocity Damping, Linear Range Understeer, etc. [Ref. 1] were measured by GM's Vehicle Dynamics

Laboratory. Test data was compared to the Ride and Handling section of the Vehicle Technical Specification for validation and development guidance.

ASSESSMENT - The final activity of the development process was to close the loop in validating vehicle performance described in the Ride and Handling section of the Vehicle Technical Specification [Ref.1].

Objective measures and subjective evaluations were used to assess the vehicle performance. They confirmed that the production C5 met its objectives of high level handling characteristics and ride quality.

On-Center steering performance is more precise than C4. Handling is more nimble and linear, which translates into a very predictable vehicle. Limit handling is extremely forgiving with less tractive force steer and improved drop throttle characteristics. Maximum lateral acceleration is increased significantly.

Ride quality is enormously enhanced over the C4 and comparable to many sedans. This is a remarkable achievement considering the relatively stiff nature of the standard equipment EMT tires. Impact hardness is much better and structural memory shake is almost entirely eliminated. Steering wheel kick is negligible. Coarse road noise is noticeably less audible and body motions are less disturbing. There is an overall plushness not found in sports cars with the high level handling capabilities of the Corvette.

CONCLUSION

The 1997 Chevrolet Corvette's highly optimized yet simple suspensions, combined with other key vehicle subsystems and components (body structure, crossmembers, steering system and tires) produced significant improvements in handling, especially overall balance, integration, and predictability, and large gains in ride and isolation.

An exhaustive team effort produced the ride and handling related chassis components and systems introduced on the 1997 Chevrolet Corvette. Initially, vehicle level specifications based on customer input and guidance from recognized experts set the direction for chassis design. Computer simulations of vehicle and subsystem performance plus expert advice established design requirements. Early mule vehicle feedback provided valuable information on concept feasibility and complex interactions. The use of premium and innovative materials and components allowed design solutions to be executed in the hardware.

Development engineers then tuned the whole package into a pleasing, capable vehicle for the customer. The vehicle engineering loop was closed by validating vehicle performance with measured objective metrics that were compared to the Ride and Handling section of the Vehicle Technical Specification.

Above all, it was Management vision and leadership in partnership with Engineering that cultivated the people and resources necessary to produce the all-new suspension, steering, and tire designs unique to C5. The result was a no-compromise balance of ride and handling which extended and expanded upon the Corvette's unique heritage [Ref. 2].

ACKNOWLEDGMENTS

The development of the C5 suspension and steering system was the result of an exceptional team effort by a group of individuals too numerous to mention. However, the authors would be remiss if they failed to acknowledge the contributions of the following individuals: Paul Cavanaugh, Darin Dellinger, Brian Deutschel, Steve Fuja, John Heinricy, Jim Lloyd, Dave McLain, Jeff Roethlisberger, Joe Ryan, Hank Schmid, Rex Stump, Dick Topping, Kyle Tucker, and Dave Wickman.

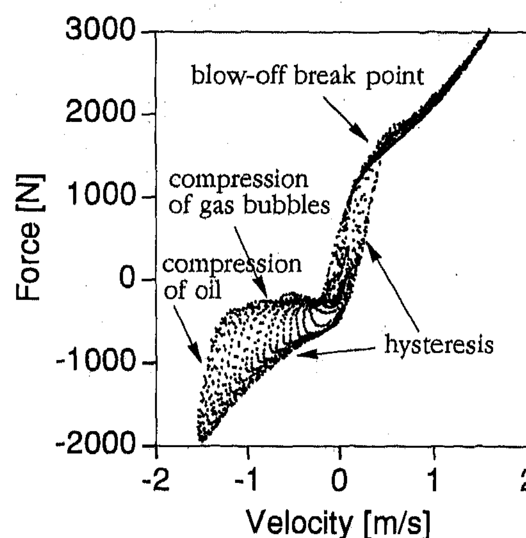
ABSTRACT

A physical model is proposed to account for the hysteretic effects of automotive shock absorbers. Besides the oil compressibility, the compressibility of a variable gas phase in the shape of bubbles are the root of these dynamic effects. Due to the pressure dependent solubility of gas in the liquid the gas bubbles appear or disappear thus changing the compressibility characteristics.

The model is used to identify the internal architecture of the damper, i.e. the valve parameters, and the hysteretic effects simultaneously. Some justifiable assumptions are introduced to estimate directly from damper force, piston displacement and velocity measurements.



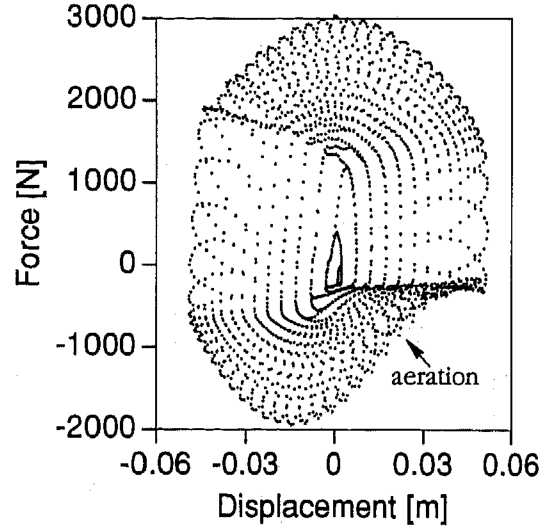
1 INTRODUCTION

The dampers are characterized by three facets. Firstly, when the characteristic diagram of a damper is observed, the force turns out to be a nonlinear function of velocity, due to the nonlinear pressure drop across the valve assemblies as a function of flow [1]. The two most important nonlinear effects are the bilinear character [2], that makes the damper force in the compression phase (negative damper velocities) smaller than in rebound phase (positive damper velocities), and the softening effect that appears from a certain break point, determined by the velocity, at which pressure-controlled blow-off valves open (Figure 1).

A second aspect is the oil temperature dependence of the damper force [3]. The force is determined by the oil viscosity, which, in turn, is strongly influenced by the oil temperature. Due to viscous losses, the oil temperature increases and consequently changes the damper characteristic. For short excitations (typically less than 1 minute), this effect is negligible.

Finally, the appearance of hysteresis loops, especially for higher excitation frequencies, is a third facet [4]. These are partly caused by the compressibility of the damper oil and to less extent by the compliance of the cylinder walls. These phenomena are well documented in the literature but the influence of gas bubbles in the oil is modelled inadequately.

Figure 1: Characteristic diagram



Lang [5] was the first to model the bubbles with some heuristic rules as an evaporation of damper oil, known as cavitation. However, Segel and Lang concluded that a more probable hypothesis is to assume that the bubbles are not formed from vapour but from nitrogen gas, emanating from the reserve chamber [6]. This effect

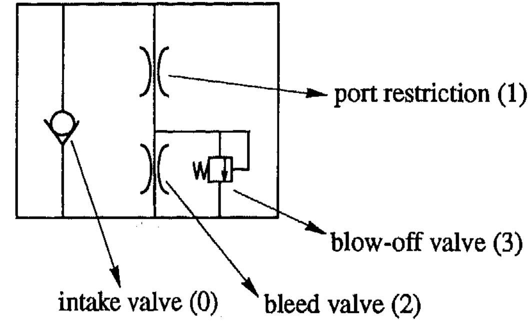
is known as frothing. Morman [7] elaborated their work and implemented the gas bubbles as a gas volume that was alternatively compressed and expanded according to the isentropic law.

This did not explain the sudden appearance or disappearance of the bubbles observed when experiments were performed on transparent dampers. This lacuna is partly studied in this paper. The two basic ideas are the transfer of bubbles between the three chambers and the pressure dependent solubility of the gas in the damper oil. When the pressure increases, the solubility increases and the bubbles disappear because the gas dissolves in the liquid and vice versa. An identification procedure that estimates this effect directly from force and velocity measurements is demonstrated.

The 'aeration' effects are also observed as asymmetries on the measured work diagram (Figure 2). The characteristic diagram (Figure 1) and work diagram were measured on a Mc-Pherson strut typically used on the front suspension of a standard Porsche 911. A modulated signal consisting of the sum of two sines with the same amplitude and close frequencies is used as excitation signal.

Figure 2: Work diagram

2 MODELING DAMPERS



2.1 Valve modeling

2.1.1 The total valve characteristic

The dynamics of the damper force is governed by the time history of the internal pressure drops, which are caused by valve assemblies. In Figure 3 a valve assembly is shown schematically.

An intake valve (0) or check valve offers little resistance to flow in one direction but restricts flow in the opposite direction. The port restriction (1) is a pre-orifice placed in series with two valves: a bleed valve (2), typically realized with notches, and a blow-off valve (3). The bleed valve or initial orifice provides a highly restricted flow path between two chambers. The blow-off valve, also called control valve, is a spring-controlled valve that only opens at a specified pressure differential across the valve.

Figure 3: Valve assembly (schematic)

The bleed valve and the port restriction are passive elements that in the turbulent regime cause a pressure drop that is almost quadratic as a function of flow rate [1]:

Restriction characteristics:

$$\begin{cases} \Delta p_1 = K_1 Q_1^{\frac{7}{4}} & \text{(a)} \\ \Delta p_2 = K_2 Q_2^{\frac{7}{4}} & \text{(b)} \end{cases} \quad (1)$$

Control valves are more complex because they consist of moving elements. Lang worked out a nonlinear dynamical model that exhibits an extensive amount of hysteresis even when the valve inertia and damping are neglected due to the friction effects [5]. In this paper a simplified characteristic derived from the former is used [8]:

Static blow-off characteristic:

$$Q_3 = G(\Delta p_3 - \Delta p_0)\sqrt{\Delta p_3} \quad (2)$$

For $\Delta p_3 > \Delta p_0$, G is the blow-off conductivity factor. For $\Delta p_3 \leq \Delta p_0$, the blow-off valve remains closed and G is zero.

For the combination of the three different valves, the laws for parallel (3) and series (4) flow are used. For parallel flow, the pressure drops are the same but the respective flow rates are added to obtain the total flow. For series flow, the two respective flows are equal but the pressure drops are added to obtain the total pressure drop.

Parallel flow: $\begin{cases} \Delta p_2 = \Delta p_3 \\ Q_2 + Q_3 = Q_{tot} \end{cases}$ (3)

Series flow: $\begin{cases} \Delta p_{tot} = \Delta p_1 + \Delta p_2 \\ Q_1 = Q_{tot} \end{cases}$ (4)

The total valve characteristic is described by equations (5) and (6) where the flow rates Q_1 and Q_3 were eliminated by combining (1)-(4):

$$Q_{tot} = Q_2 + G\left(K_2 Q_2^{\frac{7}{4}} - \Delta p_0\right)\sqrt{K_2} Q_2^{\frac{7}{8}} = f_Q(Q_2) \quad (5)$$

$$\Delta p_{tot} = K_1 Q_{tot}^{\frac{7}{4}} + K_2 Q_2^{\frac{7}{4}} \quad (6)$$

For a pressure drop Δp_{tot} larger than the blow-off pressure Δp_0 this set of equations is implicit in both variables because no exact analytical solution exists. In order to recover Δp_{tot} when Q_{tot} is given, a lot of numerical algorithms can be used [9]. Nevertheless, an approximate analytical solution is presented to lower the computation time.

2.1.2 An explicit total valve model

For a pressure drop Δp_{tot} larger than the blow-off pressure Δp_0 the right hand side of equation (5) is expanded into a Taylor series around the blow-off flow rate Q_{20}:

$$Q_{tot} \approx \sum_{i=0}^{D} \frac{\partial^{(i)}}{\partial Q_2^{(i)}} f_Q(Q_2)\bigg|_{Q_2 = Q_{20}} (Q_2 - Q_{20})^i \quad (7)$$

$$\text{with } Q_{20} = \left(\frac{\Delta p_0}{K_2}\right)^{\frac{4}{7}} \quad (8)$$

A second order expansion (D=2) can easily be inversed and given Q_{tot}, Q_2 is calculated, viz:

$$Q_2 = Q_{20} + \frac{\sqrt{A_1^2 + 4A_2(Q_{tot} - Q_{20})} - A_1}{2A_2} \quad (9)$$

$$\text{with } \begin{cases} A_0 = f_Q(Q_{20}) = Q_{20} \\ A_1 = \frac{\partial}{\partial Q_2} f_Q(Q_2)\bigg|_{Q_2 = Q_{20}} = 1 + \frac{7\Delta p_0^{\frac{3}{2}} G}{4Q_{20}} \\ A_2 = \frac{\partial^2}{\partial Q_2^2} f_Q(Q_2)\bigg|_{Q_2 = Q_{20}} = \frac{35\Delta p_0^{\frac{3}{2}} G}{16 Q_{20}^2} \end{cases} \quad (10)$$

and finally Δp_{tot} is obtained from expression (6). The positive root (9) is chosen to obtain a positive real value according to the physical constraints. Higher order approximations can be used [8]. This explicit total valve characteristic will be used in the identification procedure.

2.1.3 An explicit inverse total valve model

For purpose of simulation, an inverse total valve model is needed where the flow rate Q_{tot} is calculated as a function of the total pressure drop Δp_{tot}. An approximate analytical solution is introduced similar to the one presented in section 2.1.2. The total pressure drop is written as a function of Δp_2 by combining equations (1)-(4):

$$\Delta p_{tot} = K_1\left[\left(\frac{\Delta p_2}{K_2}\right)^{\frac{4}{7}} + G(\Delta p_2 - \Delta p_0)\sqrt{\Delta p_2}\right]^{\frac{7}{4}} + \Delta p_2 = f_\Delta(\Delta p_2) \quad (11)$$

The right hand side of this equation is developed into a Taylor series around the blow-off pressure Δp_0 :

$$\Delta p_{tot} \approx \sum_{i=0}^{D} B_i (\Delta p_2 - \Delta p_0)^i \quad (12)$$

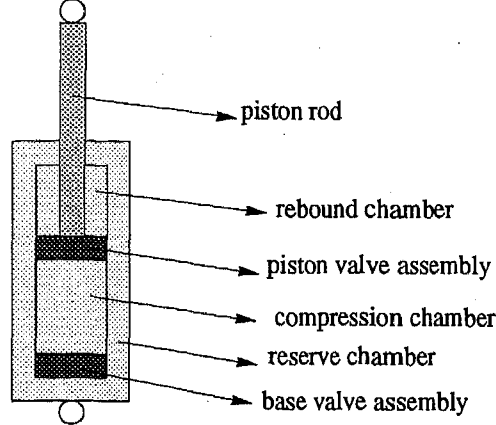
$$\text{with } B_i = \frac{\partial^{(i)}}{\partial \Delta p_2^{(i)}} f_\Delta(\Delta p_2)\bigg|_{\Delta p_2 = \Delta p_0} \quad (13)$$

A second order series is inversed to obtain the solution for Δp_2 as a function of Δp_{tot}:

$$\Delta p_2 = \Delta p_0 - \frac{B_1 - \sqrt{B_1^2 + 4B_2(\Delta p_{tot} - B_0)}}{2B_2} \text{ with} \quad (14)$$

$$\begin{cases} B_0 = \Delta p_0\left(1 + \frac{K_1}{K_2}\right) \\ B_1 = \left(1 + \frac{K_1}{K_2}\right) + \frac{7}{4} G K_1 \sqrt{\Delta p_0}\left(\frac{\Delta p_0}{K_2}\right)^{\frac{3}{7}} \\ B_2 = \frac{G K_1}{32\sqrt{\Delta p_0}}\left(\frac{\Delta p_0}{K_2}\right)^{\frac{3}{7}}\left[52 + 21 G K_2 \sqrt{\Delta p_0}\left(\frac{\Delta p_0}{K_2}\right)^{\frac{3}{7}}\right] \end{cases} \quad (15)$$

Once Δp_2 is calculated, Q_{tot} is obtained by combining equations (1) and (4):



$$Q_{tot} = \left(\frac{\Delta p_{tot} - \Delta p_2}{K_1}\right)^{\frac{4}{7}} \quad (16)$$

2.2 Damper dynamics

The dual tube shock absorber consists of three chambers (Figure 4). In the internal tube, the portion of the cylinder above the piston is known as the rebound

chamber, and the portion of the cylinder below the piston is known as the compression chamber. The space between the outer and inner tube is called the reserve chamber. The reserve chamber is partly filled with nitrogen gas to compensate the volumetric changes, engendered by the inward/outward motion of the piston rod.

Figure 4: Dual tube shock absorber (schematic)

Every chamber with volume V is filled with an oil mass m_o, a bubble gas mass m_{gb} and within the reserve chamber an extra homogeneous gas volume V_{ge}. Using the density of oil ρ and the ideal gas law, the chamber volume is obtained, viz:

$$V = \frac{m_o}{\rho} + \frac{m_{gb}RT}{p} + V_{ge} \qquad (17)$$

The bubbles are compressed and expanded under isotherm conditions (T=cste) because due to the very small bubble diameter any heat produced inside the bubbles is transferred to the surrounding liquid instantaneously. However, the expansion and compression of the large homogeneous gas volume are better modelled under adiabatic conditions which are described by the isentropic law (with $\gamma = 1.4$):

$$V_{ge} = \sqrt[\gamma]{\frac{p_{initial}}{p}} V_{initial} = \frac{\xi}{\sqrt[\gamma]{p}} \qquad (18)$$

$$\text{with } \xi = p_{initial}^{1/\gamma} V_{initial} \qquad (19)$$

The compressibility of the oil makes the density dependent on the chamber pressure p. The relative change in volume is considered to be proportional to the applied pressure within a range up to a pressure of 10^7Pa:

$$\frac{V_0 - V}{V_0} = \alpha p \qquad (20)$$

Consequently, the actual density is calculated from:

$$\rho = \frac{\rho_0}{1 - \alpha p} \qquad (21)$$

For sake of convenience, the ratio r between gas bubble mass and oil mass is introduced by

$$r = \frac{m_{gb}}{m_o} \qquad (22)$$

Substitution of (18), (21) and (22) into (17), results in

$$V = \left[\frac{(1-\alpha p)}{\rho_0} + \frac{rRT}{p}\right] m_o + \frac{\xi}{\sqrt[\gamma]{p}} \qquad (23)$$

Derivation of (23) with respect to time, gives the rate of change in volume:

$$\dot{V} = Q - \left(\frac{\alpha}{\rho_0} + \frac{rRT}{p^2}\right)\dot{p} m_o - \frac{\dot{r}RT}{p} m_o - \frac{\xi \dot{p}}{\gamma \sqrt[\gamma]{p^{\gamma+1}}} \qquad (24)$$

Some dampers are designed through the use of baffles or membranes in such a way that no gas from the homogeneous gas phase is drawn into the inner cylinder, i.e. ξ is constant. Furthermore, the changes in chamber temperature T are assumed to be negligible. Q is defined as the net mass flow in the chamber:

$$Q = \left[\frac{(1-\alpha p)}{\rho_0} + \frac{rRT}{p}\right] \dot{m}_o \qquad (25)$$

The fundamental difference for the definition of the flow in comparison with the models of Lang [5] and Morman [7] is the fact that bubbles are also included in the flow and transferred between chambers. This assumption is sustained by Stokes' formula, which is explained later.

For the rebound chamber e.g., Q is the flow $Q|^r_{r \to c}$ between the compression chamber and the rebound chamber and is dependent on the two respective chamber pressures (see former section). Due to the effect of expansion the flow $Q|^c_{r \to c}$ that penetrates the compression chamber and originally drawn from the rebound chamber will be different from $Q|^r_{r \to c}$. If the conservation law of mass is expressed we obtain:

$$\dot{m}_o = \frac{Q|^r_{r \to c}}{\frac{1-\alpha p_r}{\rho_0} + \frac{rRT}{p_r}} = \frac{Q|^c_{r \to c}}{\frac{1-\alpha p_c}{\rho_0} + \frac{rRT}{p_c}} \qquad (26)$$

A similar relationship is found for the flow between compression chamber and reserve chamber:

$$\frac{Q|^s_{s \to c}}{\frac{1-\alpha p_s}{\rho_0} + \frac{rRT}{p_s}} = \frac{Q|^c_{s \to c}}{\frac{1-\alpha p_c}{\rho_0} + \frac{rRT}{p_c}} \qquad (27)$$

For sake of convention the flow calculated from the flow-pressure characteristics (section 2.1.3) will be on the side of the chamber from where the liquid originates.

The second term in (24) is due to the compressibility of the gas and oil mixture. It was shown that this term can

also account for the compliance of the cylinder walls [5], [10].

The third term is due to the solubility of the gas in the liquid, which is described by Henry's law [11]:

$$p = H\frac{m_{gs}}{V_{oil}} \tag{28}$$

where H is a function of the mixture and temperature. Since both are assumed to be given, H is further considered to be a constant. m_{gs} is the mass of gas in solution. The solved gas mass is calculated from (28) via substitution of the oil volume with the respective density and oil mass as follows

$$m_{gs} = \frac{m_o p}{\rho_0 H} \tag{29}$$

The fraction r can thus be obtained from the total gas mass m_{gt} and the gas mass in solution m_{gs}

$$r = \frac{m_{gt}-m_{gs}}{m_o} = r_t - \frac{p}{H\rho_0} \tag{30}$$

The total fraction r_t is assumed to be constant because this fraction can only change with a convection stream of bubbles relative to the fluid. Experiments with transparent absorbers have shown that the bubbles have a negligible velocity relative to the fluid. Stokes' formula [11] gives a rough estimate of the relative velocity of the bubbles in the oil:

$$v = \frac{(\rho_{oil}-\rho_{gas})\,d^2 g}{18\mu} \tag{31}$$

This formula emanates from the balance between the Archimedes force, due to the difference in densities, and the viscous friction force. If typical values of ρ_{oil}= 935kg/m^3 (density of oil), ρ_{gas}= 1.3 kg/m^3 (density of gas), d = 1e-4m (diameter of gas bubble), g = 9.81 m/s^2 (acceleration of gravity), μ = 0.037kg/ms (dynamic oil viscosity) are used for bubbles whose diameter is less than 1e-4m the relative speed of the bubbles is approximately 0.001m/s. Compared with the flow speed of the oil (above 0.01m/s), this is, indeed, negligible.

From (30), it is obvious that above a critical pressure p_k all bubbles disappear (r=0), which means that all gas remains in the solution, with:

$$p_k = r_t H\rho_0 \tag{32}$$

By substituting (30) in (23) and solving for m_o we get

$$m_o = \frac{V-\frac{\xi}{\gamma\sqrt{p}}}{\frac{(1-\alpha p)}{\rho_0}+\frac{r_t RT}{p}-\frac{RT}{H\rho_0}} \tag{33}$$

Substitution of (30) in (24), leads to

$$\dot{V} = Q-\left(\frac{\alpha}{\rho_0}+\frac{r_t RT}{p^2}\right)\dot{p}m_o-\frac{\xi\dot{p}}{\gamma\gamma\sqrt{p^{\gamma+1}}} \tag{34}$$

Substitution of (33) into (34) yields:

$$\dot{V} = Q-\frac{\left(V-\frac{\xi}{\gamma\sqrt{p}}\right)\left(\frac{\alpha}{\rho_0}+\frac{r_t RT}{p^2}\right)\dot{p}}{\frac{(1-\alpha p)}{\rho_0}+\frac{r_t RT}{p}-\frac{RT}{H\rho_0}}-\frac{\xi\dot{p}}{\gamma\gamma\sqrt{p^{\gamma+1}}} \tag{35}$$

The chamber volumes can also be obtained from the respective geometric relations for the rebound chamber volume:

$$V_r = (L-x)A_r \tag{36}$$

and the compression chamber volume:

$$V_c = (L+x)A_c \tag{37}$$

The volumes are dependent on the displacement x of the piston from the mid position where L is the half length of the inner cylinder. The cross area A_r of the rebound chamber is smaller than the cross area A_c of the compression chamber due to the presence of the piston rod with cross area A_d :

$$A_r = A_c - A_d \tag{38}$$

The volume V_s of the reserve chamber is a known constant value. The dynamics of the global system is described by a set of three differential equations that show how the pressures in the three individual chambers vary as a function of pressure, displacement and velocity. Combination of expressions (35)-(37) yields:

Rebound chamber: $(p_r < p_k)$

$$\dot{p}_r = \frac{[Q|^r_{c\to r}+\dot{x}A_r]}{(L-x)A_r}\frac{\left[\frac{(1-\alpha p_r)}{\rho_0}+\frac{r_t RT}{p_r}-\frac{RT}{H\rho_0}\right]}{\left(\frac{\alpha}{\rho_0}+\frac{r_t RT}{p_r^2}\right)} \tag{39}$$

Compression chamber: $(p_c < p_k)$

$$\dot{p}_c = \frac{[(Q|^c_{s\to c}-Q|^c_{c\to r})-\dot{x}A_c]}{(L+x)A_c}\frac{\left[\frac{(1-\alpha p_c)}{\rho_0}+\frac{r_t RT}{p_c}-\frac{RT}{H\rho_0}\right]}{\left(\frac{\alpha}{\rho_0}+\frac{r_t RT}{p_c^2}\right)} \tag{40}$$

Reserve Chamber:

$$\dot{p}_s = -\frac{Q|^s_{s\to c}}{\frac{\left(\frac{\alpha}{\rho_0}+\frac{r_t RT}{p_s^2}\right)\left(V_s-\frac{\xi}{\gamma\sqrt{p_s}}\right)}{\frac{(1-\alpha p_s)}{\rho_0}+\frac{r_t RT}{p_s}-\frac{RT}{H\rho_0}}+\frac{\xi}{\gamma\gamma\sqrt{p_s^{\gamma+1}}}} \tag{41}$$

After a number of strokes the bubbles and air in solution are homogeneously distributed in the three chambers therefore it is justified that the ratio r_t is the same in all chambers. After a sufficiently long rest period, the bubbles rise to the top of the rebound chamber and a large gas bubble is formed. If a new excitation is engaged with a slow rebound stroke, the gas will be evacuated through the highly restrictive space between the piston rod and rod guide into the reserve chamber. Before experiments are carried out, it is common to reset the damper with a slow sinusoidal displacement, which is referred to as the 'priming' sequence.

Except for the reserve chamber, ξ is zero. Equations (39)-(41) are formed for pressures below the critical pressure p_k. The reserve chamber is normally designed in such a way that higher pressures do not appear but this is not true for the other two chambers. For pressures higher than the critical pressure, equations (39)-(40) reduce to (42) and (43).

Rebound chamber: $(p_r \geq p_k)$

$$\dot{p}_r = \frac{[Q|^r_{c\rightarrow r} + \dot{x}A_r]}{(L-x)A_r}\frac{(1-\alpha p_r)}{\alpha} \tag{42}$$

Compression chamber: $(p_c \geq p_k)$

$$\dot{p}_c = \frac{[(Q|^c_{s\rightarrow c} - Q|^c_{c\rightarrow r}) - \dot{x}A_c]}{(L+x)A_c}\frac{(1-\alpha p_c)}{\alpha} \tag{43}$$

3 IDENTIFICATION

3.1 Assumptions

When the internal pressures are measured directly, it is possible to use the set of equations in the former section. When the identification is to be performed on force data, the problem turns out to be non-trivial. A possible approach is based on the use of parameter-sensitivity functions [12]. This method finds the parameters with a gradient method where the gradients are calculated from a related set of differential equations. In the present paper, in order to simplify the identification procedure, some assumptions are used as follows.

Firstly, it occurs that the pressure in the reserve chamber changes very little, compared with the two other. The homogeneous gas phase in the reserve chamber disables any large pressure variability and it is justified to assume that the pressure p_s remains constant. This pressure is determined from the static damper force F_0 at rest [8].

The force acting on the piston rod is calculated as:

$$F = A_r p_r - A_c p_c \tag{44}$$

At rest, the pressures in all chambers are the same and equal to the reserve chamber pressure. Substitution of $p_r = p_c = p_s$ into (44) leads to an expression for p_s:

$$p_s = \frac{F_0}{(A_r - A_c)} = -\frac{F_0}{A_d} \tag{45}$$

Since A_r is smaller than A_c, the static force is negative and it will slowly push the piston rod out of the damper body if no counter force is applied.

Secondly, during a compression stroke, fluid is forced to flow up from the compression chamber to the rebound chamber through the rebound intake valve in the piston head. During a rebound stroke, fluid from the reserve chamber is drawn through the compression intake valve in the base assembly to the compression chamber. These intake valves offer little resistance to flow but restrict flow in the opposite direction when the pressure differential is reversed. For convenience the respective pressure drops are set to zero for the appropriate phases, so that we get:

$$\begin{cases} p_c = p_s & \text{for} \quad F \geq F_0 \quad \text{(rebound)} \\ p_r = p_c & \text{for} \quad F \leq F_0 \quad \text{(compression)} \end{cases} \tag{46}$$

3.2 Simplified set of equations

The assumptions cited in section 3.1 reduce the number of independent pressure variables from three to one. The rebound chamber pressure p_r is the remaining independent state variable. The assumptions also leave undetermined $Q_{c\rightarrow r}$ during the compression stroke and $Q_{s\rightarrow c}$ during the rebound stroke. The set of three equations is thus rearranged so that these terms do not appear. For $(p < p_k)$, expressions (47) and (48) are used, instead, for $(p \geq p_k)$, expressions (49) and (50) are used.

Rebound phase: identical to (39)

$$\dot{p}_r = \frac{(Q|^r_{c\rightarrow r} + \dot{x}A_r)}{(L-x)A_r}\frac{\left(\frac{(1-\alpha p_r)}{\rho_0} + \frac{r_t RT}{p_r} - \frac{RT}{H\rho_0}\right)}{\left(\frac{\alpha}{\rho_0} + \frac{r_t RT}{p_r^{\,2}}\right)} \tag{47}$$

Compression phase: combining (39) and (40)

$$\dot{p}_r = \frac{-(Q|^c_{c\rightarrow s} + \dot{x}A_d)}{L(A_r + A_c) + xA_d}\frac{\left(\frac{(1-\alpha p_r)}{\rho_0} + \frac{r_t RT}{p_r} - \frac{RT}{H\rho_0}\right)}{\left(\frac{\alpha}{\rho_0} + \frac{r_t RT}{p_r^{\,2}}\right)} \tag{48}$$

Rebound phase: identical to (42)

$$\dot{p}_r = \frac{(Q|^r_{c\rightarrow r} + \dot{x}A_r)}{(L-x)A_r}\frac{(1-\alpha p_r)}{\alpha} \tag{49}$$

Compression phase: combining (42) and (43)

$$\dot{p}_r = \frac{-(Q|^c_{c\to s} + \dot{x}A_d)}{L(A_r + A_c) + xA_d}\frac{(1-\alpha p_r)}{\alpha} \qquad (50)$$

3.3 Identification procedure

The assumptions enable us to calculate the rebound pressure p_r directly from the measured damper force F:

$$p_r = \frac{F + A_c p_s}{A_r} \text{ for rebound} \qquad (51)$$

$$p_r = \frac{F}{A_r - A_c} \text{ for compression} \qquad (52)$$

This pressure is also defined as the measured rebound pressure $p_r|_{meas}$. The first derivative $\dot{p}_r$ can be obtained in time domain as well as in frequency domain since periodic excitations are applied.

Given the motion of the damper $(x, \dot{x})$ and the internal pressure and its first derivative $(p_r, \dot{p}_r)$, it is possible to get (a) the flow rate $Q|^r_{c\to r}$ between compression and rebound chamber during the rebound stroke for $(p_r < p_k)$ from (47) and (32):

$$Q|^r_{c\to r} = \frac{\left(\frac{\alpha}{\rho_0} + \frac{r_t RT}{p_r^2}\right)(L-x)A_r\dot{p}_r}{\frac{(1-\alpha p_r)}{\rho_0} + r_t RT\left(\frac{1}{p_r} - \frac{1}{p_k}\right)} - \dot{x}A_r \qquad (53)$$

and for $(p_r \geq p_k)$ from (49):

$$Q|^r_{c\to r} = \frac{\alpha(L-x)A_r\dot{p}_r}{(1-\alpha p_r)} - \dot{x}A_r \qquad (54)$$

and (b) the flow rate $Q|^c_{c\to s}$ between compression and reserve chamber during the compression stroke for $(p_r < p_k)$ from (48) and (32):

$$Q|^c_{c\to s} = -\frac{\left(\frac{\alpha}{\rho_0} + \frac{r_t RT}{p_r^2}\right)(L(A_r + A_c) + xA_d)\dot{p}_r}{\frac{(1-\alpha p_r)}{\rho_0} + r_t RT\left(\frac{1}{p_r} - \frac{1}{p_k}\right)} - \dot{x}A_d \qquad (55)$$

and for $(p_r \geq p_k)$ from (50):

$$Q|^c_{c\to s} = -\frac{\alpha(L(A_r + A_c) + xA_d)\dot{p}_r}{(1-\alpha p_r)} - \dot{x}A_d \qquad (56)$$

These flow rates lead us to the respective pressure drops in equations (6) and (9), and consequently to the modelled rebound pressure $p_r|_{mod}$. The rebound pressure is calculated as (a) the sum of p_s and the pressure drop over the base valve assembly during compression, and (b) the sum of p_s and the pressure drop over the piston valve assembly during rebound.

Each valve assembly is characterized by four independent parameters: K_1, K_2, G and Δp_0. The global dynamics are characterized by three parameters: α, r_t and p_k. The geometric parameters A_r, A_c, V_s and L, and the initial oil density ρ_0 are assumed to be known or given. An identification procedure estimates the three dynamic parameters and the two times four valve parameters in a least squares sense. The estimates are obtained from minimization of a cost function defined as

$$Z = \sum_{i=1}^{N} \frac{(p_r(t_i)|_{meas} - p_r(t_i)|_{mod})^2}{N} \qquad (57)$$

where the pressures are sampled at regular time instants $t_i = i/f_{sample}$ with N the number of samples and f_{sample} the sample frequency.

3.4 Estimate evaluation

The square root of Z is the Root Mean Square (RMS) residue between the measured and modelled values. A similar residue is calculated for the damper force as the square root of a cost function Z':

$$Z' = \sum_{i=1}^{N} \frac{(F(t_i)|_{meas} - F(t_i)|_{mod})^2}{N} \qquad (58)$$

The modelled damper force is obtained from inversion of equations (51) and (52), viz

$$F|_{mod} = A_r p_r|_{mod} - A_c p_s \text{ for rebound} \qquad (59)$$

$$F|_{mod} = -A_d p_r|_{mod} \text{ for compression} \qquad (60)$$

The residue originates from model errors, measurement noise and numerical errors. The variance σ^2 or level of measurement noise is estimated from M periods provided that the temperature effects are not important:

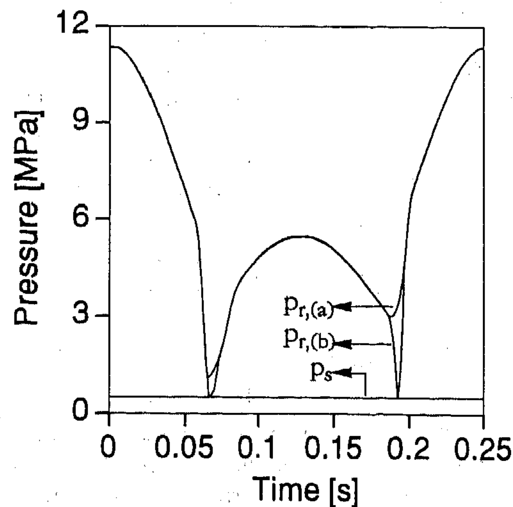
$$\hat{\sigma}^2 = \sum_{i=1}^{N}\sum_{j=0}^{M-1} \frac{\left(F(t_i + j\tau)|_{meas} - \overline{F(t_i)}|_{meas}\right)^2}{N(M-1)} \qquad (61)$$

$$\text{with } \overline{F(t_i)}|_{meas} = \sum_{k=0}^{M-1} \frac{F(t_i + k\tau)|_{meas}}{M} \qquad (62)$$

and $\tau = N/f_{sample}$ the excitation period. In the case that the uncertainty bound for the noise is equal to the model error the RMS residue will be equal to $\sqrt{2}\sigma$ in the absence of important numerical errors. The presence of numerical problems is detected by observing the condition number of matrix calculations during optimization.

For the final evaluation of the model the residue will be compared to $\sqrt{2}\sigma$. If the residue is much smaller than this value the identification will suffer from overmodeling which means that the model is probably modeling a part of the noise spectrum. Some model parameters are not estimated accurately due to masking by measurement noise. It is recommended to perform a new set of more accurate measurements (less corrupted with noise) or to remove the deficient parameters because they do not contribute to the model in a relevant way for the given experiments.

On the other hand if the residue is much larger than $\sqrt{2}\sigma$ this means that the model is probably too simple to accurately describe the measurement results. A more complex model is then recommended to overcome the deficient fit.



4 RESULTS

4.1 Simulation of internal pressures

In order to verify the effect of the assumptions, a damper is simulated (a) with the full set of equations (39)-(43) and (b) with the simplified set of equations (47)-(50). The set of ordinary differential equations is solved using fourth and fifth order Runge-Kutta formulas [13]. A sinusoidal excitation x is used with an amplitude of 5 cm and a frequency of 4Hz. The set of parameters is defined in Table 1 (appendix). The simulation results are shown in Figure 5.

If we compare the rebound pressure for (a) the full and (b) the simplified set we observe the largest discrepancy when the velocity of the piston approaches zero, i.e. at the time the damper switches from rebound to compression stroke or vice versa.

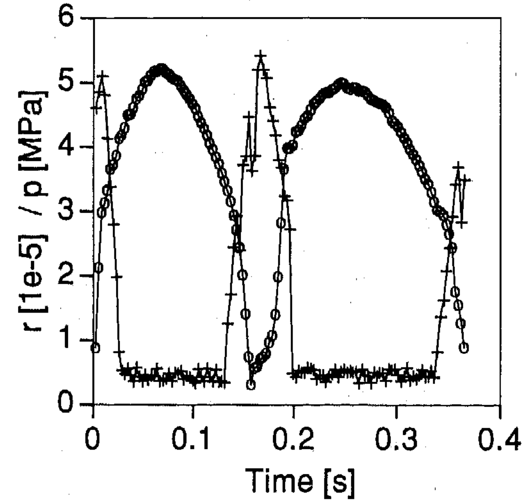


Figure 5: Simulated rebound pressures

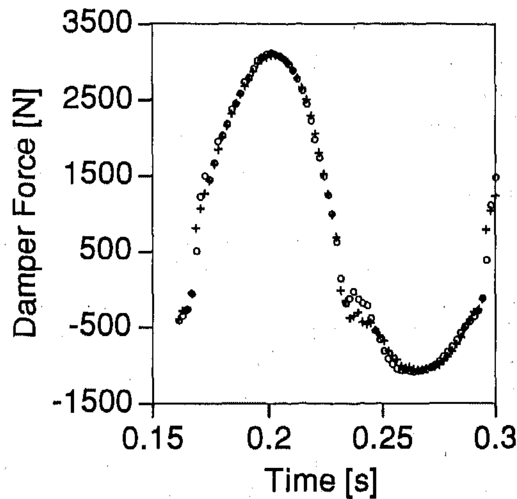
4.2 Experimental gas fraction, r

Using an inverse calculation in [14] an approximation of the time history of the fraction r is obtained [(+) in (Figure 6)].

Figure 6: Experimental bubble gas fraction r(t)

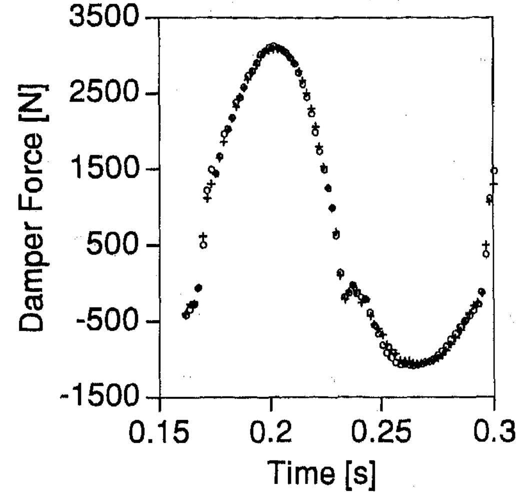
Firstly, a similar model where the fraction r was assumed to be constant (i.e. H=∞) similar to Morman's model was fitted to measurements obtained from a beating signal. The modelled damper force did not explain certain effects that will be shown in a later section. Then it was assumed that all model parameters were exact and the fraction r was calculated to make the model match the experiments. A plot of the rebound pressure (o) and the resulting fraction are given in Figure 6. The fraction remains at a low level (around 5e-6) for a long portion of the excitation time but when the pressure decreases (close to zero piston velocity) the mass of gas bubbles increases and vice versa. This phenomenon is explained by Henry's law as will be shown in the next section. However the fraction r from the inverse calculation does not reach zero probably because the parameters were obtained from a fit where a constant time-averaged value for r was obtained. This probably introduced a bias on all parameters leading to the offset for the calculated fraction.



Furthermore it is also experienced from Figure 6 that the critical pressure at which the fraction reaches its minimum is different from the pressure at which the fraction rises from that minimum. For both rebound and compression strokes bubbles start appearing around 3MPa while the fraction only reaches its minimum around an effective pressure of 4MPa. This delay is probably due to the solving of bubbles that does not take place immediately as assumed by Henry's law due to the finite diameter of bubbles.

4.3 Identification results

A shock absorber was excited with a beating signal with an approximate excitation period of 4 seconds. Then measurements of damper force, piston displacement and velocity were processed to fit the parameters of the given model. The same test set-up as presented in [1] was used. A second model was fitted where the fraction r was assumed to be constant. This is equivalent to fitting the first model with p_k having a fixed infinite value ($p_k=\infty$). The cost function was then minimized using a Levenberg-Marquardt algorithm [9].



Detailed results of the measured force (o) and the force reconstructed from the ($p_k=\infty$)-model (+) are shown in Figure 7. The model fits satisfactorily when the force reaches its maximum and minimum values; but when the force gets close to zero a larger discrepancy is observed, especially around t=0.235s. This is not the case when the full model ($p_k<\infty$) is fitted (Figure 8).

Figure 7: Fit of model (r=cste) to measurements

In order to give an objective quality measure on both fits the standard deviation σ of the measurement noise is calculated according to (61) from 4 consecutive periods. It is assumed that temperature effects are negligible over this short period (4 x 4s = 16s). It was shown in [14] that the force experiences a linear trend of about 40N over this time. The estimate of σ equals **52N/sample**. The RMS residues for both models are respectively (a) for the (r=cste)-model **99N/sample** and (b) for the full model **82N/sample**. The improvement is not very important but this is due to the minor importance of this second order effect of the pressure dependent solubility described by Henry's law. The residue of the full model is close to the limit $\sqrt{2}\sigma$ **=73N/sample** which means that a good fit has been performed according to the discussion in section 3.4.

Figure 8: Fit of model (r≠cste) to measurements

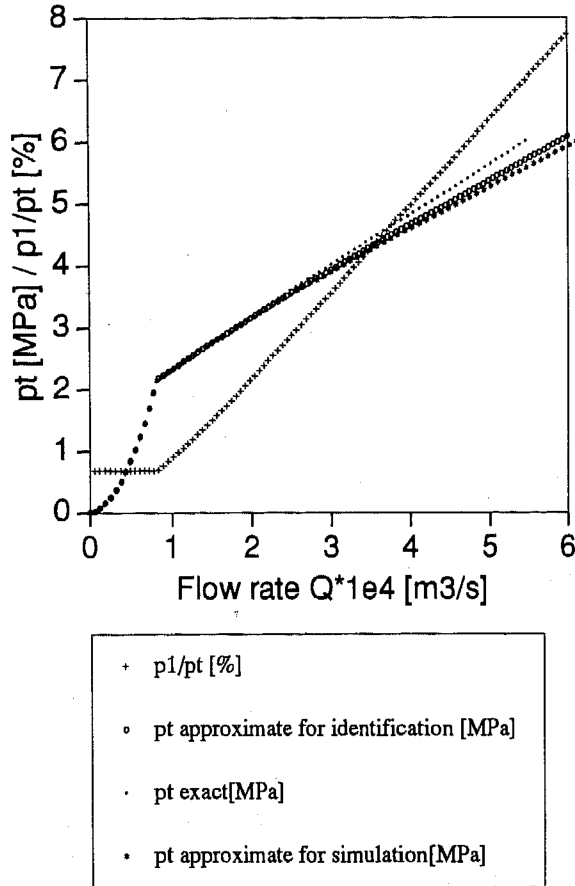
The fitted and fixed parameters of the full model are given in Table 2 (appendix)

4.4 Discussion

The compressibility of the mixture of gas and fluid is determined by the factor

$$\text{compressibility} = \frac{\alpha}{\rho_0} + \frac{r_t RT}{p_r^2} \qquad (63)$$

Dependent on the rebound pressure, one of the two terms will be dominant compared to the other. Using the fitted parameters in Table 2 it is possible to determine the pressure at which both terms are equal:



$$p_r = \sqrt{\frac{r_t RT\rho_0}{\alpha}} = 4.37MPa \qquad (64)$$

This is a rather high value due to mixing of oil and gas phase caused by the specific geometry and tuning of the tested strut. Below this pressure, it is unjustified not to take the influence of gas bubbles into account. Models [2], [3] and [10] that only use compressibility of fluid and possibly the elasticity of cylinder walls to account for hysteretic effects would induce important predictive errors for this absorber under test. However some dampers are found where the gas phase is separated from the fluid by a membrane [4] or a floating piston which is typical for a mono-tube shock absorber [1]. If care was taken to remove all dissolved air or bubbles in the fluid before manufacture of the damper, e.g. by heating the oil, these models will work. Models [15] and [16] that do not take oil compressibility into account have no realistic predictive power concerning damper hysteresis.

It is clear from Table 2 that the pressure drop over the leak restriction is much more important than the drop over the port restriction. A difference of two orders of magnitude for the restrictions of the rebound valve assembly as well as the compression valve assembly

suggests a possibility to neglect the port restriction.

Figure 9: Total valve characteristic of the piston

In Figure 9 the total valve characteristic of the identified piston assembly is shown with the tokens (.), (o) and (•), respectively, for the exact equations (5) and (6), the approximate equations (6) and (9) used for identification and the approximate equations (14) and (16) used for simulation. Above the blow-off pressure a quasi linear pressure drop as a function of flow rate is observed. The ratio of the port pressure drop to the total pressure drop $\Delta p_1/\Delta p_{tot}$ is presented with (+). Below the blow-off flow rate the ratio is indeed very small (less than 1%) but the ratio increases almost linearly above the blow-off break point. Consequently, for higher pressure drops neglecting the port restriction will induce larger simulation errors.

The relative error induced by the approximate valve equations is around 5% for a pressure drop of 4MPa and 12% for a drop of 6MPa. The pressure drop for a relative error of 10% lies about 5.3MPa. Both approximations give an underestimate of the actual pressure drop.

For the damper temperature, T=323K was used which is possibly not the real temperature because dampers easily experience an increase of 50K from the initial temperature [2]. Nevertheless, the identification can handle this problem because the two factors T and r_t appear coupled [equations (53) and (55)] and the latter is estimated. For instance, when the assumed temperature, used in the identification procedure, turns out to be lower than the real temperature the estimator will compensate this by a larger value of r_t and vice versa.

5 FUTURE DEVELOPMENTS

5.1 Valve modeling

A more complex model for the valve assemblies may improve the predictive power of the full model although it was argued in [7] that the valve inertia and linear damping used in [5] are almost undetectable. However it has been observed that the sharp blow-off edge (Figure 9) is often rounded [8], possibly because the blow-off valve starts leaking before the blow-off pressure Δp_0. An empirical transition coefficient was used in [1] to account for this effect. The blow-off valve in [5] is assumed to translate up and down during compression and rebound respectively. In reality a modern blow-off valve consists of a disk spring clamped on the inner side and opening by bending.

5.2 Friction

McPherson struts are dampers that allow side loading. When a large side load is applied to the strut, large values of friction are detected between the piston and the inner tube and between the rod guide and the damper rod. The rod guide and damper rod are highly finished because the largest values of friction appear between them due to the lever effect. For low velocities even sticktion (sticking friction) can appear. An elaborated model has been synthesized by Armstrong-Hélouvry [17] to account for Coulomb friction, Stribeck friction, frictional memory, dwell time, etc.

Nevertheless, when no side loading is applied, a simple model can accurately describe friction where the damper force is calculated viz:

$$F = A_r p_r - A_c p_c + F_c sign(\dot{x}) \qquad (65)$$

F_c is the Coulomb friction and typical values within the range of 0-100N have been recorded.

5.3 Bubble dynamics

Henry's law describes the effect of bubbles present in the fluid very well. Experiments with transparent dampers show that the bubbles are present in the form of a diffusion which means that the diameter of the bubbles is very small (typically less than 0.1mm). This is probably due to the large strokes that push the fluid

with bubbles through the narrow openings of the valve. However, for a small stroke larger bubbles are expected and this changes the value of the critical pressure. A delay for solving bubbles was also experienced in section 4.2. A model that accounts for any size of bubbles can possibly improve simulation results.

5.4 Temperature effects

The next most challenging aspect of damper modeling is certainly the modeling of temperature effects. A change in temperature affects the valve parameters due to a change in viscosity. The temperature dependent part of the valve parameters has been identified in [1]. If the inside temperature is measured, it should be possible to account for these effects but when the temperature is not measured directly, the problem becomes non-trivial and a predictive model for the oil temperature describing a heat balance must be used.

The heating source within the absorber is easily identified with the product of velocity and force. However a lumped heat capacitance approach is questionable and furthermore the problem of heat evacuation remains. Heat is evacuated by convection which is dependent on cooling, humidity and isolation of the damper. Finally for the identification of a model that includes temperature effects a more complex and longer excitation signal must be used.

5.5 Identification

It was shown in section 4.1 that the assumptions used for convenience of identification give rise to a discrepancy in particular when the piston velocity approaches zero. It is also at that time that the bubbles will induce important hysteresis as described by the law of Henry. The question as to how both phenomena correlate should be investigated by using the full set of three differential equations.

Secondly, the velocity and displacement are measured and thus corrupted with measurement noise. The use of the output error approach can cause bias errors on the parameters. An Error-in-Variables (EV) approach [18] where errors on all variables are accounted for may solve this problem. An EV estimator will be helpful especially around zero velocity where the model is more sensitive to a shift in velocity.

6 CONCLUSION

A model has been presented for the nonlinear and hysteretic behaviour of shock absorbers. The model has been identified using some convenient and justifiable assumptions. It has been shown that the hysteresis is caused by oil compressibility and more importantly by compressibility of present gas bubbles. For higher pressures the solubility of nitrogen in oil increases and the bubbles disappear. This effect seems to be important and cannot be neglected without introducing considerable errors. The presented model can easily be used either for identification or for simulation. The parameters are directly related to the internal architecture of the damper.

Effect of Steering-Housing Rubber Bushings on the Handling Responses of a Vehicle

Jungho Park and Parviz E. Nikravesh
The University of Arizona

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

An investigation of the effect of rack-housing rubber bushings on the handling characteristics of a vehicle is presented using a sophisticated three-dimensional vehicle model based on multibody dynamic analysis method. Previous research on this problem has been limited to a transfer function model for a simplified one- or two-dimensional steering subsystem. This paper uses a multibody modeling approach to find the effects of the steering-system compliance on the complete vehicle system. Sample simulations for circular cornering and pulse steering show that the steering-system compliance is the source of the frequency peak in the yaw rate to hand-wheel angle response function.

INTRODUCTION

The rotation of the steering hand-wheel provides the rotation of the road-wheel around the kingpin axis (steering axis). Conversely, tire forces and moments could rotate the steering hand-wheel, which is called the reversibility of the steering system. However, the reduction ratio of a steering gear produces some amount of irreversibility. In general, the steering system is reversible for light vehicles and semi-reversible for heavy vehicles. The reversibility allows jolts from irregularities in the road surface to be transmitted to the steering hand-wheel. In order to diminish this problem, a suitable compliance is introduced to the steering system. The means of providing such compliance are the rubber-elastic connections and the steering-housing rubber bushings. However, it is generally known that the steering compliance degrades the handling performance of a vehicle. The steering system not only poses a ride-quality problem due to the hand-wheel vibration, but also influences the lateral stability of a vehicle. Therefore, the steering-system dynamics have long been a subject for investigation, using mathematical models for steering systems.

Slibar and Paslay [1], Fiala [2], and Bohm [3] have found that the steering-system compliance influences the directional stability of the vehicle system. Campbell [4] pointed out that the compliance or free play in a steering system could lead to the phenomenon known as "shimmy", where the front wheels flutter in and out with a relatively small magnitude. Shock load in the tire lateral force excites the shimmy. Another excitation source is a single bump or a pothole in the road which causes angular deflection of the wheel axis, which in turn results in steering oscillations due to the gyroscopic torque of the front wheels. The latter case is especially evident in the beam-axle front suspension becaue the left and right wheels roll together.

Lanchester [5] and Bastow et al. [6-7] also discussed a steering-vibration problem which is variously described as front wheel wobble, wheel flap or veer vibration. They described the veer vibration problem as the interaction between the front end mass connected to the kingpin pivots, the lateral compliance inherent in the steering system, and the self-aligning torque of the front tires. Ignoring the yaw motion of a car, they constructed a model for the front end of a car as shown in Figure 1. The wheels pivot about points P which are the points where the effective caster applies. It should be noted that the distance between points C and P is different from the lever-arm length of the steering arm. The effective mass M may be smaller than the front end mass of the car. The lateral compliance is lumped as the two springs K between the effective mass and the kingpin pivots.

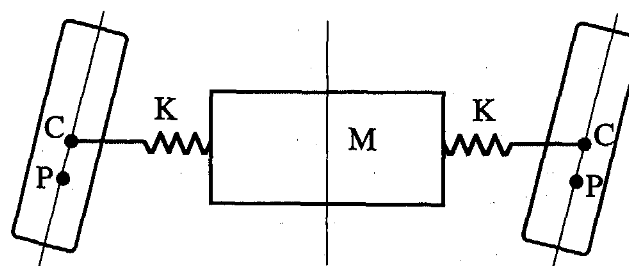

Figure 1. Front end model of a car for veer vibration

Segel [8] proposed a quasi-linear representation of a steering system which is a one-dimensional mechanism having two degrees of freedom with Coulomb friction. Figure 2 depicts the schematic of Segel's steering-system model. He incorporated the steering system model in a linear vehicle model with three degrees of freedom. Using the combined model, he studied the influence of the steering system parameters on the vibration modes of the free-control vehicle. Mabrouka et al. [9] used Segel's mathematical model to investigate the effect of tire lateral flexibility on the dynamic behavior of the steering system.

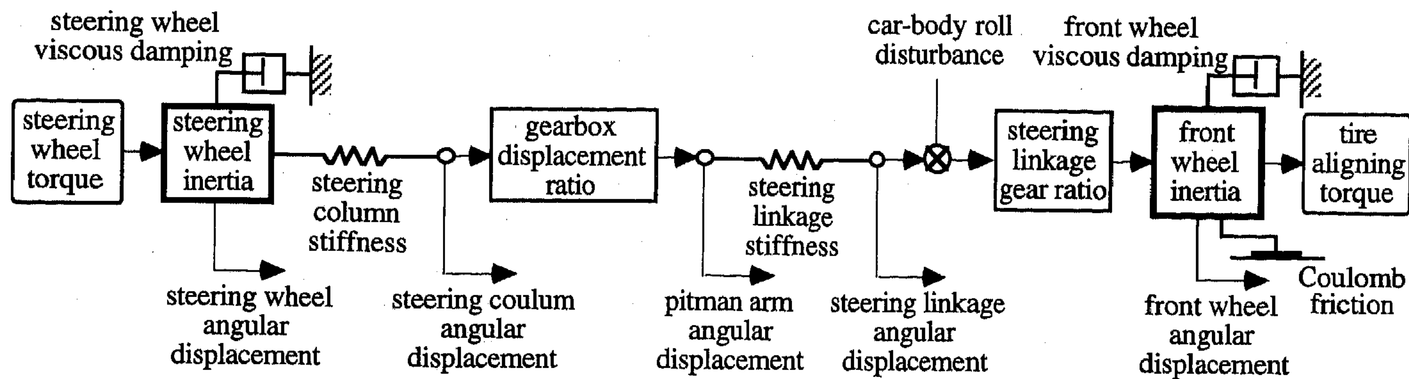

Figure 2. Segel's discrete model for the Pitman-arm steering system

Gillespie [10-11] suggested a lumped parameter model for a steering subsystem. Figure 3 depicts the schematic of his model. The model is a two-dimensional representation of a steering mechanism including the composite stiffness, K_{ss}, between the steering gearbox and the road wheels. He developed the modeling equations based on the geometry of the mechanism and the relationship between the forces and displacements. He suggested possible improvements to the model such as the modeling of the steering gearbox as the effective steering ratio with the appropriate input/output torque relationships and the addition of Ackerman steer angle relationships between the road wheels. MacAdam et al. [12] also used a similar steering-subsystem model and combined it to a vehicle model.

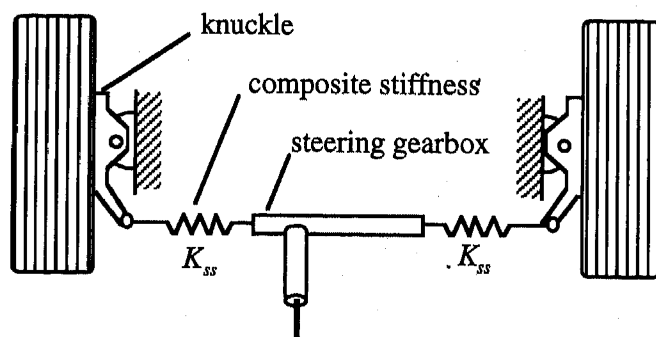

Figure 3. Lumped parameter model for the steering system

Ellis [13] introduced both one and two degrees of freedom models for the steering system. His one degree of freedom model is a single spring-mass system where all of the elasticity of the steering mechanism is concentrated into the single spring. His two degrees of freedom model is the extension of the one degree of freedom model by adding the yaw acceleration of the vehicle to the angular acceleration of the front wheels. He incorporated the steering-system equations into the vehicle equation. He showed through various simulations that the compliance of the steering mechanism produced an under-steer tendency to the vehicle for steady-state cornering situation and affected the transient response of the vehicle.

The aforementioned steering-vibration models are basically one- or two-dimensional representations of a steering subsystem, which neglect the gyroscopic effect of the rotating wheels. However, as Campbell [4] pointed out, the gyroscopic effect of front wheels not only induces an excitation torque but also provides an additional inertia effect to the vibration. Other factors that are ignored are the effects of the caster angle, the trail (the caster offset), the kingpin offset, and the geometric effect of the steering and suspension mechanisms. In order to consider these effects, the steering-system model should be three-dimensional.

This paper presents a sophisticated three-dimensional multibody representation of the total vehicle, where the steering-system model is combined with the vehicle model. The vehicle model has a rack-and-pinion steering mechanism, where the rack housing (steering housing) is mounted to the car body by rubber bushings providing lateral compliance of the rack housing with respect to the car body. Using the developed model, an investigation is performed to assess the effect of the stiffness of the rack-housing rubber bushings on the handling characteristics of the vehicle. Sample simulations for a steady-state circular cornering and a pulse steering maneuver [14-15] are performed using three different stiffness levels of the rack-housing rubber bushing. Another simulation without rack-housing rubber bushings (rigid-mounting case) is also performed for the purpose of comparison. The simulation results show that the steering-system compliance is the source of the frequency peak in the yaw rate to hand-wheel angle response function.

MULTIBODY REPRESENTATION OF STEERING SYSTEM

The available studies on the steering compliance have been focused on the analysis of the shimmy and veer vibration of the steering system using simplified one- or two-dimensional models for the steering subsystem, whereas this paper presents a sophisticated three-dimensional multibody representation of the rack-and-pinion steering system as a part of the complete vehicle model.

Figure 4 shows a typical rack-and-pinion steering mechanism. The rack-housing is mounted on the car body by the rubber bushings such that the rack-housing has some lateral compliance. The tie rods link the rack-bar and the knuckles. The connection between them are rod ends (ball joints) whose compliance is, in general, negligible compared to that of the rack-housing bushing.

Figure 5 presents a multibody representation of the rack-and-pinion steering system. In order to allow a relative lateral motion of the rack-housing, a translational joint connects the car body and the rack-housing. A translational spring-damper

element connected between the car body and the rack-housing represents the stiffness and damping of the rack-housing rubber bushing. Considering the nonlinearity of rubber bushings, the spring and damping characteristics of the spring-damper element can generally be expressed as a function of rubber-bushing parameters such as deflection (d), deflection speed ($\dot{d}$), and actuation frequency (ω):

$$K = f(d, \dot{d}, \omega)$$
$$C = g(d, \dot{d}, \omega) \quad (1)$$

where K is the spring coefficient, C is damping coefficient, and f and g are polynomial functions. These kinds of nonlinear characteristics can be easily implemented in user-supplied subroutines of a general-purpose multibody dynamic analysis program [18]. The rack-bar is connected to the rack-housing by another translational joint allowing its relative lateral shift. In addition to the translational joint, a steering constraint defined between the rack-housing and the rack-bar determines the relative shift of the rack-bar. The tie-rod with two rod ends is modeled as a massless spherical-spherical constraint [17] because its inertia is relatively small and can be transferred to the inertia of the rack-bar.

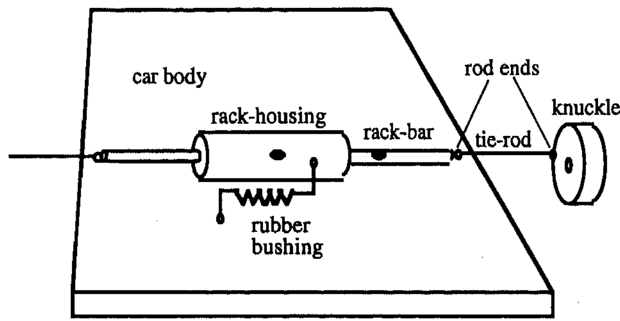

Figure 4. Typical rack-and-pinion steering system

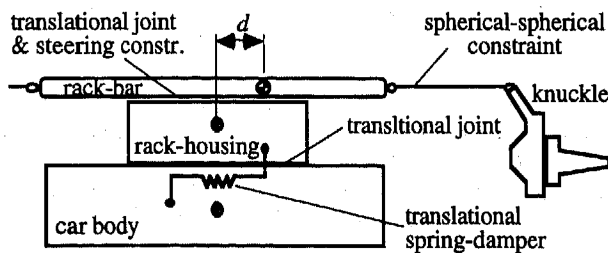

Figure 5. Multibody representation of rack-and-pinion steering system

In order to provide steering angles to the front wheels, some relative shift of the rack-bar with respect to the rack-housing should be mathematically enforced in the equations of motion of the vehicle. In the case of the joint coordinate formulation [18] used in this study, such enforcement can be easily done by introducing a simple constraint for the joint coordinate corresponding to the relative rack-bar shift. Let θ_{rb} be the joint coordinate for the relative rack bar-shift. Then, the simple constraint equation is

$$\Phi \equiv \theta_{rb} - \theta(t) = 0 \quad (2)$$

where $\theta(t)$ is the user defined time-history for the relative rack-bar shift. The first time derivative of Equation (2) yields the velocity constraint equation which contains the Jacobian, $\mathbf{C} \equiv \partial\Phi / \partial\theta$, where θ is the vector of joint coordinates. The second time derivative of Equation (2) yields the acceleration-constraint equation.

Some of the commercially available multibody dynamics programs use a set of so-called absolute coordinates to formulate the equations of motion. In the case of the absolute coordinate formulation, assume that the center of gravity (CG) of the rack-bar is off-center when it is in neutral steering position. Let d be the distance from the CG of the rack-housing to the CG of the rack-bar, and let l be the target value of the distance, i.e., the steering command in the rack-bar position (Figure 5). Then, the kinematic steering constraint for the relative location of the rack-bar can be expressed as a scalar equation:

$$\Phi \equiv d^2 - l^2 = 0 \quad (3)$$

This steering constraint is also called the displacement constraint equation. The square of the distance d can be computed using the absolute locations of the rack-housing and the rack-bar as:

$$d^2 = |\bar{r}_j - \bar{r}_i|^2$$
$$= (r_j(x) - r_i(x))^2 + (r_j(y) - r_i(y))^2 + (r_j(z) - r_i(z))^2 \quad (4)$$

where $\bar{r}_i = (r_i(x) \quad r_i(y) \quad r_i(z))$
$\bar{r}_j = (r_j(x) \quad r_j(y) \quad r_j(z))$

The first time derivative of Equation (3) yields the velocity constraint equation which contains the Jacobian, $\mathbf{D} \equiv \partial\Phi / \partial \boldsymbol{q}$, where $\mathbf{q}$ is the vector of absolute coordinates. The second time derivative of Equation (3) yields the acceleration-constraint equation.

In the joint coordinate formulation, it can be shown [16-18] that the equations of motion for a multibody system not containing any closed kinematic loops can be described as a set of ordinary differential equations as:

$$\boldsymbol{M}\ddot{\theta} = \boldsymbol{f} \quad (5)$$

where $\boldsymbol{M}$ is the generalized inertia matrix, $\ddot{\theta}$ is the vector of joint accelerations (which contains $\ddot{\theta}_{rb}$), and $\boldsymbol{f}$ is the vector of generalized forces. However, when closed kinematic loops are present in a multibody system, Equation (5) finds a slightly different form as:

$$\begin{bmatrix} \boldsymbol{M} & \mathbf{C}^T \\ \mathbf{C} & \mathbf{0} \end{bmatrix} \begin{bmatrix} \ddot{\theta} \\ \nu \end{bmatrix} = \begin{bmatrix} \boldsymbol{f} \\ \varepsilon \end{bmatrix} \quad (6)$$

where **C** represents the Jacobian of all of the constraints (closed loop constraints and the steering angle constraint), ν is a vector of Lagrange multipliers, and ε contains the terms in the acceleration constraints which do not contain accelerations (quadratic velocity and time dependent terms).

In the case of the absolute coordinate formulation, the equations of motion for a multibody system are written as [17]:

$$\begin{bmatrix} \mathbf{M} & \mathbf{D}^T \\ \mathbf{D} & \mathbf{0} \end{bmatrix} \begin{bmatrix} \ddot{\mathbf{q}} \\ \lambda \end{bmatrix} = \begin{bmatrix} \mathbf{g} \\ \gamma \end{bmatrix} \qquad (7)$$

where $\mathbf{M}$ is the mass matrix, , $\mathbf{g}$ is the vector of external forces and moments, $\mathbf{D}$ is the Jacobian matrix, λ is a vector of Lagrange multipliers, and λ is the vector of right-hand-side terms in the acceleration constraints (quadratic velocity and time dependent terms). It should be noted that the acceleration constraints contain all of the joint constraints and the steering constraint.

For the simulation case of no rack-housing bushing (rigid mounting), additional simple constraint may be introduced between the rack-housing and the car body. The simple constraint is a deletion of a specific relative degree of freedom in the equations of motion. Therefore, the simple constraint can be easily implemented in the joint-coordinate-based equations of motion. If a simple constraint is applied to the translational degree of freedom of the rack-housing with respect to the car body, the rack-housing would behave just as if it were fixed to the car body (Figure 6).

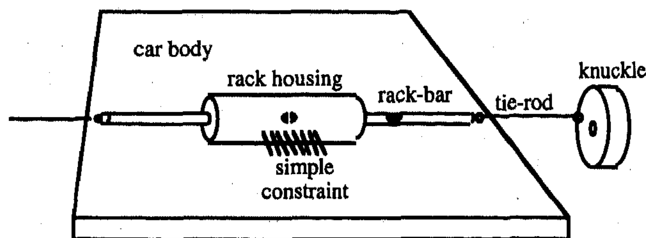

Figure 6. Rack-and-pinion steering without bushing effect

The steering-system model mentioned above is combined with the vehicle model described in Appendix A forming a complete vehicle system. Figure 7 shows how the driving simulation using the complete vehicle model is performed. In the figure, the simulation data file contains the time history of a user-defined open-loop rack-bar shift command which is used in the dynamic analysis program as an input to the kinematic rack-bar shift constraint.

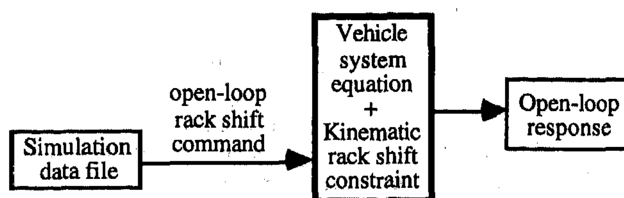

Figure 7. Control of rack-and-pinion steering mechanism

SIMULATION RESULTS AND DISCUSSION

Computer simulations using a sophisticated three-dimensional vehicle model and a general purpose multibody dynamic analysis program are presented for a steady state circular maneuver and a pulse steering maneuver. The purpose of the steady state circular maneuver is to obtain information about the influence of rack-housing bushing on the steady state handling characteristics of a vehicle. The pulse steering maneuver reveals how the flexibility of tires affects the motion of a vehicle in transient state. Simulation results for the pulse steering maneuver is analyzed in both time- and frequency-domain. Time-domain evaluations were conducted based on the maximum values of rubber bushing deflection, vehicle yaw rate, roll rate, and lateral acceleration. Frequency-domain evaluations were conducted using frequency response functions of yaw rate, roll rate, lateral acceleration, and tire cornering powers, that were obtained by the fast Fourier transformation (FFT) of the time-domain response. For comparative study, the rack-housing bushings are assumed to have linear spring and damping characteristics. In addition, the damping coefficient of the bushing is assumed to be 1% of its stiffness value. However, nonlinear characteristics can be easily modeled in a multibody dynamic analysis program if the nonlinear data is available.

3D VEHICLE MODEL - To investigate the effect of the steering-system compliance through computer simulations, a sophisticated three-dimensional vehicle model which accurately represents a mid-size sedan is constructed as presented in Appendix A. In brief, the vehicle model is a rigid multibody system composed of thirty-one rigid (non-deformable) bodies and thirty-six kinematic joints or constraints. The vehicle model includes all rubber-flexibility effects such as rack-housing compliance, suspension compliance, and tire lateral flexibility. The vehicle model has a total of twenty two degrees of freedom: 6 for the car body, 4 for the wheel travel, 4 for the suspension longitudinal compliance, and 4 for the tire lateral flexibility.

STEADY STATE CIRCULAR TEST - In the steady-state circular test, an open-loop steering command (input) is provided as a fixed rack-bar shift of 6.6 mm to the right with respect to the rack housing, which corresponds to about 1.4 degrees left turn of the steering road-wheel. Initially, the steering command is set to zero, and then gradually it rises up to 6.6 mm which is held constant so that the motion of the vehicle model reaches a steady state. The simulation is performed for 60 and 80 km/h cases. A standard rack-housing bushing with the stiffness of 951.2 kN/m and the damping of 9.512 kN-sec/m is used for both simulation cases. Steady-state values for 60 km/h steady-state circular test are listed in Tables 1, and those for 80 km/h are listed in Tables 2.

The simulation results show noticeable lateral shift of the rack-housing: 1.549 mm (23.4% of 6.6 mm, the relative rack-bar shift) for 60 km/h case; 2.091 mm (31.7% of 6.6 mm) for 80 km/h case. Thus, the steering compliance reduces the absolute rack-bar shift and the net steering angles, resulting in under-steer tendency in the vehicle. However, the deformations of the suspension-rubber bushings are less than 0.25 mm for both 60 and 80 km/h cases. This implies that the suspension longitudinal compliance plays a negligible role in the steady-state circular maneuver. The longitudinal compliance is known to be effective on a rough terrain.

Table 1. Steering and body data at 60 km/h

Items	Without Lat. Compliance	With Lateral Compliance
Rack-housing shift (mm)	1.427	1.549
Avg. steering angle (deg)	2.404	2.338
Yaw rate (deg/sec)	13.72	13.36
Lateral accel. (m/s^2)	3.989	3.886
Roll angle (deg)	1.377	1.014
Path Radius (m)	69.54	71.45

Table 2. Steering and body data at 80 km/h

Items	Without Lat. Compliance	With Lateral Compliance
Rack-housing shift (mm)	1.870	2.091
Avg steering angle (deg)	2.171	2.055
Yaw rate (deg/sec)	14.50	13.76
Lateral accel. (m/s^2)	5.620	5.339
Roll angle (deg)	1.942	1.334
Path Radius (m)	87.73	92.40

PULSE STEERING TEST - The frequency-domain analysis using a pulse-steering input is called the "pulse steering technique" [19]. The open-loop steering inputs that have been used for the frequency-domain analysis are pulse input, sinusoidal sweep input, discrete sinusoidal input, and random sweep input. Heydinger et al. [20] pointed out that the pulse steering technique is generally faster and cheaper than the alternative test methods without sacrificing accuracy. They also found that the frequency-response results are relatively insensitive to the pulse shape and size, provided that the pulse input have sufficient power to excite the vehicle system. The open-loop pulse steering input used in this paper is a sinusoidal pulse with the magnitude of 3 mm in relative rack-bar shift and the duration time of 0.4 second as shown in Figure 9 (a).

For frequency-domain analysis, fast Fourier transformation (FFT) of time domain data of selected cornering parameters is performed to obtain frequency response functions (FRF), and then complex-cornering powers are computed based on a simplified bicycle model of the vehicle (refer to Appendix B). Figure 8 presents the procedure of frequency-domain analysis for computing the frequency-response functions for yaw rate to hand-wheel angle (YR/MA), lateral acceleration to hand-wheel angle (LA/MA), and roll rate to hand-wheel angle (RR/MA); and for generating complex-cornering powers for front- and rear-wheel sets.

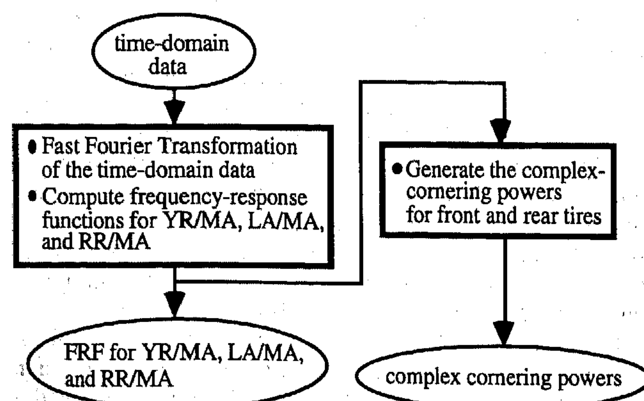

Figure 8. Schematic of frequency-domain analysis procedure

Simulations are performed for four different levels of rack-housing rubber bushings as listed in Table 3. The rigid mounting does not have any elasticity such that the rack-housing is rigidly mounted on the car body. The time-domain plots are presented in Figure 9, and the frequency-domain plots are presented in Figure 10.

Table 3. Simulation cases for pulse steering test

Type of bushing	Stiffness (kN/m)	Damping (kN-sec/m)	% of Standard
Soft	571	5.71	60%
Standard	951.2	9.512	100%
Hard	1,332	13.32	140%
Rigid	infinite	infinite	infinite

Time-domain simulation results show that the peak deformation of rack-housing bushing increases as the bushing gets softer (Figure 9 (c)). The magnitude of deformation is noticeable even though the front-wheel trail is only 16 mm. The trail is the lever arm for cornering forces which are produced by 3.08 degrees of caster angle. The peak deformation is 1.1 mm for the hard-bushing case (37% of 3 mm max. rack-bar shift), 1.26 mm for the standard-bushing case (42%), and 1.6 mm for the soft-bushing case (53%). This steering-subsystem compliance not only reduces road-wheel steering angles but also induces transient fluctuation of steering angles (Figure 9 (b)). In the figure, the peak steering angle is 1.26 degrees for the hard-bushing case (10.6% reduction compared to 1.41 mm of the rigid-bushing case), 1.21 degrees for the standard-bushing case (14.2% reduction), and 1.11 degrees for the soft-bushing case (21.3% reduction). The reduced steering angle directly affects the tire forces (Figure 9 (d)), the lateral acceleration (Figure 9 (f)), the yaw rate (Figure 9 (g)), and the roll rate (Figure 9 (h)), resulting in the under-steer tendency to the vehicle (Figure 9 (j)). It noteworthy that the case of soft rack-housing bushing shows prolonged vibration of rack-housing (Figure 9 (c)), which affects not only the handling characteristics (Figure 9 (f)) but also the ride quality of a vehicle (Figure 9 (g) & (h)).

Frequency-domain results show that rack-housing bushing is the source of the peak frequency in yaw rate to hand-wheel angle response function (Figure 10 (a)): It is clearly seen in the figure that the rigid bushing case does not have a peak frequency. As the stiffness of the rack-housing bushing decreases, the peak frequency gradually moves to higher frequencies. Figure 10 (e) presents roll rate to hand-wheel angle response function. As in the case of the yaw rate to hand-wheel angle response function, the peak frequency of the roll rate to hand-wheel angle response increases from 0.65 Hz (rigid bushing case) to 1 Hz (soft bushing case). For all frequency response functions except the one for rear cornering power, low-frequency (less than 5 Hz) gains decrease as rack-housing bushing becomes softer. This implies that steering-subsystem compliance tends to reduce the handling-responsiveness of the vehicle.

SUMMARY AND CONCLUSIONS

A multibody approach to the investigation of the relationship between the steering-system compliance and the dynamic characteristics of a vehicle has been presented. Three different stiffness/damping levels of rack-housing rubber bushing along with a rigid mounting are used for comparative

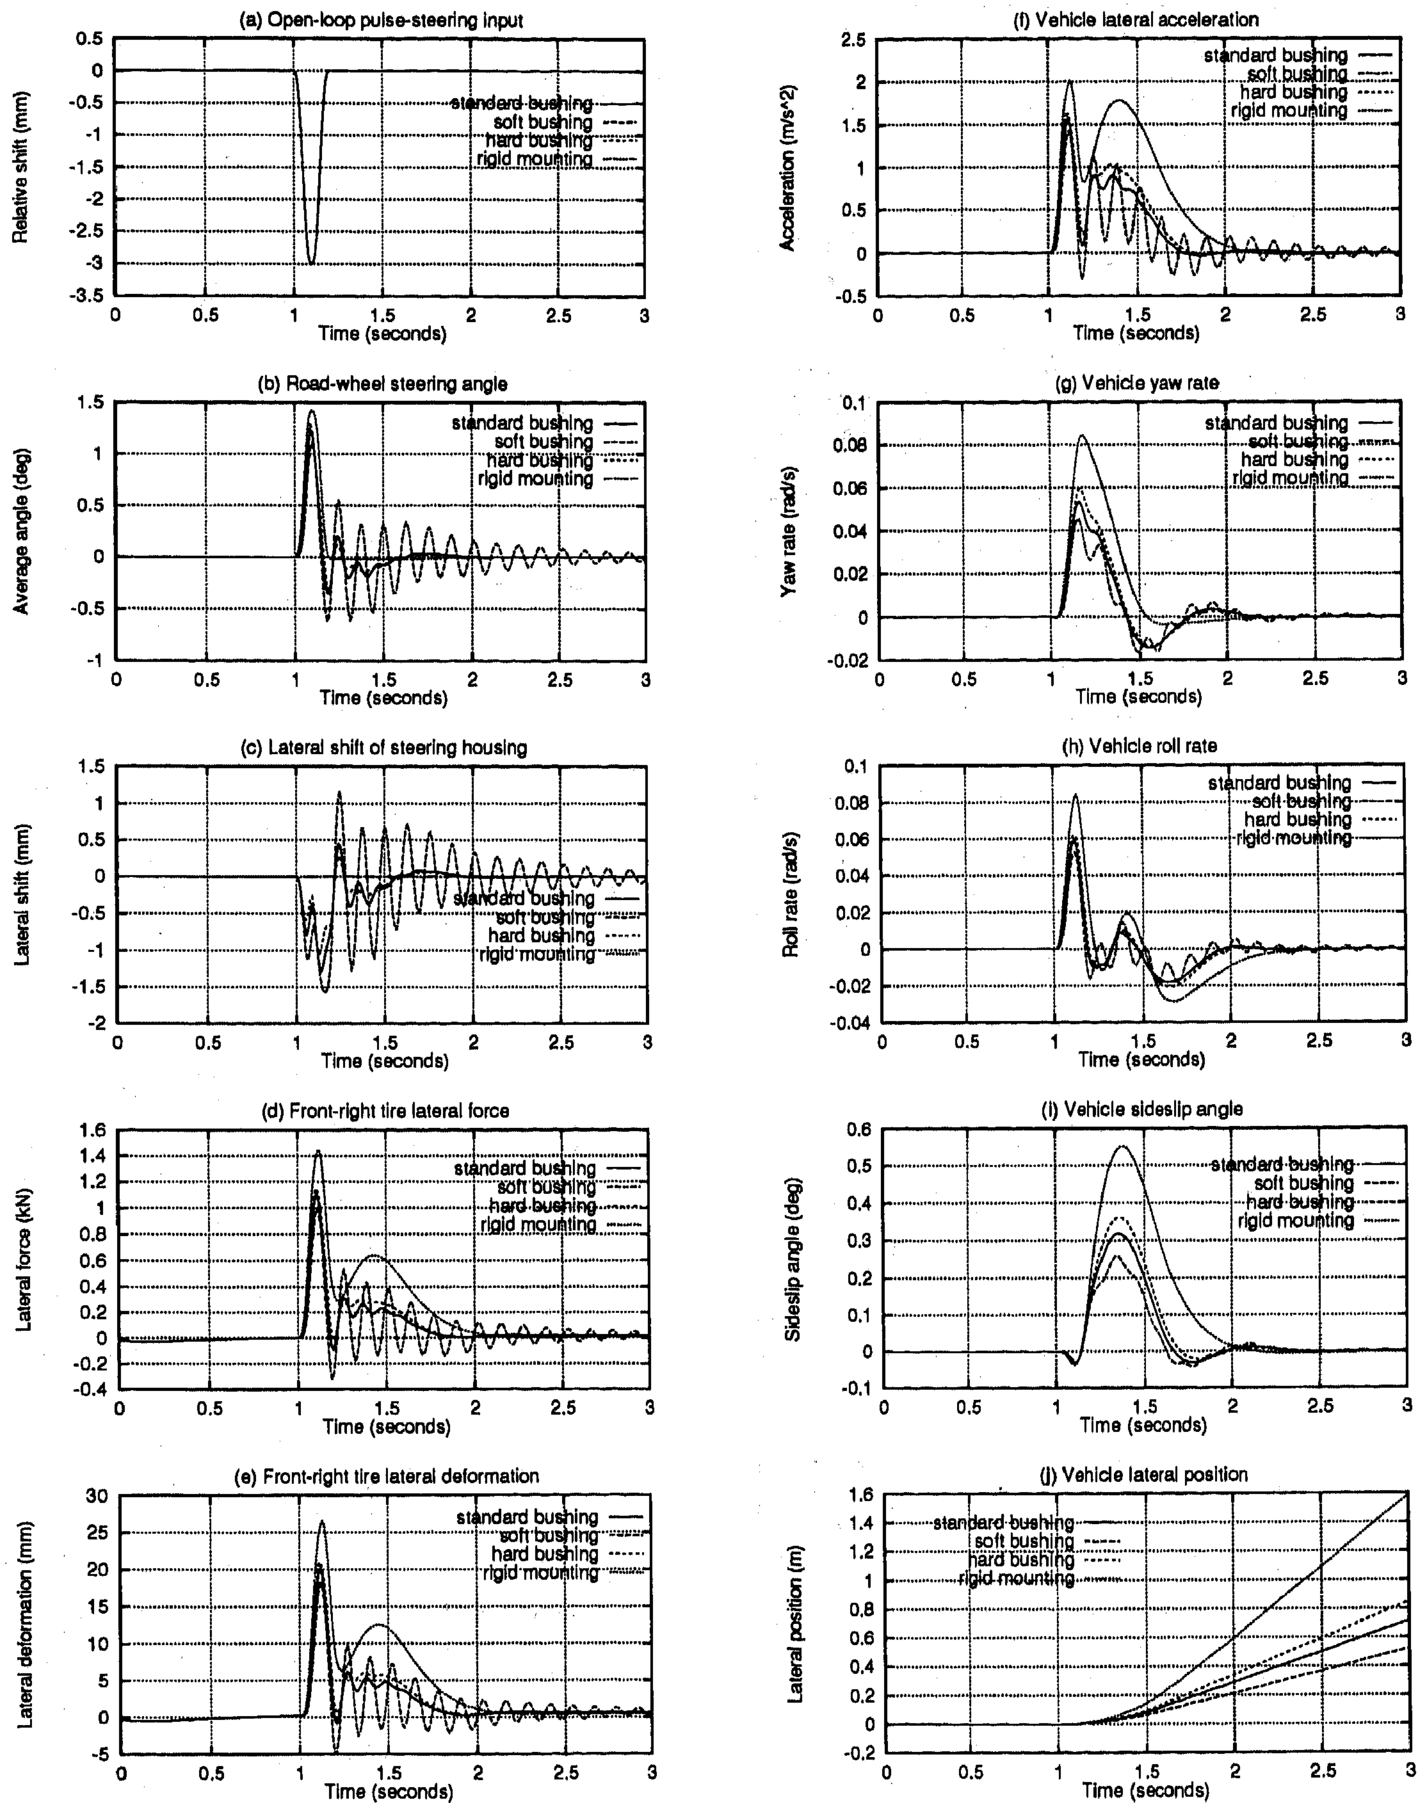

Fig 9. Time-domain responses for the pulse steering test

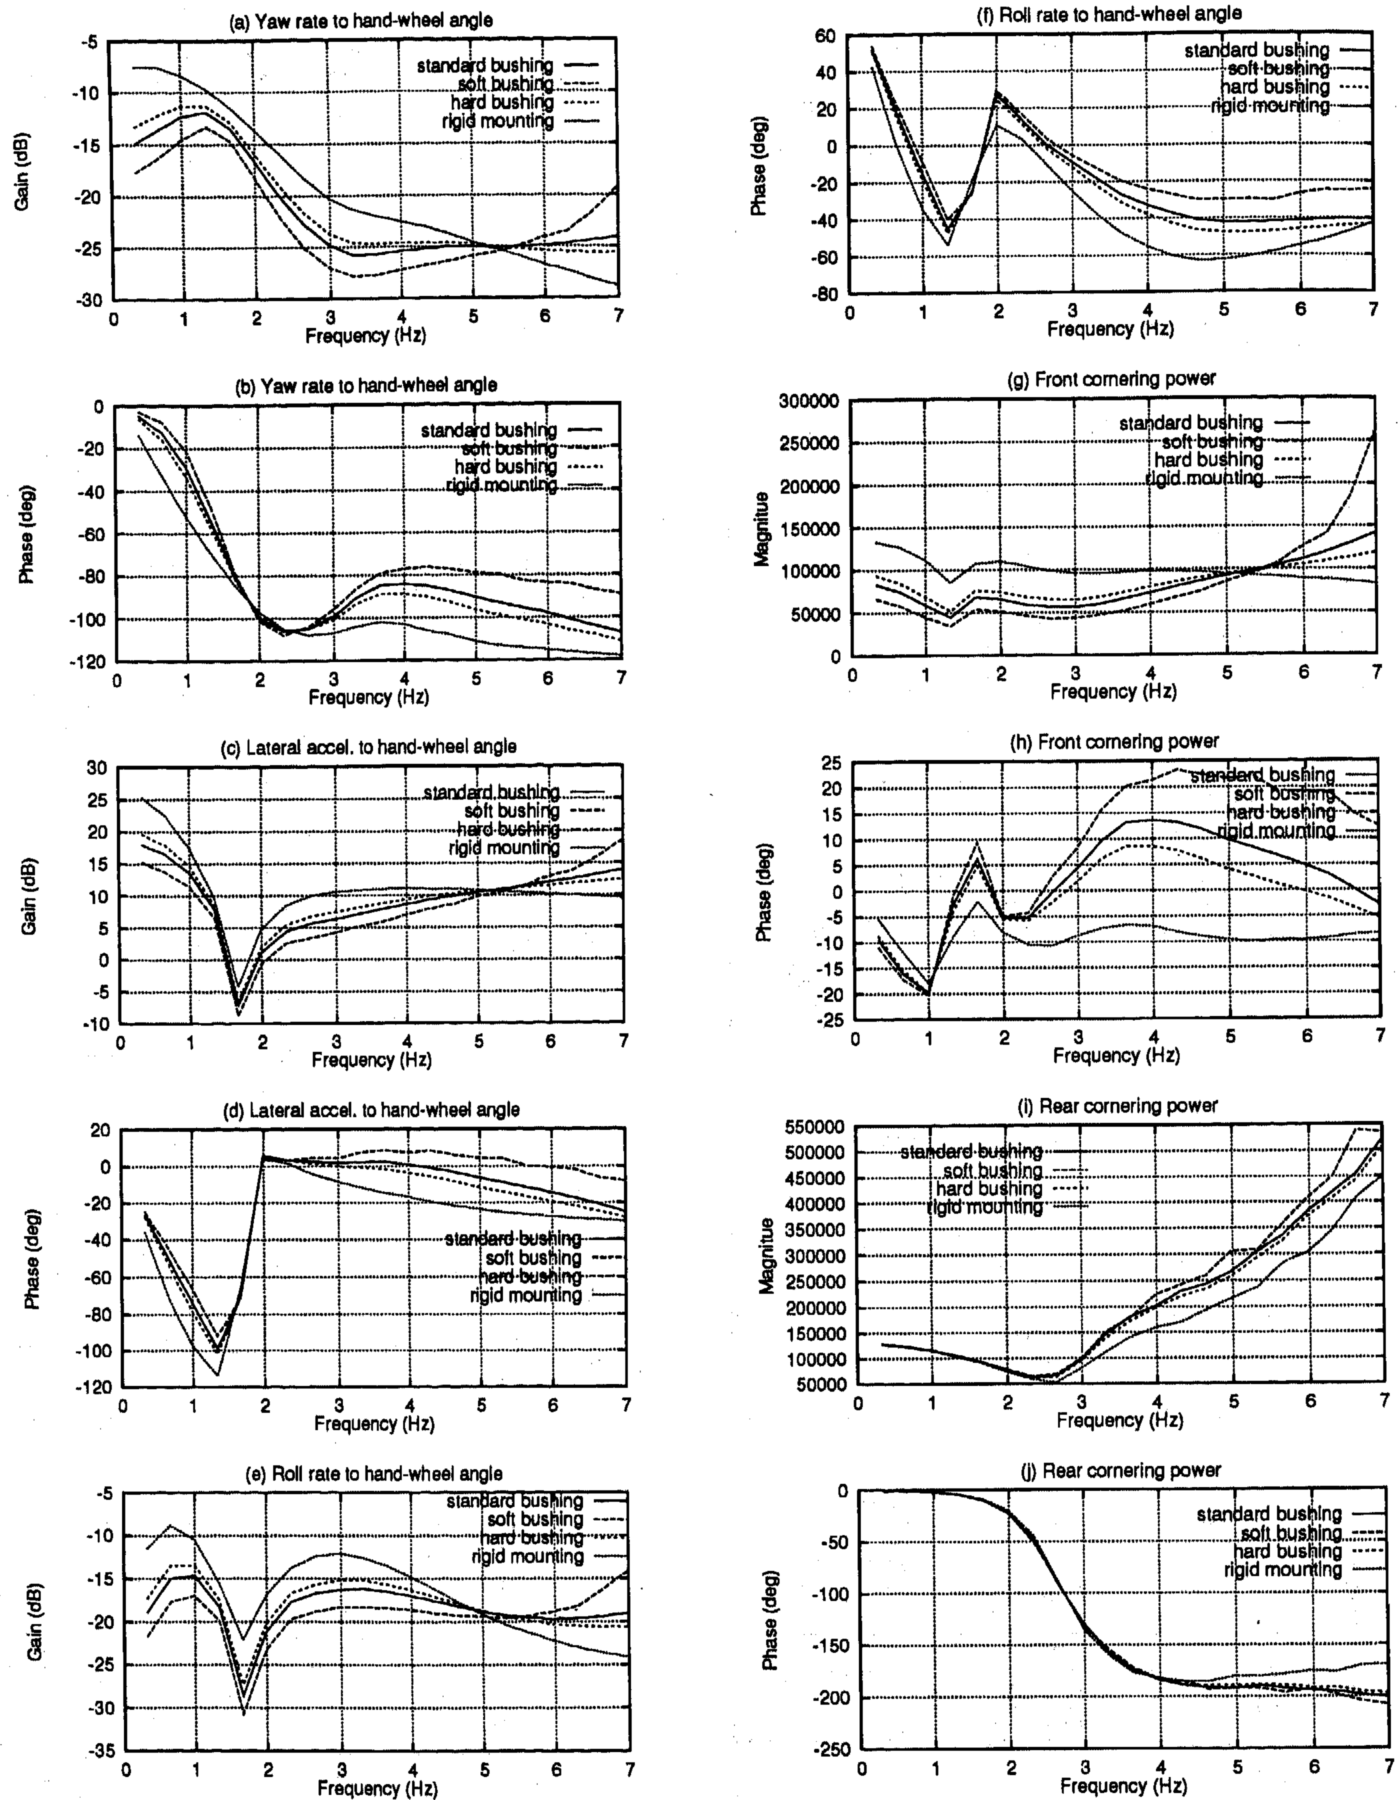

Fig 10. Frequency-domain responses for the pulse steering test

study. Computer simulations are performed for a steady state circular maneuver and a pulse steering maneuver. It has been shown that a sophisticated three-dimensional multibody model of the vehicle including the steering system is an effective tool for the investigation of total vehicle handling characteristics. Key points of the findings may be summarized as follows:

- Rack-housing rubber bushings are intended to isolate the steering hand-wheel from road-induced vibrations. However, they change the dynamic performance of a vehicle by creating an under-steering tendency and a less responsive vehicle.
- The time-domain simulation results show that the steering-system compliance reduces the handling sensitivity of the vehicle and that a too much compliance could induce steering-system vibration that lasts for several seconds.
- Comparison of the frequency-domain simulation results with and without the rack-housing rubber bushing show that the steering compliance is the source of the peak frequency in the yaw rate to hand-wheel angle response function.
- The frequency-domain simulation results also show that the increase in the compliance of the steering system reduces the peak frequencies and the magnitudes of not only the yaw rate but also the roll rate response functions.
- The simulation results indicate that longitudinal suspension compliance has negligible effect on the pulse steering response.

APPENDIX A: 3D VEHICLE MODEL

The vehicle model used in this paper is an enhanced version of the model used in [19]. This sophisticated three dimensional rigid-multibody vehicle model closely represents a typical mid-size sedan. A schematic of the model with body numbers and joint types is shown in Figure A-1. The multibody modeling of this system with the joint coordinate formulation [16-18] assumes the car body (body 1) to be the only floating base-body in the system. Other bodies form branches extending out from the base-body. The vehicle model

has super-strut front suspensions and quadra-link rear suspensions, both of which are variants of a McPherson strut suspension.

The front wheels are steered by a rack-and-pinion steering mechanism, where the shift of the rack-bar relative to the rack-housing determines the steering angles of the front wheels through the tie-rods. The rack-housing is kinematically joined to the chassis by a translational joint and a rubber-bushing element. A kinematic steering constraint defined between the rack-bar and rack-housing governs the relative shift of the rack-bar. Suspension rubber bushings are modeled by using supplementary bodies (24-31), joints (29T-36T), and translational spring-damper elements of which characteristics are based on a test data but are simplified to be linear.

Any accurate vehicle ride simulation would require a realistic tire model. For this study, the Magic Formula tire model [20] is used. In this tire model, the interacting forces and moments between the tire and the road surface are determined based on empirical formulas as a function of tire orientation, velocity, and radial stiffness. The tire coefficients in the formulas are for the 195/60R13 tire. The tire model is defined on the ring bodies 16 through 19. The tire lateral flexibility is modeled based on the "ring body" concept [21]. Spring-damper elements that represent the tire lateral stiffness and damping are defined between the ring bodies and the cylinder bodies (bodies 10 through 13). The vehicle model represents a front wheel drive car. Therefore, torque of the two front wheels are feedback controlled to maintain a constant vehicle speed. Speed-dependent rolling resistance is applied to all wheels.

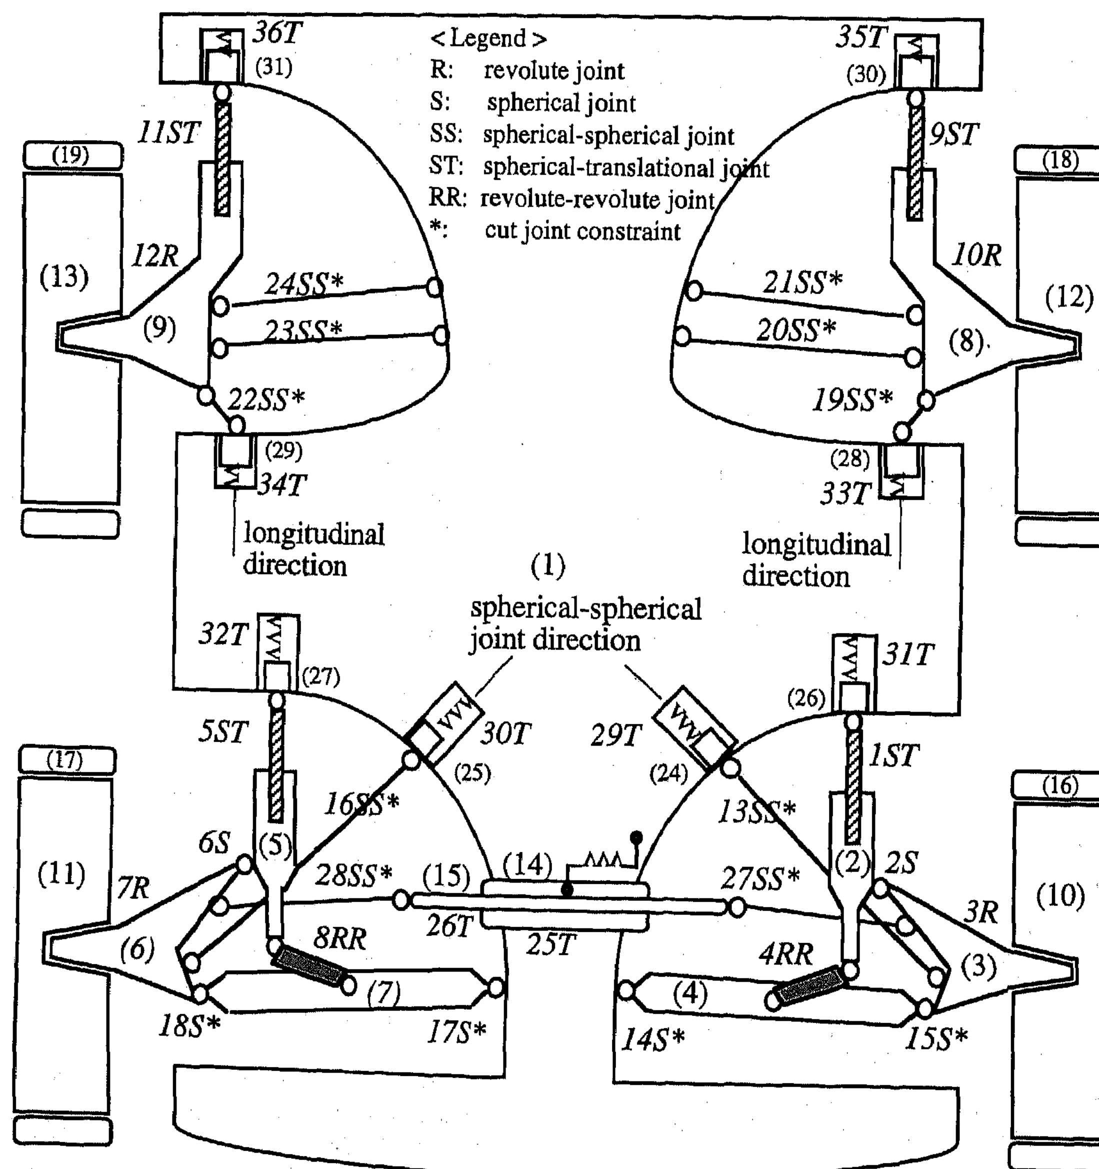

Figure A-1. Schematic of the vehicle model

APPENDIX B: COMPLEX CORNERING POWER

Campbell [4] defined cornering power as cornering force divided by the slip angle required to generate the force. The cornering power is the most important performance parameter of tires. According to Campbell, the factors influencing the cornering power are wheel load, tire profile (aspect ratio), camber angle, tire longitudinal force, and rim width of wheel. Normally, the cornering power designates static cornering power since it is computed from steady-state cornering parameters. A simple extension of the static cornering power to the transient region is called the "dynamic cornering power" which is naturally a function of time. The dynamic cornering power transformed into frequency-domain is called the "complex cornering power".

In order to obtain complex cornering power, let's assume that a planar motion of a vehicle can be simplified as a bicycle model as shown in Figure B-1. In the figure, variables are defined as below:

m : sprung mass of the vehicle (kg)
I : chassis yaw moment of inertia ($kg-m^2$)
l : wheel base (m)
a : distance from chassis CG to front axle (m)
b : distance from chassis CG to rear axle (m)
V : velocity vector of chassis CG (m/sec)
u : forward velocity component (m/sec)
v : lateral velocity component (m/sec)
δ : direct steering angle (radian)
ξ : indirect steering angle due to rolling, compliance, chassis deformation, etc.
β : course angle of the vehicle (radian)
w : yaw rate of the vehicle (rad/sec)
F : cornering force at tire (N)
C : cornering power (N/deg)

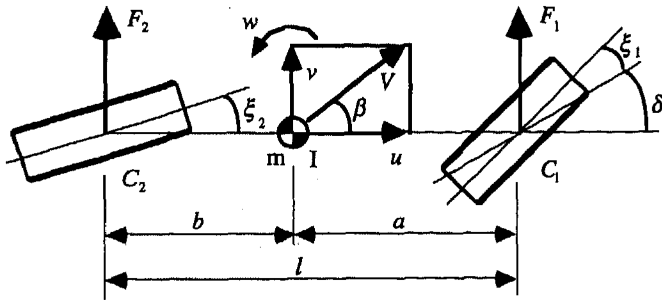

Figure B-1. Bicycle model of a vehicle

The indirect steering angle is a steering angle due to any indirect steering effects such as roll steer, compliance steer, steering due to chassis deformation, etc., with the exception of the direct steering angle command The influence of the indirect steering angle can be equivalently included into the cornering power, producing equivalent cornering power C^*. Then the tire slip angle, α, should also be changed to the pseudo slip angle, α^*. Figure B-2 presents the equivalent model. The relationship between the two slip angles is

$$\alpha_i^* = \alpha_i - \xi_i$$

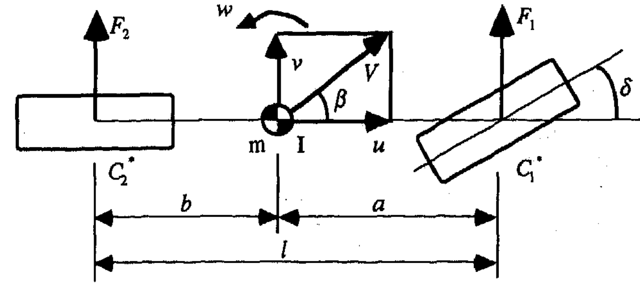

Figure B-2. Equivalent bicycle model of a vehicle

Since the cornering force should be consistent in each model, the cornering forces can be expressed as

$$-F_i = C_i\alpha_i = C_i^*\alpha_i^* \qquad \text{(B.1)}$$

Then, the equivalent cornering power can be defined as

$$C_i^* = C_i\alpha_i/\alpha_i^* = C_i\alpha_i/(\alpha_i - \xi_i)$$

or

$$C_i^* = C_i(\alpha_i^* - \xi_i)/\alpha_i^* = C_i(1 + \xi_i/\alpha_i^*)$$

Once the equivalent cornering power is obtained, the indirect steering angle is given by

$$\xi_i = \alpha_i(1 - C_i/C_i^*) \qquad \text{(B.2)}$$

The above discussion which is based on steady-state time-domain can be expanded to the transient frequency-domain by applying Laplace transformation. In the frequency-domain, each variable should be a complex number, and we can use the term 'complex' implying an expansion from steady-state time-domain to transient frequency-domain.

Now let's consider the equation of motion for the equivalent model in Figure B-2.

$$m \cdot u(\beta(s) \cdot s + w(s)) = F_1(s) + F_2(s) \qquad \text{(B.3)}$$
$$I \cdot w(s) \cdot s = a \cdot F_1(s) - b \cdot F_2(s) \qquad \text{(B.4)}$$
$$F_i(s) = C_i^*(s) \cdot \alpha_i^*(s) \qquad \text{(B.5)}$$
$$\alpha_1^*(s) = \beta(s) + a \cdot w(s)/u - \delta(s) \qquad \text{(B.6)}$$
$$\alpha_2^*(s) = \beta(s) - b \cdot w(s)/u \qquad \text{(B.7)}$$

where s is a complex number in Laplace transformation, and it is expressed as

$$s = -j\omega = -j2\pi f$$

where $j = \sqrt{-1}$. Let's suppose following time domain data are available from multibody dynamic simulation of a vehicle:

MA(t) : hand wheel (steering wheel) angle
YR(t) : yaw rate = w(t)
LA (t) : lateral acceleration of the vehicle

Then , through FFT of these time domain data and through some complex domain operations, transfer functions of YR(s)/MA(s) and LA(s)/MA(s) can be obtained. Therefore, we can use following normalized terms for yaw rate and lateral acceleration in Laplace domain:

$$w(s) = YR(s)/MA(s) \quad (B.8)$$
$$la(s) = LA(s)/MA(s) \quad (B.9)$$

In addition, steering angle in Laplace domain can be expressed using a steering gear ratio and a frequency domain steering model. If we assume that the steering gear ratio, GR, is constant and that the steering model can be represented as a simple first order delay of

$$st(s) = \frac{1}{1+\tau s} \quad (B.10)$$

where τ is a time constant, then the steering angle can be represented as

$$\delta(s) = GR \cdot st(s) = \frac{GR}{1+\tau s} \quad (B.11)$$

From equation (B.3), the lateral acceleration in frequency domain is

$$la(s) = u \cdot (\beta(s) \cdot s + w(s)) \quad (B.12)$$

From this equation, he frequency-domain course angle of the vehicle can be expressed as

$$\beta(s) = (la(s)/u - w(s))/s \quad (B.13)$$

Then, the pseudo slip angles of tire can be calculated by

$$\begin{aligned} \alpha_1^*(s) &= \beta(s) + a \cdot w(s)/u - \delta(s) \\ &= \beta(s) + a \cdot w(s)/u - GR/(1+\tau s) \\ \alpha_2^*(s) &= \beta(s) - b \cdot w(s)/u \end{aligned} \quad (B.14)$$

Cornering forces are obtained from equations (B.3) and (B.4) as

$$\begin{aligned} F_1(s) &= (b \cdot m \cdot la(s) + I \cdot w(s) \cdot s)/(a+b) \\ F_2(s) &= (a \cdot m \cdot la(s) - I \cdot w(s) \cdot s)/(a+b) \end{aligned} \quad (B.15)$$

Then, the complex (dynamic) equivalent cornering power is given from equation (B.1) by

$$\begin{aligned} C_1^* &= -F_1(s)/\alpha_1^*(s) \\ C_2^* &= -F_2(s)/\alpha_2^*(s) \end{aligned} \quad (B.16)$$

ABSTRACT

Compliance elements such as bushings of a suspension system play a crucial role in determining the ride and handling characteristics of the vehicle. In this research, a general procedure for the optimum design of compliance elements to meet various design targets is proposed. Based on the assumption that the displacements of elastokinematic behavior of a suspension system under external forces are very small, linearized elastokinematic equations in terms of infinitesimal displacements and joint reaction forces are derived. Directly differentiating the linear elastokinematic equations with respect to design variables associated with bushing stiffness, sensitivity equations are obtained. The design process for determining the bushing stiffness using sensitivity analysis and optimization technique is demonstrated.

INTRODUCTION

Bushings are widely used in a vehicle suspension system to improve ride characteristics. The elastic behavior of bushings, however, inherently causes change of wheel attitude due to the forces applied to the tire, which has significant effects on handling characteristics. Thus, when designing a suspension system, the effects of bushings should be considered carefully in view of handling as well as ride characteristics. Compliance characteristics of suspension systems can be accounted for in the light of the changes of static design factors such as toe angle, camber angle and, longitudinal and lateral deflections of the wheel due to the forces and moments applied to the tire-road contact patch. The effects of these characteristics on handling were investigated by Bundorf[1],[2]. The compliance effects on ride have been also taken into consideration to design a suspension system[3].

Compliance characteristics of a suspension system can be measured through the Suspension Parameter Measuring Devise(SPMD)[4]. However in the early developing stage of a suspension, there should be an analytical means for calculating compliance characteristics. Simple calculation by 2-dimensional analysis can be adopted, but its accuracy is open to doubt. Recently, more accurate computation of compliance characteristics has been tried by elastokinematic analysis techniques for multibody systems. These methods find the solutions by simultaneously solving the kinematic constraint equations and force equilibrium equations. However, the drawback of these approaches is that the solution process is very sensitive to the initial estimates of the solutions. To resolve these problem, the method of minimizing the potential energy of the system has been proposed[5].

The magnitude of wheel attitude change due to external forces at the tire contact point is nearly proportional to the magnitude of force, thus this behavior can be considered to be linear. So, in this study, based on the assumption that the displacements of suspension systems under the external forces are very small, a linear form of the elastokinematic equations in terms of infinitesimal displacements and joint reactions forces is derived. The equations can be applied to any form of suspension once the types of kinematic joints and bushings are identified. The validity of the method can be proved through the comparison of the results from any established elastokinematic analysis software such as ADAMS or DADS. By directly differentiating the linear elastokinematic equations with respect to design variables associated with bushing stiffness, sensitivity equations can be obtained. Then, using the results of sensitivity analysis, an optimization process to meet the various compliance targets is to be performed.

DERIVATION OF LINEAR ELASTOKINEMATIC EQUATIONS

To obtain linear equations for elastokinematic behavior of a suspension system, it is assumed that the displacements of the suspension system supported by kinematic joints and elastic elements are small under the action of external forces. Let the generalized coordinates for a suspension element be the small displacements of the Cartesian coordinates, as shown in Fig.1

$$\Delta \mathbf{q}_i = \{\Delta \mathbf{r}, \Delta \boldsymbol{\pi}\}_i^T = \{\Delta x, \Delta y, \Delta z, \Delta \pi_x, \Delta \pi_y, \Delta \pi_z\}_i^T \quad (1)$$

where, $\Delta \mathbf{r}_i$ and $\Delta \boldsymbol{\pi}_i$ are respectively the vectors for small translational and rotational displacements in the inertial reference system.

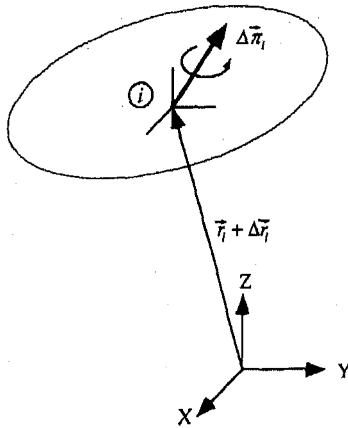

Fig. 1 Generalized coordinates

Assume that the suspension system under the action of external forces is in equilibrium state. The kinematic joints of the suspension can be represented as some algebraic constraint equations, where the general form can be expressed as;

$$\boldsymbol{\Phi}(\mathbf{q}) = \mathbf{0} \quad (2)$$

For small displacement $\Delta \mathbf{q}$, the constraint equation must satisfy the following condition

$$\Delta \boldsymbol{\Phi} = \boldsymbol{\Phi}_{\mathbf{q}} \Delta \mathbf{q} = \mathbf{0} \quad (3)$$

where $\boldsymbol{\Phi}_{\mathbf{q}}$ is Jacobian matrix of kinematic constraints.

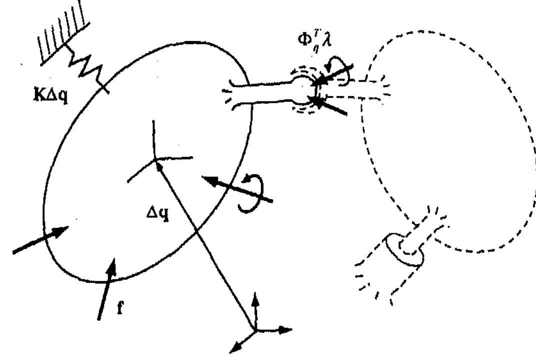

Fig.2 Force-displacement diagram between the bodies

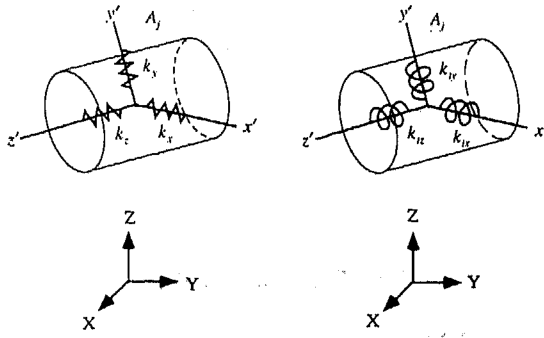
The displacements of a body under external forces can be assumed to be small if the elastic stiffness is big enough to exert sufficient reaction forces. This assumption is very plausible for vehicle suspension systems where, in general, very large bushing stiffness are used. The sum of external forces acting on the body is equal to the sum of elastic reaction forces of the bushings and constraint reaction forces of the joints as shown in Fig. 2. This equilibrium condition can be written as

$$\boldsymbol{\Phi}_{\mathbf{q}}^T \boldsymbol{\lambda} + \mathbf{K}\Delta \mathbf{q} = -\mathbf{f} \quad (4)$$

where $\mathbf{K}\Delta \mathbf{q}$ is the elastic reaction forces due to small displacements exerted by elastic elements such as springs or bushing elements, $\mathbf{f}$ is the external force, $\boldsymbol{\lambda}$ is Lagrange multiplier and, $\boldsymbol{\Phi}_{\mathbf{q}}^T \boldsymbol{\lambda}$ is the term associated with constraint reaction forces.

Eqs. (3) and (4) can be combined to a matrix form.



$$\begin{bmatrix} \mathbf{K} & \boldsymbol{\Phi}_{\mathbf{q}}^T \\ \boldsymbol{\Phi}_{\mathbf{q}} & 0 \end{bmatrix} \begin{Bmatrix} \Delta \mathbf{q} \\ \boldsymbol{\lambda} \end{Bmatrix} = \begin{Bmatrix} -\mathbf{f} \\ \mathbf{0} \end{Bmatrix} \quad (5)$$

Eq. (5) is the governing equations for elastokinematic behavior of a suspension system that undergoes a small displacement due to the external forces. The left hand side of Eq. (5) is symmetric if stiffness matrix K is symmetric, which will be demonstrated later. To solve the equations, stiffness matrix and constraint Jacobians should be determined.

The elastic elements of a suspension system such as bushings and springs can be specified as 3 translational springs and 3 rotational springs, as shown in Fig. 3, in the local coordinate system. Stiffness matrices in the local coordinate system can be expressed as

$$\mathbf{K}_T{}' = \begin{bmatrix} k_x & 0 & 0 \\ 0 & k_y & 0 \\ 0 & 0 & k_z \end{bmatrix} \quad (6)$$

$$\mathbf{K}_R{}' = \begin{bmatrix} k_{tx} & 0 & 0 \\ 0 & k_{ty} & 0 \\ 0 & 0 & k_{tz} \end{bmatrix} \quad (7)$$

(a) Translational spring element (b) Rotational spring element

Fig. 3 Modeling of bushing as spring elements

Stiffness matrices defined in terms of the local coordinate system can be transformed into stiffness matrices in the global coordinate system by multiplying by the transformation matrix.

$$\mathbf{K}_T = \mathbf{A}_j \mathbf{K}_T{}' \mathbf{A}_j{}^T \quad (8)$$

$$\mathbf{K}_R = \mathbf{A}_j \mathbf{K}_R{}' \mathbf{A}_j{}^T \quad (9)$$

where $\mathbf{A}_j$ is the rotational transformation matrix transforming from the local coordinate system to the global coordinate system. Since stiffness matrices are defined in the global coordinate system as Eqs. (8) and (9), elastic reaction forces are to be derived in the global coordinate system.

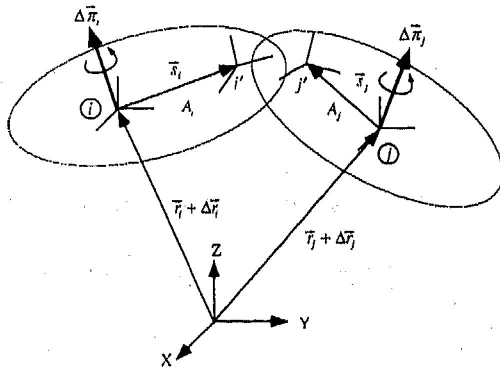


Fig. 4 Relative displpacements between body i and body j

In Fig. 4, the local coordinate system attached to each body has the same orientation as the global coordinate system. $\mathbf{s}_i$ and $\mathbf{s}_j$ are respectively position vectors from the origins of the local coordinate systems of body i and j to the local coordinates for elastic elements, i' and j' body i and body j. $\mathbf{A}_i$ and $\mathbf{A}_j$ are transformation matrices from the local coordinate systems of elastic elements to the global coordinate system of body i and body j respectively. Small displacements at i' and j' can be expressed in terms of generalized coordinates as

$$\Delta\mathbf{r}_i{}' = \Delta\mathbf{r}_i + \Delta\tilde{\boldsymbol{\pi}}_i \mathbf{s}_i = \Delta\mathbf{r}_i - \tilde{\mathbf{s}}_i \Delta\boldsymbol{\pi}_i \quad (10)$$

$$\Delta\mathbf{r}_j{}' = \Delta\mathbf{r}_j - \tilde{\mathbf{s}}_j \Delta\boldsymbol{\pi}_j \quad (11)$$

where the tilde operator '~' represents a skew-symmetric matrix.

Forces of the elastic elements exerted on the body i can be computed by premultiplying stiffness matrix $\mathbf{K}_T$ of Eq. (8) to the relative displacement $\Delta\mathbf{r}_i{}' - \Delta\mathbf{r}_j{}'$.

$$\mathbf{F}_i = -\mathbf{K}_T(\Delta\mathbf{r}_i - \Delta\mathbf{r}_j - \tilde{\mathbf{s}}_i \Delta\boldsymbol{\pi}_i + \tilde{\mathbf{s}}_j \Delta\boldsymbol{\pi}_j) \quad (12)$$

The total moment exerted on body i is the sum of moments associated with force $\mathbf{F}_i$ and pure moments generated by relative rotation between bodies.

$$\mathbf{T}_i = \tilde{\mathbf{s}}_i \mathbf{F}_i - \mathbf{K}_R({}_i\Delta\boldsymbol{\pi}_i - \Delta\boldsymbol{\pi}_j) \quad (13)$$

Similarly, force and moment exerted on body j can be expressed as

$$\mathbf{F}_j = -\mathbf{F}_i \quad (14)$$

$$\mathbf{T}_j = \tilde{\mathbf{s}}_j \mathbf{F}_j + \mathbf{K}_R({}_i\Delta\boldsymbol{\pi}_i - \Delta\boldsymbol{\pi}_j) \quad (15)$$

Arranging Eqs. (12)~(15), the relationship between force and displacement can be given as

$$\begin{Bmatrix} \mathbf{F}_i \\ \mathbf{T}_i \\ \mathbf{F}_j \\ \mathbf{T}_j \end{Bmatrix} = \left[\begin{array}{cc|cc} -\mathbf{K}_T & \mathbf{K}_T\tilde{\mathbf{s}}_i & \mathbf{K}_T & -\mathbf{K}_T\tilde{\mathbf{s}}_j \\ -\tilde{\mathbf{s}}_i\mathbf{K}_T & \tilde{\mathbf{s}}_i\mathbf{K}_T\tilde{\mathbf{s}}_i - \mathbf{K}_R & \tilde{\mathbf{s}}_i\mathbf{K}_T & -\tilde{\mathbf{s}}_i\mathbf{K}_T\tilde{\mathbf{s}}_j + \mathbf{K}_R \\ \hline \mathbf{K}_T & -\mathbf{K}_T\tilde{\mathbf{s}}_i & -\mathbf{K}_T & \mathbf{K}_T\tilde{\mathbf{s}}_j \\ \tilde{\mathbf{s}}_j\mathbf{K}_T & -\tilde{\mathbf{s}}_j\mathbf{K}_T\tilde{\mathbf{s}}_i + \mathbf{K}_R & -\tilde{\mathbf{s}}_i\mathbf{K}_T & \tilde{\mathbf{s}}_j\mathbf{K}_T\tilde{\mathbf{s}}_j - \mathbf{K}_R \end{array}\right] \begin{Bmatrix} \Delta\mathbf{r}_i \\ \Delta\boldsymbol{\pi}_i \\ \Delta\mathbf{r}_j \\ \Delta\boldsymbol{\pi}_j \end{Bmatrix}$$

$$= \begin{bmatrix} \mathbf{K}_{ii} & \mathbf{K}_{ij} \\ \mathbf{K}_{ji} & \mathbf{K}_{jj} \end{bmatrix} \begin{Bmatrix} \Delta\mathbf{q}_i \\ \Delta\mathbf{q}_j \end{Bmatrix} \quad (16)$$

$$= [\mathbf{K}]\{\Delta\mathbf{q}\}_{i,j}$$

Since the stiffness matrix K in Eq. (16) is symmetric, it is evident that the coefficient matrix of Eq. (5) is also symmetric.

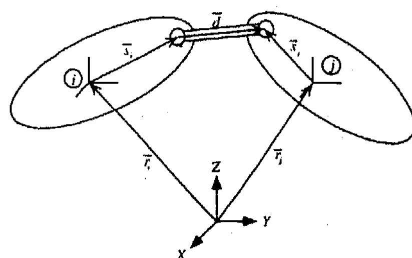

Fig.5 Displacement Constraint

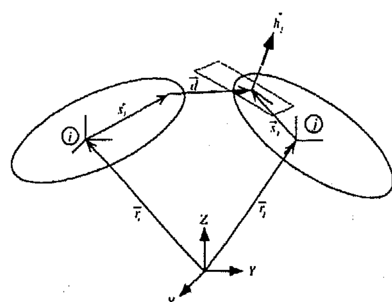

Fig. 6 Inplane constraint

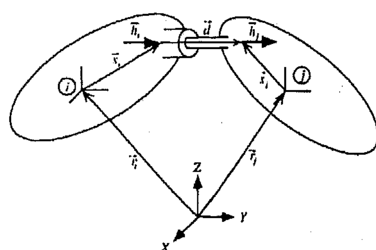

Fig. 7 Cylindrical constraint

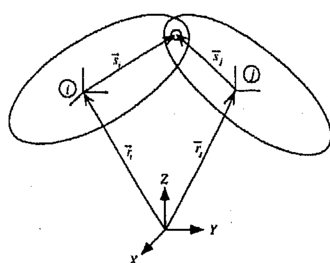

Fig. 8 Spherical constraint

Typical kinematic joints of vehicle suspension systems are shown in Fig. 5 ~ Fig. 8. Constraint Jacobians can be obtained by differentiating kinematic constraint equations. Constraint Jacobians for these joints are summarized in Table 1.

Table 1. Constraint Jacobians

Constraints	$\left[\mathbf{\Phi}_{\mathbf{q}i} \,\vdots\, \mathbf{\Phi}_{\mathbf{q}j}\right]$
Displacement	$\left[-2\mathbf{d}^T \quad 2\mathbf{d}^T\tilde{\mathbf{s}}_i \,\vdots\, 2\mathbf{d}^T \quad -2\mathbf{d}^T\tilde{\mathbf{s}}_j\right]$
Inplane	$\left[-\mathbf{h}_j^T \quad \mathbf{h}_j^T\tilde{\mathbf{s}}_i \,\vdots\, \mathbf{h}_j^T \quad -\mathbf{h}_j^T\tilde{\mathbf{s}}_j - \mathbf{d}^T\tilde{\mathbf{h}}_j\right]$
Cylindrical	$\begin{bmatrix} \mathbf{0} & \tilde{\mathbf{h}}_j\tilde{\mathbf{h}}_i & \vdots & \mathbf{0} & -\tilde{\mathbf{h}}_i\tilde{\mathbf{h}}_j \\ -\tilde{\mathbf{h}}_i & \tilde{\mathbf{h}}_i\tilde{\mathbf{s}}_i + \tilde{\mathbf{d}}\bar{\mathbf{h}}_i & \vdots & \tilde{\mathbf{h}}_i & -\tilde{\mathbf{h}}_i\tilde{\mathbf{s}}_j \end{bmatrix}$
Spherical	$\left[-\mathbf{I} \quad \tilde{\mathbf{s}}_i \,\vdots\, \mathbf{I} \quad -\tilde{\mathbf{s}}_j\right]$

CALCULATION OF COMPLIANCE

A McPherson strut suspension system is shown in Fig. 9. Body 0 represents the ground, body 1 represents the wheel assembly, body 2 represents the strut, and body 3 represents the lower control arm. Each body is interconnected by elastic elements or kinematic joints. The coordinate where elastic elements or kinematic joints are defined is denoted as i^k, where i is the number of the body and superscript k is the number of the elastic element or kinematic joint.

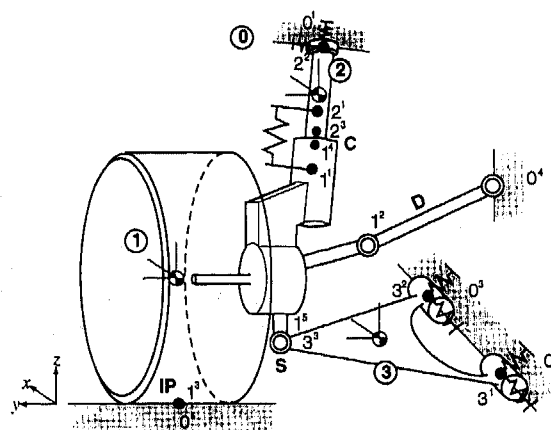

Fig. 9 Modeling of a McPherson strut suspension

Table 2. Elastic elements

index	coordinate (i - j)
1	$1^1 - 2^1$
2	$2^2 - 0^1$
3	$3^1 - 0^2$
4	$3^2 - 0^3$

Table 3. Constraint elements

index	coordinate (i - j)	type
1	$1^2 - 0^4$	D
2	$1^3 - 0^5$	IP
3	$1^4 - 2^3$	C
4	$1^5 - 3^3$	S

Connection by elastic elements is summerized at Table 2. Body 1 is connected to body 2 with a linear spring. Body 2 and body 0 are connected with a strut mount bushing. Body 3 is connected to body 0 at two points with bushings.

Kinematic constraints are summerized in Table 3. A displacement constraint is imposed on body 1 to simulate bump and rebound motion of the wheel assembly. Body 1 is connected to body 0 with an inplane constraint. The constraint between body 1 and body 2 is a cylindrical joint. Body 1 and body 3 are connected by a spherical joint.

Applying Eq. (5) elastokinematic equation of the system can be written as

$$\left[\begin{array}{ccc:c} \mathbf{K}_{ii}^1 & \mathbf{K}_{ij}^1 & 0 & \\ \mathbf{K}_{ji}^1 & \mathbf{K}_{jj}^1+\mathbf{K}_{ii}^2 & 0 & \mathbf{\Phi}_q^T \\ 0 & 0 & \mathbf{K}_{ii}^3+\mathbf{K}_{ii}^4 & \\ \hdashline \mathbf{\Phi}_{qi}^1 & 0 & 0 & \\ \mathbf{\Phi}_{qi}^2 & 0 & 0 & \mathbf{0} \\ \mathbf{\Phi}_{qi}^3 & \mathbf{\Phi}_{qj}^3 & 0 & \\ \mathbf{\Phi}_{qi}^4 & 0 & \mathbf{\Phi}_{qj}^4 & \end{array}\right] \begin{Bmatrix} \Delta\mathbf{q}_1 \\ \Delta\mathbf{q}_2 \\ \Delta\mathbf{q}_3 \\ \boldsymbol{\lambda}_1 \\ \boldsymbol{\lambda}_2 \\ \boldsymbol{\lambda}_3 \\ \boldsymbol{\lambda}_4 \end{Bmatrix} = \begin{Bmatrix} -\mathbf{f}_1 \\ -\mathbf{f}_2 \\ -\mathbf{f}_3 \\ 0 \\ 0 \\ 0 \\ 0 \end{Bmatrix} \quad (17)$$

where $\Delta\mathbf{q}_1$, $\Delta\mathbf{q}_2$ and $\Delta\mathbf{q}_3$ are generalized coordinates of body 1, body 2 and body 3, respectively. Body 0 of the ground has no degree of freedom. Equation (17) can be solved by any linear system solving method.

Table 4. Displacements of wheel due to lateral force

F_{1y} = 1000 N

$\Delta\mathbf{q}_1$	Linear Analysis	ADAMS
Δx (mm)	0.3065	0.3084
Δy (mm)	0.1579	0.1583
Δz (mm)	0.0000	-0.0003
$\Delta\pi_x$ (deg)	0.0409	0.0406
$\Delta\pi_y$ (deg)	-0.0191	-0.0189
$\Delta\pi_z$ (deg)	-0.0470	-0.0473

Compliance of the suspension system can be calculated under the lateral or longitudinal forces at the tire contact point. When the lateral force F_{1y} = 1000 N is applied, displacements of the wheel are computed. The results of $\Delta\mathbf{q}_1$ are shown in Table 4. Results are very consistent with those of ADAMS.

SENSITIVITY ANALYSIS

Sensitivity equations can be obtained by differentiating Eq. (5) with respect to a design variable associated with compliance characteristics. Representing a design variable by the symbol b, sensitivity equations can be written as

$$\begin{bmatrix} \mathbf{K} & \mathbf{\Phi}_q^T \\ \mathbf{\Phi}_q & 0 \end{bmatrix} \begin{Bmatrix} \Delta\mathbf{q}_b \\ \boldsymbol{\lambda}_b \end{Bmatrix} = \begin{Bmatrix} -\mathbf{K}_b\Delta\mathbf{q} \\ \mathbf{0} \end{Bmatrix} \quad (18)$$

where subscript b means partial differentiation. Since the coefficient matrix of Eq. (18) is the same as that of Eq. (5), only $\mathbf{K}_b$ needs to be calculated. $\mathbf{K}_b$ can be computed by directly differentiating the stiffness matrix of Eq. (16) as

$$\mathbf{K}_b = \begin{bmatrix} -\frac{\partial \mathbf{K}_T}{\partial b} & \frac{\partial \mathbf{K}_T}{\partial b}\tilde{\mathbf{s}}_i & \frac{\partial \mathbf{K}_T}{\partial b} & -\frac{\partial \mathbf{K}_T}{\partial b}\tilde{\mathbf{s}}_j \\ -\tilde{\mathbf{s}}_i\frac{\partial \mathbf{K}_T}{\partial b} & \tilde{\mathbf{s}}_i\frac{\partial \mathbf{K}_T}{\partial b}\tilde{\mathbf{s}}_i-\frac{\partial \mathbf{K}_R}{\partial b} & \tilde{\mathbf{s}}_i\frac{\partial \mathbf{K}_T}{\partial b} & -\tilde{\mathbf{s}}_i\frac{\partial \mathbf{K}_T}{\partial b}\tilde{\mathbf{s}}_j+\frac{\partial \mathbf{K}_R}{\partial b} \\ \frac{\partial \mathbf{K}_T}{\partial b} & -\frac{\partial \mathbf{K}_T}{\partial b}\tilde{\mathbf{s}}_i & -\frac{\partial \mathbf{K}_T}{\partial b} & \frac{\partial \mathbf{K}_T}{\partial b}\tilde{\mathbf{s}}_j \\ \tilde{\mathbf{s}}_j\frac{\partial \mathbf{K}_T}{\partial b} & -\tilde{\mathbf{s}}_j\frac{\partial \mathbf{K}_T}{\partial b}\tilde{\mathbf{s}}_i+\frac{\partial \mathbf{K}_R}{\partial b} & -\tilde{\mathbf{s}}_i\frac{\partial \mathbf{K}_T}{\partial b} & \tilde{\mathbf{s}}_j\frac{\partial \mathbf{K}_T}{\partial b}\tilde{\mathbf{s}}_j-\frac{\partial \mathbf{K}_R}{\partial b} \end{bmatrix} \quad (19)$$

where $\frac{\partial \mathbf{K}_T}{\partial b}$, $\frac{\partial \mathbf{K}_R}{\partial b}$ are calculated from Eqs. (8) and (9) as

$$\frac{\partial \mathbf{K}_T}{\partial b} = \mathbf{A}_j \frac{\partial \mathbf{K}_T'}{\partial b} \mathbf{A}_j^T \quad (20)$$

$$\frac{\partial \mathbf{K}_R}{\partial b} = \mathbf{A}_j \frac{\partial \mathbf{K}_R'}{\partial b} \mathbf{A}_j^T \quad (21)$$

Entries of matrices $\frac{\partial \mathbf{K}_T'}{\partial b}$ and $\frac{\partial \mathbf{K}_R'}{\partial b}$ are either 0 or 1 according to the choice of the design variable. For example, if b = K_x in Eq. (6), $\frac{\partial \mathbf{K}_T'}{\partial b}$ becomes

$$\frac{\partial \mathbf{K}_T'}{\partial b} = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix} \quad (22)$$

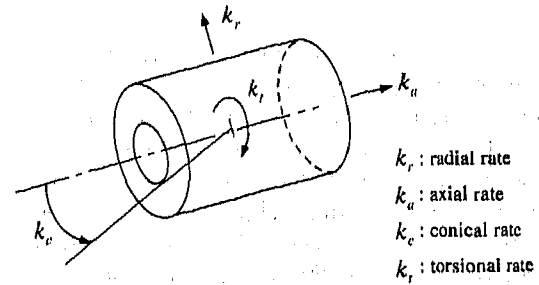

Fig. 10 Spring rates of cylindrical type bushing

Bushing elements of the McPherson strut suspension system as shown in Fig. 9 are strut mount bushing, front lower arm bushing, and rear lower arm

bushing. In this study, stiffnesses of these three bushings are selected as design variables. Since the stiffness of bushings in the radial direction is generally constant for a cylindrical type bushing, four design variables are to be considered as represented in Fig. 10.

There can be many performance variables associated with compliance characteristics of suspension system. Here, toe change G_1, camber change G_2, and lateral deflection G_3 due to the lateral force are considered. Also toe change G_4, and longitudinal deflection G_5 due to the longitudinal force are chosen as performance variables. Sensitivities for these performance targets with respect to each design variable are shown at Table 5.

Table 5. Sensitivities of compliance characteristics

Design Variables \ Sensitivity	toe change by lateral force G_1	camber change by lateral force G_2	lat. disp. change by lateral force G_3	toe change by long. force G_4	long. disp. change by long. force G_5
k_{r2}	-0.0303	-0.0214	0.0455	0.0011	0.0412
k_{a2}	0.0000	0.0000	0.0000	0.0000	0.0000
k_{c2}	0.0000	0.0000	0.0000	0.0000	0.0000
k_{t2}	0.0000	0.0000	0.0000	0.0001	-0.0012
k_{r3}	0.0129	-0.0031	-0.0326	0.0131	-0.0449
k_{a3}	-0.0001	0.0000	0.0000	-0.0376	-0.7593
k_{c3}	0.0000	0.0000	0.0000	0.0000	0.0000
k_{t3}	0.0000	0.0000	0.0000	0.0000	0.0000
k_{r4}	0.0001	-0.0004	-0.0036	0.0010	-0.2963
k_{a4}	-0.0001	0.0000	0.0000	-0.0376	-0.7593
k_{c4}	0.0000	0.0000	0.0000	0.0000	0.0000
k_{t4}	0.0000	0.0000	0.0000	0.0000	0.0000

As shown in Table 5, sensitivities of rotational stiffness of the bushings are small enough to be neglected. Radial rate k_{r2} of strut mount has significant effects on all performance variables, however, effects of axial rate k_{a2} is very small. k_{r2} of strut mount can be considered as the main design variable which affects lateral compliance characteristics. The design variables most sensitive to longitudinal compliance are k_{a3} and k_{a4}, which are axial rates of front and rear lower arm bushings, respectively.

OPTIMIZATION

Optimization of bushing characteristics is to be performed taking five performance variables, G_1, ..., G_5, into consideration. Gradients needed to perform an optimization process are provided by the derived sensitivity equations. The goal attainment method is adopted to solve the multi-objective optimization problem. This method seeks the solution by converting vector type multi-objective function $\mathbf{G(x)}$ to a single objective function using a scalar variable γ. This optimization problem can be stated as

$$\begin{aligned} &\textit{Minimize} \quad \gamma \\ &\textit{subject to} \quad \mathbf{G(x)} - \mathbf{W}\gamma \le \mathbf{G}^* \end{aligned} \qquad (23)$$

where $\mathbf{G}^*$ is a set of design goals, and $\mathbf{W}$ is the weighting factor, which is proportional to design goal $\mathbf{G}^*$. The results of optimization using the sequential quadratic programming are shown in Table 6.

Table 6. Optimization results

Performance /parameter	initial state	optimal state (goal, G*)
G_1	-0.0470	0.0055 (0.01)
G_2	0.0409	0.0145 (0.01)
G_3	0.1579	0.0055 (0.01)
G_4	-0.0404	0.0145 (0.01)
G_5	1.6709	0.7460 (1.00)
k_{r2}	1000	1870
k_{a2}	600	604
k_{c2}	1800000	1800000
k_{t2}	0	0
k_{r3}	6000	42565
k_{a3}	500	806
k_{c3}	200000	200001
k_{t3}	100000	100000
k_{r4}	2000	64444
k_{a4}	600	906
k_{c4}	300000	300001
k_{t4}	50000	50000

Values of design goal $\mathbf{G}^*$ are all set to 0.01 except for G_5^*=1.0. The design goals may be chosen differently by practical considerations. Optimal compliance characteristics are achieved near the design goal. Stiffness parameters, which have greater contribution to compliance characteristics as shown in Table 4, have changed more than other parameters. In Fig. 11 and Fig. 12, iteration history of G_1, G_5 of performance variables are shown.

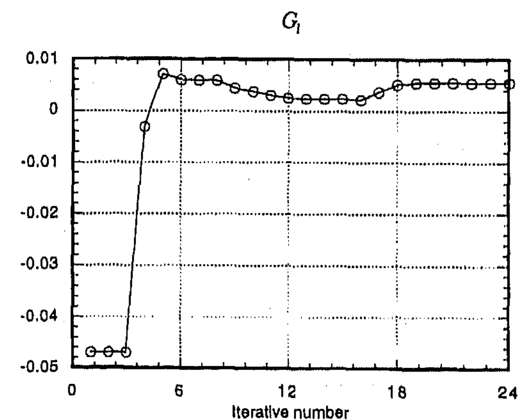

Fig. 11 Iteration history of G_1

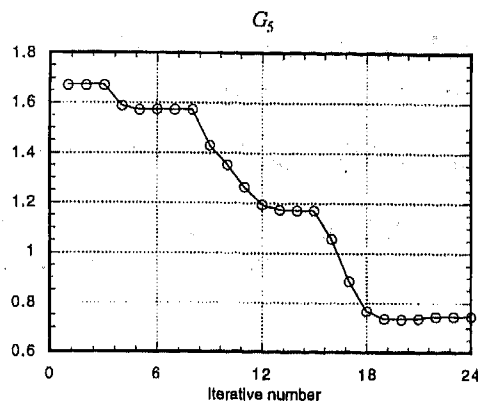

Fig. 12 Iteration history of G_5

CONCLUSION

Compliance characteristics of suspension systems have direct influence on ride and handling of a vehicle. In this study, linear elastokinematic equations have been derived to compute compliance characteristics of suspension systems. It is shown that these equations can be applied to any suspension system and are verified through the comparison with ADAMS results. Elastokinematic equations presented in this paper turned out to be not only very simple to implement, but also in close agreement with the more complex solution offered by ADAMS.

By directly differentiating the linear elastokinematic equations with respect to design variable associated with bushing stiffness, sensitivity equations are obtained. Then, sensitivity analysis with respect to stiffness of bushing elements was performed. Based on the sensitivity analysis, optimization of bushing characteristics is carried out, and the optimal solution subject to the various design targets are obtained.

An Investigation of the Feasibility of Refrigerant Charge Loss Detection Using Low Cost Measurements

University of Illinois at Urbana-Champaign

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

The feasibility of automatically detecting refrigerant charge loss in mobile air conditioning (MAC) systems by analyzing inexpensive dynamic measurements was studied. An indicator of the refrigerant inventory of the evaporator was developed. This measure, termed Time to Temperature Turning (TTT), is based on dynamic measurement of the evaporator outlet refrigerant temperature, and correlates strongly with charge level. TTT correlated well with clutch cycling behavior, a metric which is employed in current shop diagnostic practice to indicate refrigerant charge loss.

Laboratory data were generated from a factorial experiment design on the following factors: condenser air inlet temperature, condenser air flow rate, evaporator air inlet temperature, compressor speed, and refrigerant charge. Experiments to date were conducted with a dry evaporator.

INTRODUCTION

This paper reports work to date on microprocessor based refrigerant charge loss detection at the Air Conditioning and Refrigeration Center (ACRC) of the University of Illinois. The data in this report were obtained from late model original equipment manufacturer (OEM) MAC systems employing fixed displacement compressors, orifice tube expansion devices, and clutch cycling capacity control. These systems were installed and tested in the ACRC Mobile Air Conditioning (MAC) Project test facility.

MOTIVATION -. Refrigerant leakage from MAC systems contributes to environmental pollution and leads to reduced cooling system performance. Compressor lubrication in MAC refrigeration systems is provided by oil that circulates with the refrigerant. Therefore, inadequate refrigerant circulation due to low refrigerant charge may cause reduced compressor lubrication. Reduced compressor lubrication can lead to premature mechanical failure of the compressor. Under certain operating conditions, in systems employing a suction pressure controlled compressor clutch, refrigerant charge loss may induce frequent clutch cycling. Excessive clutch cycling may cause premature clutch failure and may adversely affect driveability, fuel economy and engine idling control. Early detection of charge loss would be highly desirable. The goals of the MAC project include addressing the clear need for the development of a reliable method for detecting refrigerant charge loss in MAC systems

Early detection and diagnosis of refrigerant charge loss would permit time for automatic or manual corrective actions to be taken prior to significant deterioration in performance or catastrophic system failure. A commercial diagnostic system should possess the following desirable properties: (1) be capable of accurately diagnosing a reduction in refrigerant charge, (2) require a minimal number of sensors, (3) be simple to install and reliable in operation, and (4) be low cost.

The benefits of a microprocessor based refrigerant charge leakage detection system include (1) programmability and (2) performance data analysis and record-keeping. The use of microprocessor technology in luxury and mid-size vehicles is already widespread, and is likely to grow in the future. Microprocessor based engine control systems, automatic brake systems and environmental control systems currently log and use data such as engine speed, vehicle speed, exterior air temperature, and interior air temperature. One of the goals of this project was to utilize data already available on the vehicle instrumentation bus. Clearly, such refrigerant charge diagnostic systems would first be introduced in models which already employ microprocessors.

BASIS FOR STUDY - The problem of detecting and diagnosing a loss in refrigerant charge is twofold. First, a departure from some normal, or expected, operating condition must be determined. Second, the cause of this abnormal operating state must be uniquely determined. Refrigeration systems pose a difficult problem because there are a considerable number of factors which influence system performance, and changes in these factors may produce similar system

responses. Diagnostic schemes for MAC systems are particularly difficult to develop because mobile systems rarely operate in steady state.

Both theory and practice show that the mass of refrigerant present in a refrigeration system affects the system's performance. An example from the open literature is a 1988 experimental study which investigated the effect of varying refrigerant charge in a clutch cycling, expansion valve MAC system [1]. Steady-state experiments were performed which documented the effect of reducing refrigerant charge on several key refrigerant side and air side system parameters. Significant changes in the system parameters were observed. We extended this experimental principle to studies of refrigerant system dynamic performance.

Recent literature documents several efforts made to analyze stationary air conditioning and refrigeration system performance using multiple temperature and pressure measurements [2,3,4]. The measurements are processed using one of several computationally intensive techniques (e.g. neural networks, statistical pattern recognition, or expert systems). A refrigerant monitoring device based on mechanical measurement of the quality of the refrigerant at the condenser outlet was reported in [5]. We tried to synthesize these approaches by searching for a robust, non-invasive measure of system performance requiring minimal computational overhead.

EXPERIMENT

APPROACH - The problem of refrigerant charge loss detection was considered for fixed displacement, cycling clutch, orifice tube air conditioning systems operating under a specific, limited set of operating conditions. That is, we considered the problem as one of detecting the change in refrigerant system performance, due to refrigerant charge loss, over a limited range of operating conditions which are encountered frequently in vehicle operation. This concept is an extension of current shop diagnostic practice, in which MAC systems are tested under specific operating conditions. In the shop, the existence and extent of refrigerant charge loss is determined by comparing the system response at specified conditions to reference data provided in the form of plots of condenser inlet temperature versus clutch cycling period.

TEST FACILITY - The facility used in this study is located in the Mechanical Engineering Laboratory at the University of Illinois. The facility permits the detailed study of the refrigerant side and air side performance of a modified, late model OEM MAC system under tightly controlled environmental conditions.

The refrigeration system consists of factory standard components from the air conditioning system of the 1994 Ford Crown Victoria: a fixed displacement compressor, an orifice tube expansion device, a condenser, an accumulator and an evaporator. The heat exchangers are installed in separate wind tunnels in the test facility. A copper piping system connects all the system components in a closed loop and permits the instrumentation of the refrigeration system. Refrigerant temperature and pressure are measured upstream and downstream of each major component, and refrigerant mass flow rate is measured in the vapor and liquid lines. The facility control system permits the control of the compressor speed and clutch operation.

The condenser and evaporator are housed in independent air flow loops. The facility control system allows the air flow rate through, and inlet air temperature of, each heat exchanger to be tightly controlled. This paper reports testing which was performed with a dry evaporator coil. The addition of a humidity control system to the evaporator air loop during the fall of 1996 now allows the control of evaporator air loop relative humidity. The air loops are equipped with air temperature, relative humidity and air flow rate instrumentation.

EXPERIMENT DESIGN - Diagnosis of refrigerant charge loss requires that the effect on system performance of a change in refrigerant charge (mass), m_{ref}, be evaluated with respect to the effects of varying other parameters which affect the refrigeration system operating state. These parameters include condenser air inlet temperature (T_{cai}), condenser air volume flow rate (Q_{cai}), evaporator air inlet temperature (T_{eai}), evaporator air inlet relative humidity (Rh_{eai}), evaporator air volume flow rate (Q_{eai}), and compressor speed (N_{comp}).

The baseline charge of the system was a crucial parameter we had to determine experimentally. The system performance with the initial charge would serve as the baseline to which we would compare system performance with reduced charge. We determined the initial charge for our modified system by using an industry standard charge optimization procedure. The charge we determined for the test facility differed from the charge specified by the manufacturer for the factory system. We expected this difference, and it is attributable to the refrigeration system volume added by the piping sections which support installing the system in the test facility. We also used an orifice tube diameter that was one standard size smaller (.052" vs. .057") than that specified for the factory system. We expected that these differences between the experimental system and the factory system would affect the steady state operating points of the system and the baseline system charge. However, we believe that the *dynamic* effects we observed in our study of charge reduction will be preserved. This hypothesis requires further experimental study.

We eliminated evaporator air flow rate from the study by fixing this parameter at its maximum design value. Evaporator air flow rate does have a significant effect on performance; however, we believe it is reasonable to assume that a typical mobile air conditioning system is operated in the high blower mode frequently enough to provide sufficient opportunity for an automatic diagnostic system to collect data. It would also be a simple matter to extend the technique demonstrated in this paper to include evaporator air flow rate (or equivalently, evaporator blower speed) as an additional parameter.

Evaporator air inlet relative humidity is known to have a major impact on system dynamic performance. At the time of this study, we could not control this parameter, so the study was conducted with a dry coil. The results presented herein are valid in dry climates. Further, we intend to study the effects of inlet humidity in the near future.

We limited the study to small (~ ±10%) changes in each variable of interest with respect to a nominal operating state. Our goal was to determine if relatively small losses of refrigerant charge could be detected based on small, repeated variations of system operating parameters such as would occur during normal highway driving. We defined the nominal operating state as follows: N_{comp}, 2800 rpm; Q_{cai}, 1800 cfm; T_{cai}, 110 °F; T_{eai}, 70°F; and m_{ref}, 2.85 lbm. Q_{eai} was set at 330 cfm for all tests. We based our setpoints on typical highway driving data provided by our industrial sponsors. The high pressure (clutch *on*) and low pressure (clutch *off*) cycling setpoints were set to 42 psig and 25 psig, respectively.

A 2 level, 5 factor, fractional factorial experiment design was employed to investigate the system performance. T_{cai}, Q_{cai}, T_{eai}, N_{comp}, and m_{ref} were varied, and we measured the corresponding responses of the total clutch cycling period, the clutch duty cycle, and Time to Temperature Turning (TTT). TTT is a temperature-based, indirect indication of the evaporator refrigerant inventory, and will be fully explained later. The experiment design is presented in Tables 1 and 2.

RESULTS

We found that m_{ref} is the dominant factor governing clutch cycling period, over the range of variables we studied. Tables 3 and 4 present the results of the designed experiment described in Tables 1 and 2.

Table 1. Key for Coded Experiment Design Notation

Boldface numbers in the column headings in Table 3 and in the body of Table 4 correspond to the factor tag numbers defined in Table 1.

Table 3 records the factor levels, the number of complete clutch cycles (N_c), the mean clutch cycling period (T_c), and the standard deviation (s) of the mean clutch cycling period. Table 4 reports the main effects and two factor interactions. Each experimental run lasted for 600 seconds.

We can take advantage of the experiment design and draw some preliminary conclusions from the data in Table 3. Notice that the factor levels in each of runs 1 through 8 differ from those in runs 9 through 16 in only two factors: m_{ref} and N_{comp}. Any significant difference in the response observed between, say, run 2 and run 10, was due to (1) the change in m_{ref}, or (2) the change in N_{comp}, or (3) the combined effect of both changes. Similarly, each pair of neighboring runs, starting with runs 1 and 2, differ only in N_{comp} and Q_{cai}. Table 3 clearly shows that the effect of changing of N_{comp} and Q_{cai} in tandem is small, while the effect of changing m_{ref} and N_{comp} in tandem is, in general, large. This indicates that the main effect of m_{ref} may be quite significant. Table 4 presents the calculated main effects and two-factor interactions. The calculated mean period and the standard deviation of the mean are provided at the beginning of Table 4.

The most significant main effect is due to m_{ref} (**4**), followed by T_{eai} (**3**) and T_{cai} (**2**). In addition, the heat exchanger inlet temperatures exhibit a strong 2 factor interaction (**23**). Over the range of variables studied, N_{comp} and Q_{cai} did not significantly affect clutch cycling period. The main effect due to m_{ref} is not strictly "significant" according to the rules governing interpretation of statistics computed in a designed experiment. This typically requires the main effect (or any interaction) to exceed the standard deviation by at least a factor of 2. However, the data clearly show the relative magnitude of the effects that each controlled variable (factors) had on the clutch cycling period.

Further analysis of the data showed that the *on* portion of the clutch duty cycle was significantly more sensitive than the *off* portion to changes in the refrigerant charge level. In fact, the *off* portion of the duty cycle was relatively insensitive to changes in the refrigerant charge level. The *off* cycle data are reported in Table 5.

During each *on* cycle, notice that the slope of the evaporator refrigerant outlet temperature (T_{ero}) exhibits a clear change. We associated this feature of the outlet temperature with the initial pulldown and termed it the Time to Temperature Turning (TTT). We calculated mean TTT for all runs in all experiments, and evaluated the effect of different factors on TTT. The results are presented in Table 6.

We noticed that T_{ero} behaved in a predictable way in response to the transient imposed by the cycling clutch. At the beginning of each *on* cycle, T_{ero} starts to drop. This effect is due to the saturation pressure drop associated with the reduced refrigerant density in the low pressure side piping caused by the pumping action of the compressor. At some point after the compressor comes on, the slope of T_{ero} levels off, or turns completely. This indicates that the refrigerant exiting the evaporator is superheated. We believe that this behavior is associated with the redistribution of

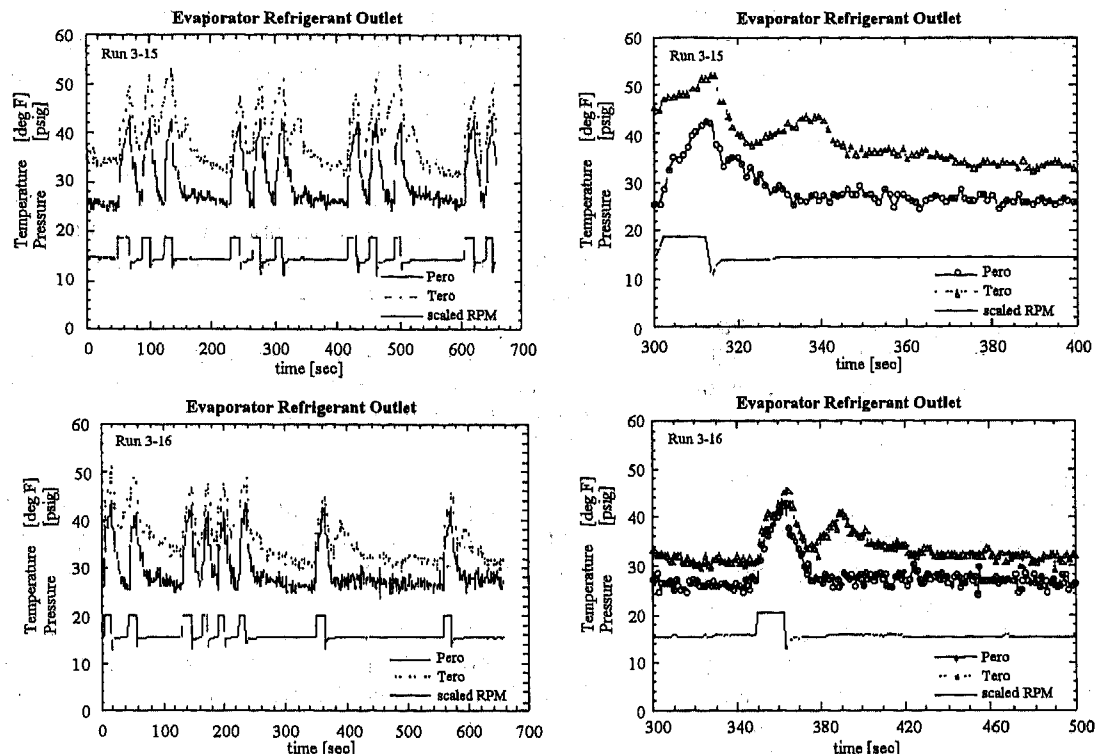
Figure 1. Evaporator Outlet Refrigerant Transient Temperature and Pressure

refrigerant which takes place each time the compressor is engaged and disengaged from the refrigerant system. We observed that this behavior, which we termed Time to Temperature Turning, is strongly correlated to refrigerant charge. Figure 1 illustrates this concept. The right hand and left hand plots of Figure 1 differ only in the amount of refrigerant charge present in the system. The right hand plot presents data collected at normal charge. (Note that the scaled RPM signal falls when the compressor clutch is engaged.)

Table 6 shows that TTT is strongly influenced by refrigerant charge, and that the difference is statistically significant at the .01 level, if we use the low charge level as a reference. That is, the mean TTT at high charge is different from the mean TTT at low charge by more than 3 standard deviations of the mean TTT at low charge.

DISCUSSION

Refer to Table 4, and notice again that the largest main effect is due to factor 4, *mref*. To be rigorously statistically significant at, for example, the .05 level, a main effect or interaction should differ from the mean response by greater than twice the sample standard deviations of the mean response. Main effect 4 is approximately 1.2 times the sample standard deviation of the mean response. From a qualitative standpoint, however, the level of refrigerant charge clearly affects system response. The analysis of factorial designs makes assumptions about the smoothness and linearity of the response function. These assumptions are not likely to be applicable to the clutch cycling period. The arithmetical statistical analysis must be supplemented with prior physical knowledge and engineering reasoning. Table 4 clearly illustrates the strong effect that refrigerant charge has on clutch cycling period and the variance of the clutch cycling period. The data imply that the clutch cycling period of this air conditioning system is a reliable indicator of the relative amount of refrigerant charge in the system.



Now consider the main effect of factors 2 and 3, *Tcai* and *Teai*. Both factors exhibit noticeable main effects, and together exhibit the largest two-factor interaction. When a significant interaction exists, no positive statement can be made about the significance of the corresponding main effects. The subject factors must be considered jointly. The physical interpretation of the **23** interaction is that the higher inlet temperatures raise the steady state condensing and evaporating pressure of the refrigerant. In addition, *Tcai* has a strong effect on the subcooling of the liquid refrigerant. As *Tcai* increases, condensing pressure and temperature increase. As condensing pressure increases, the latent heat of vaporization of R134a decreases, causing the subcooling of the refrigerant to increase for a given amount of heat rejected at the condenser. Raising either condenser or evaporator air temperature independently causes the evaporating pressure to rise; raising both temperatures causes the evaporating pressure to rise dramatically. As the evaporating pressure rises, it takes longer for the evaporator outlet pressure to "pull down" to the low pressure clutch cycling setpoint.

Table 6. Time to Temperature Turning (TTT) at Evaporator Outlet

	Mean [sec]	Std Dev [sec]
Grand avg	7.8	1.9
Charge(+)	9.2	1.9
Charge(-)	6.5	0.8
Tcai(+)	7.5	1.8
Tcai(-)	7.9	2.0
Teai(+)	7.6	1.6
Teai(-)	7.9	2.1

Refer now to Figure 1. Compare the behavior of evaporator temperature and pressure, between runs 2-4 and 2-12, during each *on* cycle. In both cases, the

Figure 2. Time history of evaporator outlet refrigerant temperature and pressure.

refrigerant temperature and pressure initially drop rapidly as the compressor evacuates the low pressure side of the refrigerant loop. In the case of run 2-4, there is insufficient refrigerant inventory in the high pressure side of the loop to reflood the evaporator and stabilize the outlet pressure. The outlet pressure drops rapidly to the low pressure setpoint and the compressor clutch trips. In run 2-12, there is sufficient refrigerant inventory in the high pressure side, at the end of the *off* cycle, to reflood the evaporator. The compressor repressurizes the condenser, and the mass flow rate of refrigerant through the orifice tube increases. After the initial evacuation, the evaporator refloods and reduces the rate of change of the decrease in evaporator outlet pressure.

During each *on* cycle, the slope of the evaporator outlet temperature signal exhibits a clear change. We explain this behavior by considering the relationship between the measured refrigerant temperature and the saturation temperature of the refrigerant. TTT is very closely related to the point at which the refrigerant state at the evaporator outlet changes from a high-quality, two-phase mixture to a single-phase, slightly superheated vapor. This is a manifestation of the refrigerant inventory available to reflood the evaporator at the end of the *off* cycle. At lower charges, the evaporator does not reflood as quickly as at higher charges, and the dry out point migrates upstream in the evaporator.

We have now described two complementary methods of measuring features of the clutch cycling transient that we can use to make diagnostic inferences about the state of refrigerant charge in the system: clutch cycling period and TTT.

Earlier, we observed that the combined effect of air side inlet temperatures was significant. The data of runs 15 and 16, in which both air inlet temperatures and the charge were set to their high level, clearly demonstrate this interaction. Refer again to Table 3 and notice that the clutch cycling period is almost twice as long in these runs as for any other run. The period, however, was highly irregular, as we illustrate in Figure 2 (see Run 3-15 and Run 3-16).

The performance of the evaporator in runs 15 and 16 exhibits characteristics of both the low charge and high charge performance of other air inlet temperature combinations. There are isolated groups of fairly regular cycling of 20-30 seconds duration. There are also long periods during which the evaporator refrigerant outlet pressure remains steady at just above the low pressure setpoint of 25 psig. At higher T_{cai}, the enthalpy of the refrigerant in the liquid line is higher than it is at lower T_{cai}. We infer that the enthalpy of the two-phase refrigerant at the inlet to the evaporator will be higher, and the evaporating pressure will be higher. At higher T_{eai}, it takes longer for the evaporator to "pull down" to a low temperature and pressure. At higher charges, the evaporator becomes an entirely two-phase device. The greater refrigerant inventory in the evaporator, coupled with higher condensing and evaporating pressures driven by higher air inlet temperatures, causes the evaporator outlet pressure to remain above the low pressure cycling setpoint. The clutch is probably tripped intermittently due to random fluctuations in the evaporator outlet pressure when the

pressure is close to the setpoint. These fluctuations are associated with the random fluctuation in the location of the dryout point in the evaporator. This fluctuation of the dryout point has been observed before, and was reported by Gruhle and Isermann [6] and others.

CONCLUSION

For the range of factors studied, we found that refrigerant charge exerted the strongest influence on the total clutch cycling period. Further, we found that the *on* portion of the compressor duty cycle and the Time to Temperature Turning (TTT) were highly sensitive to the amount of refrigerant charge in the system, and to the combined effect of heat exchanger air inlet temperatures. We found that the *off* portion of the compressor duty cycle was less affected by the amount of charge. We suggest that the clutch cycling period (or, alternatively, the *on* cycle time) and TTT together constitute a basis for the detection of refrigerant charge loss in mobile air conditioning systems. We found that the evaporator air inlet temperature and the condenser air inlet temperature exert a strong combined effect on the total clutch cycling period, and we suggest that these temperatures would have to be sensed, as well.

We found that, over the range of factors studied, compressor speed and condenser air flow rate had virtually no effect on the measured responses. We plan to verify this remark by performing experiments from which unconfounded second order interactions can be computed, and which include the effect of variations in evaporator air inlet relative humidity.

FUTURE WORK - This research opens a number of questions. The data imply that refrigerant charge loss can be separated and identified uniquely from among a number of factors which affect refrigerant system performance. This conclusion needs to be further bolstered by experiments conducted over both a wider range of operating conditions, and within a more detailed testing scheme, for example a complete factorial design.

The TTT data were generated by hand. An automated method to generate this data is necessary. One such method might employ a microprocessor which stores a number of temperature readings and calculates the slope, and rate of change of the slope, of the temperature signal on a running basis.

Fuzzy Controller for Thermal Comfort in a Car Cabin

Béatrice Gach and Michael Lang
Valeo Systèmes Thermiques

Copyright 1997 Society of Automotive Engineers, Inc.

Abstract

This paper presents two fuzzy logic based systems, developed by Valeo Thermal Systems and PSA Peugeot-Citroën, for controlling the thermal environment in a car cabin. This study aimed to simplify the control systems set up, while improving the cabin passengers comfort by taking into account the subjectivity of thermal sensation.

The first system regulates the internal cabin temperature from a temperature fixed by the user on the climate control panel. The second system proposes a new "intelligent" control panel in order to ensure a better thermal balance for the car passengers.

The two systems were installed and tuned on a Peugeot 605 vehicle, on which a standard automatic controller is already available. So, it was possible to compare the fuzzy and the classical series controllers on the same vehicle. The results show good regulation performances and demonstrate that the use of fuzzy logic reduces the development time.

1. Introduction

1.1. Context of the study

Introduced by L.A. Zadeh in 1965 [1], Fuzzy Logic has since been used successfully in many industrial applications. Its practical interest for system control is now demonstrated, especially when no model of the system to control is available.

The automotive industry, where embedded control systems are becoming commonplace, has been taking an interest in fuzzy logic for many years [3], [5], [6], [7]. A lot of automobile patents describe systems based on fuzzy logic and several standard cars are sold with fuzzy logic systems [5].

The goal of this study is to evaluate the use of fuzzy logic for controlling an automatic HVAC system. In fact, some characteristics of such a system appear to favor the use of this technology : non-linear behavior, lack of global model, subjective aspect of human thermal feeling [9].

1.2. Automatic HVAC systems

1.2.1. Principle of a car HVAC system

Every car is equipped with a heating and ventilating system in order to ensure comfortable climate conditions when the weather is cold. Today, these comfort conditions can be extended to warm seasons thanks to the addition of an AC loop. Figure 1 below shows the complete standard system.

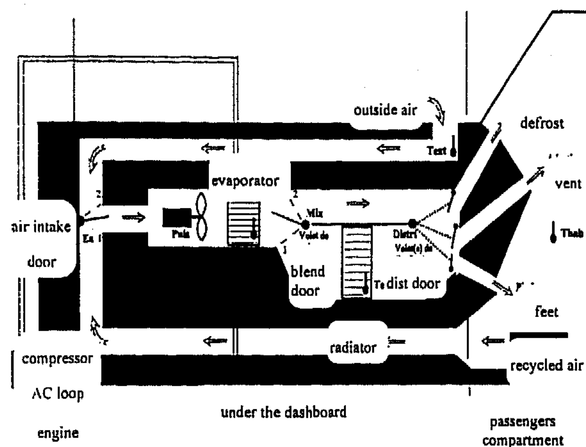

Figure 1 : Heating and air conditioning system

The inlet air (from inside or outside the car) is blown into the system by means of a blower and goes through the AC loop evaporator. A part of this air then crosses the radiator in which circulates the coolant from the motor cooling system. The other part is not heated up. The sharing of these two air masses, that are mixed downstream of the radiator, determines the final outlet air temperature.

1.2.2. Thermal comfort in a car cabin

The thermal comfort can be defined as the preservation of the body thermal balance, whatever the changes of the climatic environment. The thermal comfort conditions for buildings are well known today [2], [8]. But the results cannot be directly transposed to the car cabins that are subjected to specific constraints : forced convection and air speed, due to the closeness of air vents, great radiation influence due to the size and closeness of the windows, permanent contact with the seats, immobility, etc. Therefore, it is often difficult to tune the system to quickly obtain satisfying comfort conditions.

1.2.3. Automatic climate control in a car cabin

To more easily reach an optimal thermal comfort, an increasing number of vehicles is equipped with an electronic temperature and air flow control system. This system consists of a set of sensors and actuators , an electronic board where the controller is implemented and a control panel allowing the users to set their own desired climatic conditions.

1.3. Description of the experimental car

1.3.1. Standard series equipment

The HVAC hardware on which the fuzzy controllers were implemented is standard :

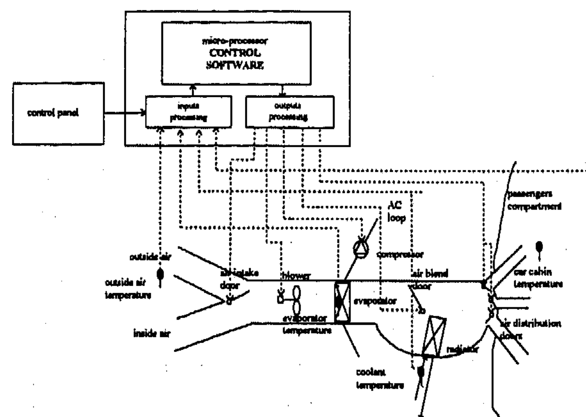

Figure 2 : Standard temperature control system

It consists of four temperature sensors, ie outside, coolant and evaporator temperature sensors to get information about the thermal state of the process and its environment, and a car cabin air temperature sensor, which is the variable to be controlled.

It also includes five actuators : **1** the blend door, to determine the temperature of the air blown in the cabin, **2** the blower voltage, that defines the airflow rate, **3** the distribution servomotor that fixes the way the air is blown in the cabin (towards the feet, the face or the windshield), **4** the air intake door, to determine the origin of the air entering the system and **4** the compressor clutch to turn the AC loop on or off.

1.3.2. New realizations

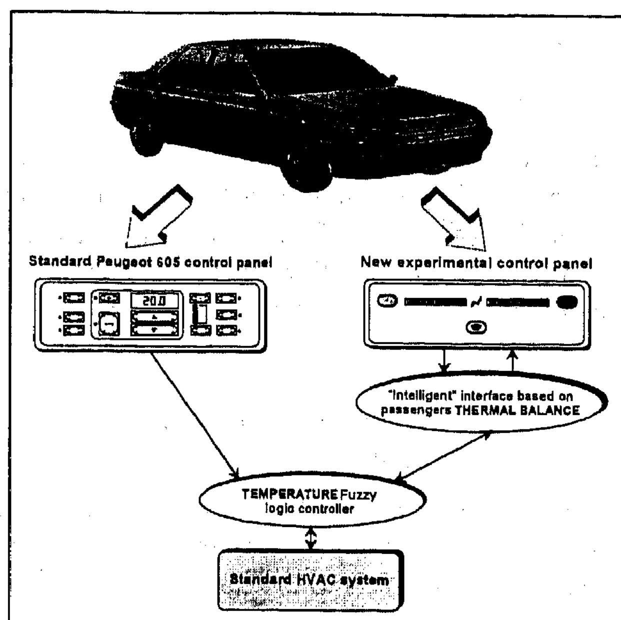

Figure 3 : systems realized

In figure 3, the system on the left consists of replacing the standard HVAC controller by a fuzzy logic one. The control panel and the HVAC system are the standard ones for the Peugeot 605.

This fuzzy controller is used by the system on the right, based on a thermal balance. New sensors are added (the same as for the previous system, plus hygrometry and car speed) and a new user interface is implemented in order to improve taking into account the subjective aspect of thermal feeling : the user doesn't indicate an absolute temperature but asks the system for cooler or warmer interior conditions.

1.3.3. Development system

The fuzzy control software is written in C. In order to test this software and to tune the controller, a specific hardware was utilized.

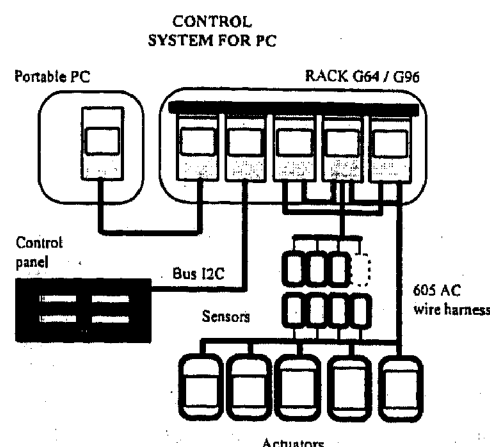

Figure 4 : on-board development system

This hardware (Figure 4) consists of a PC on board the vehicle and of a rack of Europe boards based on the G64/G96 bus, containing the interfaces. This system replaces the series control board and is connected to the vehicle wire harness.

For the thermal balance control application, the new control panel is connected to the rack with a I2C interface, that allows it to be physically separate from the control system.

The advantage of this solution is to be modular, which readily allows the addition of new sensors or actuators.

2. Fuzzy temperature regulation

2.1. Approach

Four steps were followed : 1 collection and structuration of Valeo expertise in the field of automotive climate control, **2** linguistic formulation of the desired behavior of the controller, **3** fuzzification of the system parameters, and **4** writing of the rules basis.

2.2. Fuzzy controller description

2.2.1. General structure

The fuzzy controller manages the blend, distribution and air intake doors, and the blower voltage. The compressor, which can

only be ON or OFF, is commanded by a classical binary logic.

2.2.2. *Fuzzification and defuzzification*

The input variables are fuzzified with piecewise linear membership functions. The output variables are crisp.

For each rules basis, the defuzzification method chosen is the mean of the activated outputs, weighted by their degree of activation.

Using this fuzzy process, we were able to reduce significantly the size of the final code compared to the standard control, which is a great advantage for our application.

2.2.3. *Example : blend door control*

The inputs are *epsit=tset-tint* (difference between the user's chosen set temperature and the actual car cabin air temperature) and the change of the car cabin air temperature *dtint=tint(t-1)-tint(t)*. The output is the change of the blend door position : *dv*.

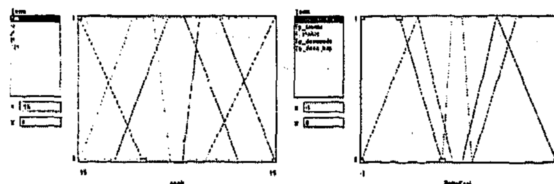

Figure 5 : Blend door control inputs fuzzification

dv	TTN	TN	N	Z	P	TP	TTP
value	-3.5	-2	-1	0	1	2	3.5

dtint \ *epsit*	TN	N	Z	P	TP
great_tp_increase	TTN	TTN	TN	Z	P
tp_increase	TTN	TN	Z	Z	TP
stable_tp	TTN	N	Z	P	TTP
tp_decrease	TN	Z	TP	TP	TTP
great_tp_decrease	N	Z	TTP	TTP	TTP

2.3. Results on the vehicle

2.3.1. *Controller tuning*

The controller was tuned from road and wind tunnel tests. This tuning lasted 4 months and took about ten days of wind tunnel tests, which is a significant reduction of time development compared with the classical controllers.

2.3.2. *Comparison with the classical series controller*

The tests were conducted in a wind tunnel in order to be able to submit the two systems (fuzzy and classical) to the same conditions.

The comparison presented here concerns the cold climates. Indeed, the heating mode is the most difficult to manage because the heat production is over-sized compared with the needs and is subject to several disturbances.

The series and fuzzy controllers were compared in two cases :

- engine ignition from a vehicle preconditioned state : the vehicle structure and the coolant liquid are at ambient temperature
- set temperature steps

The two following figures (6 and 7) show the evolution of the temperature near the driver's head and the set temperature, obtained first with the fuzzy and then with the series controller.

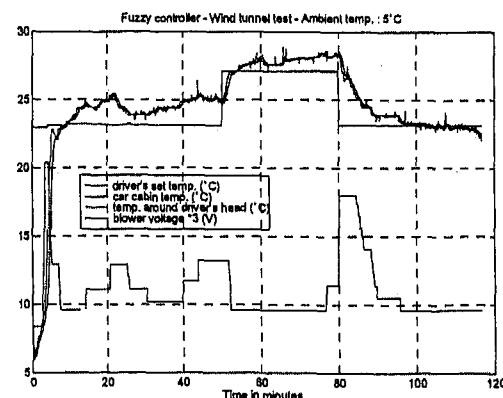

Figure 6 : fuzzy controller-wind tunnel at 5°C

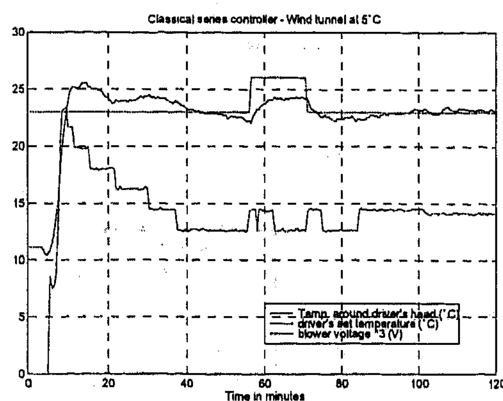

Figure 7 : classical series controller-wind tunnel at 5°C

Comparative tables :

- engine ignition from preconditioned state :

	Time for a 10°C increase near driver's head	Over shoot	Time before steady state	Max blower voltage	set temp. - cabin temp.	set temp.- driver's head temp.
Series	5 mn	1°C / 5 mn	12 mn	7.5 V	0 to 4 °C (not stab.)	1 to 2°C
Fuzzy	6 mn	3°C / 10 mn	20 mn	6.5 V	0.5 to 1°C	0°C

The fuzzy controller performances are equivalent to the classical ones, since the rise times are related to the blower voltage : the higher the blower voltage, the shorter the rise time.

- set temperature increase :

	Rise time	Overshoot	Time before steady state
Series	4 mn	no	4 mn
Fuzzy	1 mn	no	1 mn

- set temperature decrease :

	Fall time	Undershoot	Time before steady state
Series	6 mn	no	6 mn
Fuzzy	5 mn	no	5 mn

In the case of a set temperature change, the fuzzy controller has better performances.

These tables show better performances with the fuzzy controller.

2.4. Conclusion

The linguistic formulation gives the advantage to the fuzzy controller that allows :

- better understanding of the physical phenomenas involved, leading to a better controller maintainability,
- easier tuning, leading to a significant development time reduction,

for performances that are at least equivalent as those of the series controller.

The current studies concern the implementation of the fuzzy controller on the 605 series control board and its use on a Citroën ZX.

3. Thermal balance regulation

3.1. Principles of thermal balance

One characterization of thermal comfort is that the heat produced by the body is absorbed by the surroundings at the same rate, so that we do not accumulate heat or feel cold. The International Standard Organization defines PMV (Predictive Mean Vote) in ISO-7730 as an index of comfort. This approach based on the computation of a thermal balance is only validated for housing.

The thermal balance (noted L in Figure 8) is a mathematical function of six input variables (for more details see [8]) :

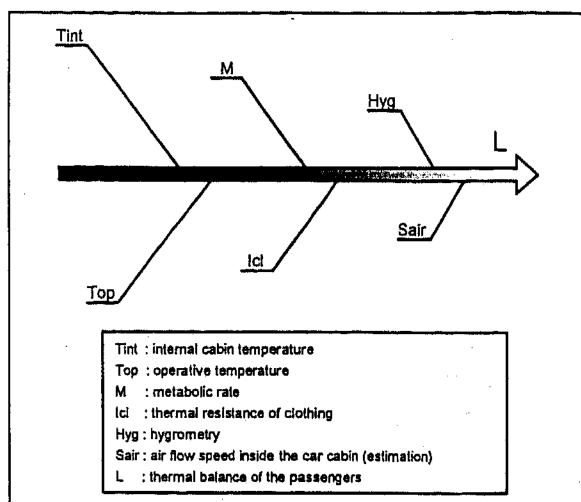

Figure 8 : parameters of thermal balance

The goal of this study is to compute this function value in the car and to control the air-conditioning so as to achieve maximum comfort level (L must be around zero). So it is possible to test this approach in an automotive context.

3.2. Architecture of global system

The principle is to use the temperature regulator presented in the second paragraph of this paper. This regulator is combined with a supervisor program which regularly calculates the value of the thermal balance.

This value is used to compute the best temperature for the thermal comfort in the car cabin. This temperature is the one which corresponds to a thermal balance around zero. This value is the new signal transmitted to the temperature regulator (Figure 10).

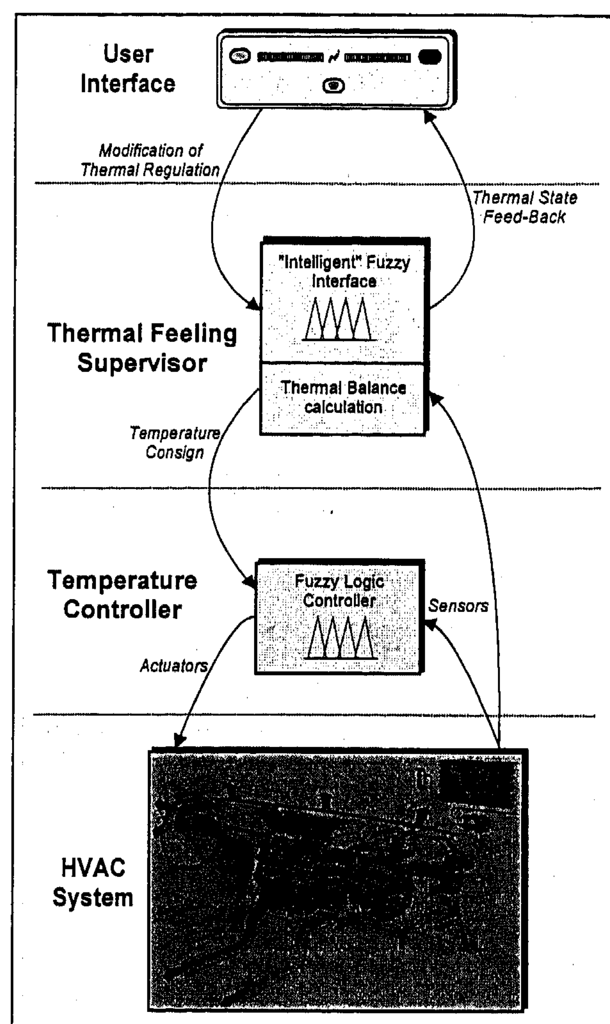

Figure 9 : architecture of global system

3.3. Working of the new control panel

The new control panel allows the user to ask for more heat or more cold. He indicates the intensity of his demand by lighting more or less L.E.D's. on the control panel (see Figure 10).

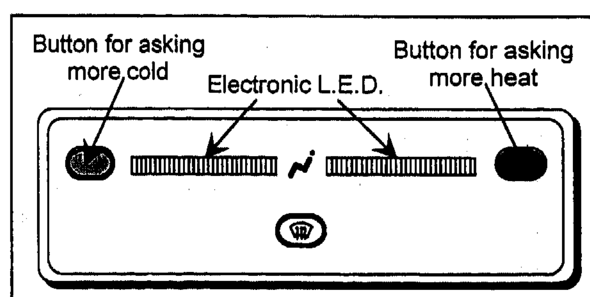

Figure 10 : new control panel

The idea is to use the action on the control panel to modify the value of the Icl parameter

(thermal resistance of clothing) in the calculation of the thermal balance. This parameter is initialized at a standard value when the system starts and is modified after each user action.

To calculate this modification (noted dIcl), we have used a fuzzy logic system with three inputs. The first one is the current value of the Icl parameter. The second one corresponds to the value of the thermal balance. The third parameter is the level of comfort wanted by the user which is quantified by the number of L.E.D's. he lit on the control panel.

For example, this figure shows the result of the calculation of dIcl depending on the desired comfort and the thermal balance :

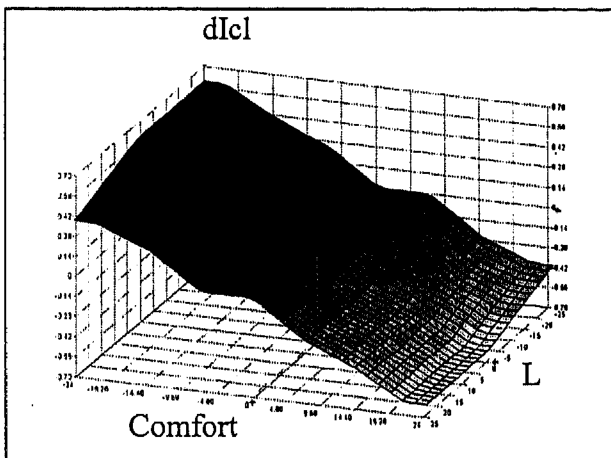

Figure 11 : control surface of dIcl

3.4. Experimental results

The complete system has been tested on ıoad by several different users. It is easy to understand though it is quite different from standard climate control panel.

To illustrate the principle of working of the new system, the graphics of the figure 12 shows the evolution of the parameters Icl and L during a test on road.

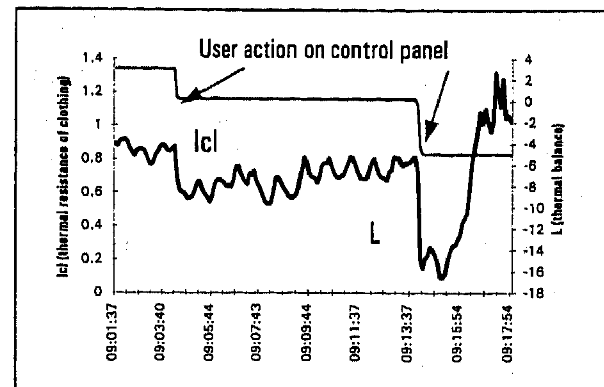

Figure 12 : evolution of Icl and L parameters

As shown in Figure 12, the user asks two times for more hot. At each time, the fuzzy interface of the control panel modifies the value of the Icl parameter. That's why the thermal balance calculated by the thermal feeling supervisor goes away from zero. A new temperature consign is calculated and transmitted to the controller. So the thermal balance returns progressively around zero.

4. Conclusions

This paper presented an actual case of use of fuzzy logic in an automotive context. It shows that for controlling a HVAC system, fuzzy logic allows to rapidly develop a first system with minimal effort. This system is then tested on roads and in a wind tunnel in order to tune it correctly.

A significant advantage of fuzzy logic is the case of tuning without writing any line code (modification or addition of rules). More over, the elaboration of the control strategy is simplified by its formulation with linguistic rules which simplify dialog with experts of the system to control.

5. Future prospects

These studies are continuing with several purposes :

- portage of the fuzzy controller on a Citroën ZX in order to evaluate its degree of portability

- implementation on a series control board;
- an ergonomic study in order to evaluate the performances of the thermal regulation not with technical criteria but with the users' point of view;
- development of a new fuzzy regulator directly based on thermal balance;

A Real-Time Computer System for the Control of Refrigerant Flow

Andy Bartlett, David Standaert, and Eric Ratts
University of Michigan-Dearborn

Copyright 1997 Society of Automotive Engineers, Inc.

Abstract

This paper presents a real-time computer system for the control of refrigerant flow in an automotive air conditioning system. This is an experimental system used to investigate the potential advantages of electronic flow control over conventional flow control (using an orifice tube or thermal expansion valve). Two features of this system are presented. First, the system organization is described. Second, the control and interface software are presented. The emphasis is on the software.

The system is organized as a closed loop control system. The inputs to the controller are measurements of the refrigerant system. In particular, thermocouples are used to measure the refrigerant temperature before and after the evaporator. The analog thermocouple signals are converted to digital form by an off-the-shelf, portable, data acquisition system (DAQ). Via a parallel port link, these digital measurements are transfered to a laptop computer. The laptop software processes the measurements and determines a desired refrigerant valve opening. Via the parallel port, the desired valve opening is passed back to the DAQ. The DAQ converts the desired setting from a digital value to a low power analog signal. Using this signal as an input, an analog power amplifier drives the valve to the desired opening. The new valve opening increases or decreases flow of refrigerant into the evaporator. This change in flow effects the temperatures measured by the thermocouples. This closes the control loop.

The software includes a real-time digital controller and a user interface. The software was custom designed using Visual Basic and runs under Windows. The DOS/Windows environment is generally problematic for real-time control, but has proven to be suitable for refrigerant flow control. Successful operation under Windows is made possible by resources provided by the DAQ, by careful limitation of Windows activities, and by the relatively slow dynamics of the air conditioner. In addition to the real-time controller, the software simultaneously provides a graphical user interface (GUI). The GUI allows the user to select and change controllers on the fly in real-time. The GUI also provides the user with a "virtual" strip chart. The strip chart aides the user in tuning the controller during operation. This software has been used on the road in a test vehicle and has proven to be very effective in the development of refrigerant flow control methods.

1.0 Introduction

This paper presents a real-time computer system for the control of refrigerant flow in an automotive air conditioning system. This is an experimental system used to investigate the potential advantages of electronic flow control over conventional flow control. Two features of this system are presented. First, the system organization is described. Second, the control and interface software are presented. Before presenting these features, previous work in the area will be reviewed.

2.0 Prior Work

This subsection will describe the traditional methods of controlling refrigerant flow and some electronic control methods that have been tried. The traditional ones will be described first. Advantages, limitations, and current status will be noted as appropriate.

One of the two most common traditional methods of refrigerant control in automobiles is the orifice tube (OT). As shown in Figure 1, the orifice is a fixed size restriction. By focusing just on the evaporator subsystem, it would appear that the orifice tube had no way to regulate the refrigerant flow. By looking at the system as a whole, it can seen that an orifice tube equipped system does make some adjustment of refrigerant flow to meet operating conditions [1]. However, it is generally agreed that the orifice tube system does not adjust flow as well as systems whose expansion orifice size is actively adjusted. The advantage of an orifice tube systems is in lower cost and increased reliability.

The second of the two most common traditional methods of refrigerant control in automobiles is the thermal expansion valve (TXV). A TXV system is shown in Figure 2. The opening of the TXV is actively adjusted based on a balance of forces. One of the forces is due to a sensing bulb placed at the evaporator output. As the outlet gets hotter, the gas in the sensing bulb gets hotter. Since the bulb and the capillary tube are essentially a closed volume system, the pressure in the bulb and tube increases. This pressure creates a force that increases the valve opening thereby increasing the flow. The increased flow reduces the superheat which reduces the bulb pressure. Eventually a balance of pressure and flow is reached. Some TXV systems use more complicated mechanisms to achieve a desirable balance [1]. The advantage of TXV systems is that they actively regulate superheat to a moderately positive value. Their disadvantage is they are less reliable than orifice tubes due to their moving parts and their relatively fragile capillary tubes.

Electronic control retrofits have been designed for some TXV systems [5]. Figure 3 shows an example. In this system, the temperature of the evaporator inlet and outlet are measured by a computer. The difference of these two temperatures gives a good approximation of superheat if the pressure drop across the evaporator is small. Based on these measurement, the computer adds more or less heat to the sensing bulb using a small electric heating pad. The goal of the retrofit is to have the system achieve a smaller superheat than the moderate one TXV systems are usually designed for. A standard TXV uses the relatively high superheat to avoid sending liquid to the compressor. The electronics can use a faster, more sophisticated design than is possible to mechanically fabricate. This is why the retrofit can safely decrease the superheat in both the transient and steady state periods.

The retrofit system is primarily for large stationary

refrigeration systems. One example is a supermarket display case. If an automobile manufacturer is going to use electronic control of refrigerant control, then it does not make sense for them to use a retrofit design. It is natural to expect that a direct design would have cost and performance advantages. In addition, the need to significantly modify the control algorithm is likely because an automotive system has more frequent and dramatic transients.

Two patents for direct electronic control of refrigerant flow were recently awarded [3] and [2]. Figures 4 and 5 show that both systems use an electronically controlled expansion valve. From a system architecture point of view, the main difference appears to be the method of measuring superheat. In Figure 4, the same approach as the retrofit system is used. Evaporator inlet and outlet temperature are measured and used to approximate superheat. In Figure 5, temperature and pressure at the evaporator outlet are measured. Using the properties of the refrigerant, these two measurements can be used to compute superheat. Based on the superheat, the computers will command new settings to the electronic expansion valves (EXV). The algorithm used to determine the valve adjustment will strongly affect the performance of the system.

It is interesting to note an SAE paper [4] related to the subject of the two patents. This paper was presented one year before the two patents were filed. This paper [4] shows what appears to be the same architecture as Figure 5. The paper [4] also shows experimental data obtained from this system.

Electronic control of refrigerant flow in automotive A/C systems is not a new idea as attested by the 1987 paper and the 1989 patents. Furthermore, electronic flow control is a feature available for large stationary A/C systems. Despite these facts, conventional flow control methods, OT or TXV, totally dominate the automotive market. The goal of the work described in this paper was to develop a prototype vehicle to investigate any potential advantages of electronic flow control.

3.0 System Organization

This section briefly describes the organization of a prototype system. This description covers the major hardware components, the instrumentation, and the electronic/computer hardware as shown in Figure 6. The computer software is not covered until the following section.

The prototype vehicle was a 1994 Lincoln Mark VIII. The prototype used production components for the condenser, evaporator, compressor, OT, accumulator, and electronic automatic temperature controller (EATC). Note that the EATC regulates cabin air temperature by controlling the compressor clutch and the air handling system, but it does not meter the flow of refrigerant.

The test vehicle was modified so that the air conditioning system could operate in conventional or electronic flow control mode. The hand operated Y-valve shown in Figure 6 allows either the OT or the EXV to meter the flow of refrigerant. Aside from some small changes in plumbing, selection of the OT system essentially gives the production Ford system.

The other setting of the Y-valve causes the refrigerant to be controlled by an EXV. Adequate electronic sensors were available so that Figure 4 or 5 could be implemented. Temperature was sensed by sheathed T-type thermocouples that were instrumented into the refrigerant flow stream. A specialized thermocouple card, IOTech DBK19, provided the interface to the small signal levels of these sensors. The pressure sensors came with built in electronics and could be interfaced directly to any general purpose Analog to Digital (A/D) converter. The A/D converter used in this project is part of a portable data acquisition board, IOTech DAQBook 100. This data acquisition board (DAQ) interfaces to any DOS/Windows compatible computer via a standard parallel port. Laptops were especially convenient for this purpose. Via the port, the sensor measurements are eventually made available to the computer. Based on these measurements, the computer uses some chosen algorithm to calculate a desired valve opening. This is desired opening is passed to the DAQ again via the parallel port. The DAQ system has a Digital to Analog (D/A) converter which it uses to put the desired opening in analog form. This analog signal is low power and can't drive the EXV. For this reason, the low power signal is passed through an analog power amplifier. The output of the power amplifier drives the valve. This completes the equipment required for the electronic flow control prototype.

In addition to electronic flow control, electronic monitoring of the entire system was also desired. For this reason numerous thermocouples and pressure sensors were directly connected to the refrigerant system. Additional thermocouples and humidity sensors were also used to measure the ambient and cabin conditions. These measurements could have been incorporated in the DAQ plus Laptop used for flow control. However, the extra measurements would have severely restricted the control capabilities given the many speed limitations of the DAQ plus laptop system. For this reason, a second laptop plus DAQ was used. One laptop plus DAQ was dedicated to control; the other was dedicated to data recording.

4.0 Real-time Software

The two laptop plus DAQ systems run two different sets of software. The data monitoring system uses a Windows based program that was supplied with the DAQ hardware. This software had adequate data collection capabilities, but it did not have real time control capabilities. Custom software was developed for the laptop plus DAQ system that performed the real time control. The overall feedback system is shown in Figure 7 where the real time software represents the shadowed blocks. The system can also run in a "test mode" as shown in Figure 8. The real time control software will be described in this section.

4.1 Oversampling and Conditioning

The real time software was written to use the scheme shown in Figure 4. This means that two thermocouple measurements are processed by the control system. Initially, two types of processing are required. First, the nonlinearities inherent in the thermocouples and the scaling due to the amplifiers must be accounted for. This shall be referred to as conditioning. Second, the noise in the measurements must be dealt with. Subroutines for conditioning the thermocouple signals were supplied by the DAQ manufacturer, and these were employed. For dealing with the noise, a custom strategy was developed.

The noise arises in many locations including the sensor, the wire harness, the interface electronics, and the A/D converter. The measurement noise could be attenuated in the digital controller or by using oversampling. The prototype system used a combination of both approaches.

A linear digital controller is identical in structure to a digital filter. If the control loop were running at a very high sampling rate, then the digital controller could include many fancy filtering effects. However, on the prototype vehicle, the controller will normally be running at less than a 10 Hertz sampling frequency. This relatively slow rate puts some constraints on high frequency filtering. Signal aliasing may also be a problem at this slow rate. Unfortunately, running at a faster rate is likely to overburden the computation and communication abilities of the laptop plus DAQ system. At a faster rate, the software may not meet the real time requirements.

To achieve the desired high frequency filtering, oversampling was used. Like most of today's A/D boards, the DAQ used in the prototype contains just a single A/D converter. Via high speed multiplex switching, many different signals can be linked one at a time to this converter. An allowable alternative is to link the same signal or sequence of signals to the converter several times in a row. This arrangement allows oversampling.

For the DAQ, a "new" signal can be linked to the A/D converter every 10 microseconds (100 kHz). If the control loop is executing every 100 milliseconds (10 Hz), then theoretically, the A/D could measure 10,000 signals in each cycle of the control loop. Due to communication and memory limits, the actual number of measurements must be smaller. At compile time, the custom software is set up to oversample each signal a certain number of times. Ten times oversampling was found to be effective at greatly reducing the high frequency noise. Measuring

each of the two thermocouples 10 times requires a total of 20 measurements by the A/D during each control loop cycle. Each set of ten samples is simply averaged to produce a filtered measurement that is used by the control loop every 100 milliseconds.

The oversampling does place a burden on the real time software. If just one sample per cycle were taken, then the control loop could be sped up a little bit. However, the speed penalty of moderate oversampling is relatively small and the noise reduction benefits are significant. Oversampling was found to be an efficient use of the prototype resources.

4.2 Superheat Calculation

The superheat calculation carried out by the software was extremely simple. It was assumed that two phase refrigerant was entering the evaporator and that there was no pressure drop across the evaporator. Under these assumptions, any superheat at the outlet would be equal to the temperature rise across the evaporator. This calculation of superheat simply involved subtracting the inlet temperature measurement TCinlet from the outlet temperature measurement TCoutlet.

Experimentation showed that there actually was a pressure drop across the evaporator of approximately 14 kPa. This pressure drop results in an error in the superheat calculation. The exact amount of error would depend on both the pressure drop and on the absolute pressure at the evaporator inlet. The evaporator inlet pressure had a fair amount of variation, but the pressure drop was always quite close to 14kPa. For the normal range of inlet pressures, the effect of a 14kPa pressure drop on R134a superheat was investigated. It was found that over the entire range the 14kPa pressure drop corresponded to a 2 K increase in the superheat. Therefore the calculation of superheat, TCoutlet - TCinlet, could be improved by adding 2 degrees Kelvin to it. From a control point of view, it would be equivalent to lowering the desired superheat by 2 K. This latter approach was used.

4.3 Desired Superheat

The desired superheat is the target value that the feedback control loop will try to achieve. When the computed superheat is higher than the desired value, the controller must eventually permit more refrigerant to flow. Conversely, the flow is decreased when the computed superheat is below the desired value. The desired superheat is simply a fixed value. Using the graphical user interface (GUI), the desired value can be readily changed during operation. When setting the desired value, the user should keep in mind that the computed superheat is approximately 2 K too low. So if the user wants a true superheat of plus one degree Kelvin, then the desired superheat should be set to minus one degree Kelvin. The lower left corner of Figures 9 and 10 shows the location in the GUI where the superheat goal is entered.

4.4 Digital Controller

The digital controller processes the superheat error to come up with a desired voltage for the EXV. The digital controller is linear for the most part so it is equivalent in structure to a digital filter. The controller does include a simple nonlinearity for anti-windup purposes. The anti-windup could restrict the controller output to the 0 to 5 volt range of the D/A. A smaller range corresponding to the response limits of the EXV were used in the prototype.

The linear portion of the controller can be described by a Z-domain transfer function (ZTF). Direct selection of a ZTF by the user faces some difficulties. If a good linear time invariant model of the plant is available, then there are many nice canned programs for automatically selecting a digital controller's ZTF. However, a good model, especially a linear one, of the refrigerant system was not available. Therefore, it was expected that the user would use heuristic rules to select and tune control features. For a control engineer, selecting features often involves selecting pole and zero locations. Many control engineers have an excellent feel for the effects of poles and zeros in the S-plane of continuous time system. Control engineers typically have a far poorer understanding of pole and zero locations in the Z-plane for discrete-time systems. One reason is that pole and zero locations in the Z-plane depend on the chosen sampling rate of the digital controller. For these reasons, the ZTF of the controller was indirectly specified.

The GUI allows the user to select a continuous time S-domain transfer function (STF). Figures 9 and 10 show the screen by which the user selects poles and zeros in the S-plane. The user may select up to three real poles, three real zeros, two pair of complex conjugate poles, and two pairs of complex conjugate zeros. The default steady state, i.e. DC gain, of the system is plus one. The user may override this choice by selecting an overall, a Proportional , an Integral, or a Derivative gain. Depending on which of the PID gains are selected, the STF can have an additional pole at the origin and/or up to two additional zeros. At any time, the user can change in real-time the number and location of poles, zeros, and gains by pressing the update button.

The prototype system is based on a digital computer so the STF selected by the user must be converted to a ZTF. The first issue in this conversion is the selection of a sampling rate. Near the top center of Figures 9 and 10 is where the user can select the desired sampling frequency. The selected frequency must not be so fast as to over burden the system. For refrigerant control with a full set of graphical displays, the system was able to readily handle rates less than 10 Hz.

After the selection of sampling rate, the method of mapping from the Z-plane to the S-plane must be selected. The bilinear transformation alias Tustin's approximation was employed in the software and was found to be effective. Given a STF H(s) and sampling rate h, the corresponding ZTF G(z) is given by simple substitution of s.

$$G(z) = H\left(\frac{2}{h}\ \frac{z-1}{z+1}\right)$$

By selecting the appropriate check box in Figures 11 and 12, the GUI allows the user to view either the ZTF or the STF.

Once the ZTF has been formed, implementing the digital controller is straight forward. Conversion of the ZTF to a difference equation is trivial. Because of the GUI allows the user a limited quantity of poles and zeros, the controller can be ninth order at worst. This means that implementation of the difference equation involves 19 multiplications and 18 additions at worst. The implementation must also store nine or fewer recent inputs and nine or fewer recent outputs. These computations were a light burden for a 486DX 25MHz laptop computer.

Before closing this subsection, some comments on the software will be made. Visual Basic is not particularly computationally oriented, but it did not hinder the implementation of the small digital controller. The formation of the STF from the selected poles, zeros, and gains had the potential to be some what cumbersome. In addition, the bilinear transformation appears to be a moderately involved symbolic processing problem. There were three keys to making the software manageable. First, a data structure was created that could handle any polynomial up to some specified maximum order. Second and third, subroutines for adding and multiplying any pair of polynomials were written. Note that the STF and ZTF are just the just the ratios of polynomials. Adding a new pole or zero to the denominator or numerator of the STF, respectively, simply involves polynomial multiplication. The bilinear transformation only involves multiplying and adding polynomials of the form q, 2z+2, and hz-h as seen in the example below.

$$H(s) = \frac{2\ s + 3}{4\ s^2 + 5\ s + 7}$$

$$G(z) = \frac{2\left(\frac{2z-2}{hz+h}\right) + 3}{4\left(\frac{2z-2}{hz+h}\right)^2 + 5\left(\frac{2z-2}{hz+h}\right) + 7} =$$

$$\frac{2\ (2z-2)\ (hz+h) + 3\ (hz+h)\ (hz+h)}{4\ (2z-2)\ (2z-2) + 5\ (2z-2)\ (hz+h) + 7\ (hz+h)\ (hz+h)}$$

The zeroth order polynomials q are the coefficients of STF. The bilinear transformation has a regular pattern and can be fully implemented with a set of nested For loops.

4.5 Graphical User Interface

The graphical user interface has two important screens. The change control GUI is illustrated in Figures 9 and 10. The use and operation of this screen was described in the previous subsection. The main GUI is illustrated in Figures 11 and 12. The key features of the main GUI will be described in this section.

The main GUI is divided into four main areas. The bottom portion of the GUI contains several check boxes, buttons, etc. that control the operation of the system and the GUI. This controls will be referenced as the other three sections are described.

The top portion of the GUI shows in tabular form the ten most recent values of the key signals. When the "Test Mode" check box is selected as in Figure 11, only the input and output of the digital controller. When the "Super Heat" mode is checked as in Figure 12, only the thermocouple and superheat values are also displayed. To reduce visual flicker and to minimize computational burden, the newest data is added to the table in a circular buffer fashion. The star at the top of the table marks the newest data, and data immediately to the right is the oldest data. By checking the Disable Output Grid box, no more new data will be inserted in the table. The real time system can operate at a higher sample rate when the various displays are individually or collectively disabled.

The upper-middle portion of the GUI shows the transfer function of the controller. By checking Continuous Time or Discrete Time, the STF or ZTF, respectively, will be displayed. For example, Figure 12 shows the following STF.

$$H(s) = \frac{-1\ s - 1}{33.3\ s^2 + 1\ s + 0}$$

The upper left corner of this region also gives the sampling rate.

The lower-middle portion of the GUI provides a virtual strip chart. By checking the appropriate boxes any or all of the signals associated with a given mode can be plotted. Figure 11 shows a plot of the Test Mode inputs and outputs. The input is a square wave from an external function generator and the output corresponds to the under damped second order system selected for the controller. Figure 12 shows all five of the signals from Super Heat Mode. The graph is not batch updated; it is a true stripchart and slowly scrolls from left to right. The signal plots, the axes, and the enable check boxes are all color coordinated to allow easy identification. To aid the user, the signals were heavily filtered before plotting so as to remove noise and jitter. This explains why the square wave in Figure 11 shows very slow transitions.

5.0 Performance

The real time system described in this paper was evaluated in Test Mode and in actual operation on the prototype vehicle. The detailed results of the refrigeration control are beyond the scope of the paper. The comments here will be restricted to the systems ability to meet the constraints of real time operation. In super heat mode, the system was fully operational at 10 Hz. This rate along with full use of the displays and of controller updates was satisfactory for the refrigeration control experiments.

In test mode, the system was capable of operating better than ten times faster. The omission of the thermocouple signal conditioning reduced the processing load. In addition, if the GUI displays of data were disabled, then much higher rates could be sustained. Figure 13 shows an oscilloscope trace where the real time system is producing an underdamped second order response at 150 Hz. When a Pentium based desktop machine was substituted for the Laptop 486, sampling rates of 500Hz were obtained.

Because the system was running under the DOS/Windows environment, it was not possible to obtain guaranteed real time performance. In the vast majority of cases, the controller output was properly updated each sample time. However, the system did fall behind in some situations. Falling behind was noticed in higher speed test mode operation and could be captured on an oscilloscope. In Figure 13, the digital system output is a staircase plot and each step has a consistent width very close to 1/(150 Hz). If Windows operating system, attempted a time consuming task such as updating an interactive screen, then the staircase plot could show one very long step followed by several short steps. In this case, samples were taken by the DAQ hardware at the appropriate times but the computer was to busy some Windows task to process the samples. Eventually Windows would return control to the real time system, and this system would try to "crunch through" the backlog as quickly as possible.

6.0 Conclusions

This paper has presented a real time computer system for the control of refrigerant flow in a prototype automobile. The system carries out digital control and provides a GUI that allows the control to be tuned on line. The GUI also provides graphical and tabular displays that assist in the tuning process. Testing on the prototype vehicle has shown that the system has the real time control capabilities required for the refrigeration control project. On road testing has shown that the system can simultaneously provide the graphical user interface and maintain a 10 Hz control loop.

7.0 Acknowledgements

This project was made possible through the support of several organizations. The authors wish to thank the Center of Engineering Education and Practice (CEEP) for three years of generous support. The authors also wish to thank the Ford University Research Program for two years of extremely helpful support. Ford Motor Company's Components Division (formerly Climate Control Division) also supported the project by providing the first and third author with faculty internship for two summers each. Ford's Alpha Division gave crucial support by providing the Mark VIII test vehicle. The University of Michigan-Dearborn Campus Grant Program gave seed support. All of this support was highly appreciated by the authors and by the many student research assistants who gained valuable experience because of it.

This project had many interdependent parts each of which was crucial to the whole. The authors would like to acknowledge the many people who did not contribute directly to the real time software but did play valuable roles in the project. Richard Terry was the key player in the mechanical aspects of the instrumentation. Tim Philippart designed and constructed the power amplifier. Dennis Kubica, Josh Isser, and Joe Jaegger assisted in the electrical aspects of instrumentation. Paul Rogers played a lead role in much of the data collection and analysis. The UMD Electrical and Mechanical Engineering Shop technicians: Jesse Cross, Martin Stenzel, Don Haidys, and Mike Solstad, also aided in the completion of the project. In addition, engineers at Ford Motor Company contributed their experience and expertise in selecting and evaluating the project. Key contributors were Chris Rockwell, Gary Dage, Bob Matteson, George Wiklund, and David Zietlow. This project lasted three long and hectic years, and there are undoubtedly other contributors that have been overlooked. The authors regret that the failings of their memories prevent them from individually acknowledging and thanking each contributor.

Hot-Wire Velocity Measurements of Defroster and Windshield Flow

Bashar S. AbdulNour
Ford Motor Co.

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

Hot-wire anemometry is used to experimentally determine the velocity field in the vicinity of the defroster nozzle jet flow and windshield interior surface. It provides quantitative velocity measurements necessary to determine the heat transfer coefficient on the windshield. Measurements are useful when used as a design tool to predict defroster and windshield flow. A modified traverse device was constructed to carry the hot-wire probes. The results obtained from the modified technique are more accurate and provides a valuable insight into the boundary-layer structure over the windshield.

INTRODUCTION

Measurements of jet flows are of interest in many automotive applications. For example, hot-wire measurements were used to investigate the velocity field due to automotive air registers (AbdulNour et al., 1996). In particular, these measurements can be used for design and development purposes. Also, if numerical codes can successfully compute these 3-D flows, then the verified computations can be used as an analytical design tool. Velocity surveys on the interior windshield surface of a 1995 Lincoln Mark VIII vehicle due to a defroster jet are reported herein. The present study identifies the techniques and results from this investigation. Specifically, it identifies the preparation for the flow visualization and testing results. It also identifies the hot-wire techniques that were used and presents the velocity field results.

The standard technique to perform hot-wire measurements on the windshield entails the use of a plexiglas template to replace the windshield. A straight hot-wire anemometer is inserted into the holes of the template to a specified depth into the interior surface (usually 7mm) to carry out the measurements. The probe is rotated until a maximum signal is detected on the signal processor. The magnitude and direction of the velocity is then determined, with the direction being the normal to the straight hot-wire. A typical result is shown in Fig. 1.

The present experimental technique provides a significant improvement over previous practices, since the data are far more informative than those wherein one fixed z-location (normal to the windshield interior) were to be used. Also, measurements on the glass surface (and not the composite material with upstream holes) are clearly more representative of the prototype flow field. Flow disturbance effects by such holes is of concern, and the theoretical smoothness constraint of covering the holes represents a formidable challenge to the conduct of an unbiased experiment. Mean and rms velocity data were also acquired in systematic traverses above the exit plane of the defroster nozzle. These surveys showed significant non-uniformities. The details come at the expense of development time and material as well as machining costs, but are deemed worthy for the enhanced contribution of the results.

FLOW CONDITIONS

Throughout this investigation, the total volumetric flow rate of air through the defroster nozzle was 101.4 cfm. This flow rate corresponds to a vehicle in defrost/max heat mode. The average uniform velocity U at the exit of the nozzle was calculated to be 5.2 m/s based on the measured effective exit area of 0.0092 m^2. Examining the Reynolds number of the flow based on the hydraulic diameter D_H, we obtain

$$Re_H = \frac{UD_H}{\nu} \approx 1.21 \times 10^4$$

at the nozzle exit. In the above, D_H is defined as four times the vent exit cross-sectional area divided by the wetted perimeter (D_H = 0.037 m), and v is the kinematic viscosity at a temperature of 300 K and atmospheric pressure. This value for the Reynolds number suggests that the flow is indeed turbulent.

FLOW VISUALIZATION

A template, using a nominal 100x100 mm square grid array, was used to define the measurement locations. Flow directions were obtained using wool tufts attached to the inside of the windshield. Velocity surveys of the streamwise mean velocity magnitude $\bar{V}_s = [\bar{u}^2 + \bar{v}^2]^{1/2}$ and rms intensity $\tilde{V}_s = (\overline{V'^2})^{1/2}$ were acquired at the accessible sites; u and v are the x-component and y-component velocity, respectively. The former are characterized by typical wall jet velocity distributions: $V_s = 0$ at z = 0 (plane of windshield), $\bar{V}_s$ = maximum at $z \approx \delta$, and $V_s \rightarrow 0$ as $z/\delta \geq 5$. The $V_s(x,y,z)$ time series data were taken at 7-10 z-locations over the windshield surface. The above nomenclature along with the general shape of the wall jet velocity profile are illustrated in Fig. 2.

The template, previously used as a replacement windshield with holes for probe inserts, was used to mark (via a grease pencil) the measurement locations on the outside of the windshield. Wool yarn was then strung through these marked points and secured to the outside of the windshield using transparent tape. Wool tufts for flow visualization were then attached to the inside of the windshield at the crossing points of the yarn grid. These were made by pulling a few threads of the yarn a short distance from the full body of the yarn tuft. (The latter was of order 15-20 mm in length.) It was ensured that the tufts were supported without bias, *i.e.*, that the bending strength of the few threads was sufficiently small.

Photographs were taken of the tuft orientations in the defroster jet flows by exposing the film for a suitably long period to capture the extent of the tuft oscillations. No attempt was made to average the resulting images. The mean flow direction, $\bar{\theta}(x, y)$, where $\theta = \tan^{-1}(v/u)$ as shown in Fig. 3, was inferred as the midpoint of the extremes of the tuft positions. The very slow response time of the massive tuft (i.e., $\rho_{tuft} \gg \rho_{air}$) made it problematic to use information such as relative light exposure to infer the percentage of time spent in a given portion of the angular range. In most cases, this inference is quite acceptable in the following sense. The hot-wire will essentially rectify the velocity reading as

$$V_{indicated} = V_{actual} \cos(\theta_{actual} - \theta_{probe}) .$$

Hence, even if the excursions of the tuft directions are ±20 degrees, the uncertainty is bounded by $V_{indicated} \leq (\pm 0.94) V_{actual}$ with a most probable excursion nominally equal to 40% of this θ value. Hence, for this estimate, the cosine is 0.99 and the estimated actual velocity is

$$V_{actual} = \frac{V_{indicated}}{0.99} = 1.01\, V_{indicated} .$$

The data from the photographs was transcribed to a graphical representation to show the mean values of the orientations $\bar{\theta}$; refer to Fig. 3. Specifically, x = 0, y = 0 are at the center and lowest point of the measurement grid and with y > 0 representing positions on the driver's side. Hence, a right-hand coordinate system has z > 0 pointed into the passenger compartment.

VELOCITY FIELD MEASUREMENTS

Velocity Survey Capabilities and Probe Alignment - An inability to specify a priori the most effective heights for the hot-wires due to the variable boundary-layer thickness led to a reconsideration of the standard approach. Additionally, the presence of cutout holes upwind of the measurement sites was a concern. If sealed by plugs it would be difficult to ensure a satisfactorily flush condition (≤ 0.25 mm). If sealed by tape, there would be a wide field of distributed roughness elements with dimensions large enough to disturb the flow. Note that any such roughness should be less than 5 *wall units* (Potter and Foss, 1982) to have a negligible effect. It is difficult to estimate v/u_τ for this flow field. However, if one uses $200 \doteq \delta/(v/u_\tau)$ as a minimal ratio between δ and a wall unit, then for $\delta \doteq 0.7$ cm, $v/u_\tau = 0.035$ mm, and a roughness element should be smaller than 0.18 mm, which is a challenging target. The present technique, in which there are no upwind disturbances for a given measurement, is a clear improvement.

An initial traverse device was constructed and used for initial measurements at 10 x,y-locations and 7 z-locations off the surface. The probe axis was aligned with the previously determined flow direction at each point and was affixed (on the interior of the windshield) through a magnet on the outside of the windshield. This device, although serviceable, incorporated one z-location measurement for one traverse position. It was elected to fabricate another unit, depicted in Fig. 4, that could accommodate 2 or 3 probes on a common support. This support could be removed and transferred to the

traverse rig for pre- and post-calibrations without risking a break in the electrical connections. (Note that such a disconnect/connect sequence can significantly alter the calibration values for a hot-wire.)

The second unit was then used to re-execute the z-surveys at the original 10 locations as well as at the remaining measurement sites that were accessible given the windshield-dash height restrictions. The time series data from these surveys were then used to create $\bar{V}_s(x, y, z)$ and $\tilde{V}_s(x, y, z)$ values. This traverse device presents a relatively bluff obstruction to the flow. A series of measurements were executed that showed there to be, at most, a negligible contamination of the measurements as a result of the traverse device.

Reference Velocity - Given that the flow system might not operate at a fixed condition, care was taken to continuously monitor the pressure at an arbitrary position in the supply plenum. A lead was inserted upstream into the defroster nozzle for this purpose. This lead was inserted into the plenum and the indicated pressure was used to define the state of the system. A reference velocity was then defined by the differential pressure between the plenum and the closed passenger compartment; that is

$$u_{ref} = \sqrt{\frac{2}{\rho}[p_{pl} - p]} \ .$$

The time averaged u_{ref} for a given 20-second sample $(\ )_i$ of the hot-wire was recorded and used as follows: $\bar{V}_s(x, y, z)]_i/u_{ref}]_i$ and $\tilde{V}_s(x, y, z)]_i/u_{ref}]_i$ were tabulated for each location. An ensemble mean value was then computed as

$$\langle u_{ref} \rangle = \frac{1}{N}\sum_{i=1}^{N} u_{ref}]_i$$

and the individual measurements are brought into relative agreement as

$$\bar{V}_s(x, y, z) = \frac{\bar{V}_s(x, y, z)]_i}{u_{ref}]_i}\langle u_{ref} \rangle \ .$$

This process was repeated for the standard deviations $\tilde{V}_s$. Using this procedure, the dimensional velocities at all locations are made compatible with each other in spite of the flow system variations.

RESULTS AND DISCUSSION

Velocity surveys over the windshield at surfaces spaced at z = 1.78, 6.5, and 17.8 mm from its interior surface are shown in Fig. 5a-c; the rms values of the velocity measurements at z= 6.5 mm are shown in Fig. 6. Also, detailed velocity measurements within the shear layer at several representative x- and y-locations (see Fig. 3) on the driver side of the windshield are shown in Fig. 7a-f. All the results are consistent with the wall jet velocity profile (in magnitude and direction) due to the impingement of the defroster jet flow on the windshield.

In addition, a hot-wire probe was traversed along the length of the defroster exit opening and at a distance of 24 mm above the grill surface; a schematic is shown in Fig. 8. We also determined the values of the velocity at 32 mm. Since the pressure gradient and effective shear terms (for the majority of the flow) were expected to be quite small, it was expected that these two planes would exhibit quite similar velocities. Because of this expectation, only a few repeat measurements were executed at 32 mm and 24 mm from the grill.

The results of the longitudinal survey along the centerline at 24 mm above the defroster exit on the driver side are presented in Fig. 9, while the details of the traverse velocity survey at positions 4 and 8 are shown in Fig. 10a-b. Subsequent processing, however, showed that substantial variations existed in these sample data. One source for such discrepancy is the presence of strong spanwise flows. Strong non-uniformities are evident in the velocity surveys. Note that the peak velocity is representative of the maximum stagnation pressure provided by the fan. The lesser velocities in the survey indicate inefficiencies of the delivery system in that the peak velocities show excess kinetic energy with respect to that required to provide a given flow rate. This effect can be expressed as the *kinetic energy flux correction factor* (Potter and Foss, 1982).

CONCLUDING REMARKS

The standard hot-wire measurement technique is susceptible to error due to the presence of holes in the windshield template. The employed modified technique provides more accurate results and clarifies the boundary-layer structure over the windshield. In addition, it is flexible and does not require a plexiglas template. Measurements can be used as a design tool to predict the velocity distribution due to defroster nozzle jet flow and determine the heat transfer coefficient on the windshield.

ABSTRACT

The important problems to be tackled from the point of view of preventing global warming are to save the power consumption of car air conditioning systems and reducing the refrigerant used in those systems.

Our approach to the task is to enhance system efficiency by utilizing sub-cooling at the outlet of the condenser and also to reduce the amount of refrigerant through a refrigerant behavior pattern analysis.
This approach has created a simple system construction using an integrated condenser/receiver device.

INTRODUCTION

The car air conditioning system has become indispensable in the provision of comfort and safety. The system, however, affects fuel economy and presents lingering concerns about global warming due to the HFC134a refrigerant, which has recently been adopted as a refrigerant to thoroughly solve the ozone depletion problem.[1][2]
Accordingly our most important task from an environmental point of view is to make a system which consumes less power and uses less refrigerant.

The purpose of this paper is to explain the behavior of the refrigeration cycle from the standpoint of the amount of refrigerant, performance and stability, and to achieve these requirements, in addition to suggest a car air conditioning system which fulfills the important factor of being easy to install.

The car air conditioning system is the simplest vapor-compression type refrigeration cycle, composed of a compressor, condenser, expansion valve, evaporator and refrigerant tank.

In conventional car air conditioning systems which are expensive and not easy to install, improved efficiency was achieved by improving the performance of system components such as condenser and compressor, rather than modifying the structure of such systems.
From the point of view of preventing global warming, the reduction of the amount of refrigerant is also important in addition to obligation regarding refrigerant recovery and the refrigerant recovery machine.
However, only attempts to reduce the size of each system component's inner volume have been made, and inroads into the review of the entire system have rarely been made.

This paper describes the system which achieves high efficiency together with a reduction of the amount of refrigerant through a review of the entire system.

BEHAVIOR OF CURRENT REFRIGERATION CYCLE

In many car air conditioning systems (Japan and EU, someparts of US), a receiver incorporating a dryer, a filter and a sight glass to check the amount of refrigerant are installed in the downstream of the condenser (Fig. 1). This receiver absorbs fluctuations in the required refrigerant amount inside the refrigeration cycle caused through changes in operation conditions, while maintaining constant performance and quality against leakage of refrigerant from hoses. Thus, the system is filled with refrigerant so that the liquid surface is formed in the receiver and only transparent liquid with no gas is observed through the sight glass.
Fig. 2 shows the behavior of the refrigeration cycle vs refrigerant amount. At point (A), only liquid is observed through the sight glass after gas completely disappears. Fig. 3 shows the location and amount of the refrigerant for this point. Recently, the condenser is filled with a smaller inner volume of refrigerant due to the introduction of the small capacity multi-flow condenser, while in receiver, there still exists a lot of refrigerant even at this point (A).

This extra amount of refrigerant (150g) should be attentioned. This is because disturbance of the liquid surface caused by refrigerant flowing in from the top of the receiver draws in gas from the outlet at the bottom of the receiver, thus requiring more refrigerant to maintain a certain liquid surface. In other words, this extra amount of refrigerant is required at least to make sure that no gas enters so that only the liquid flows out. From the standpoint of environmental protection, this extra amount of refrigerant must be attentioned.

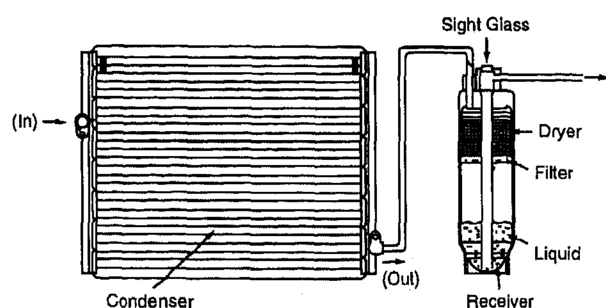

Fig. 1 Current Refrigeration Cycle

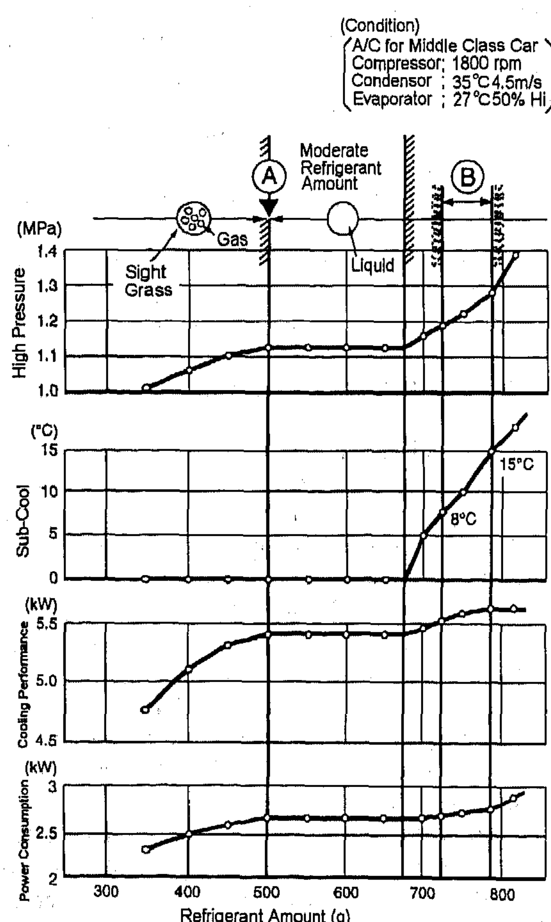

Fig. 2 The Behavior of the Refrigeration cycle vs Refrigerant Amount

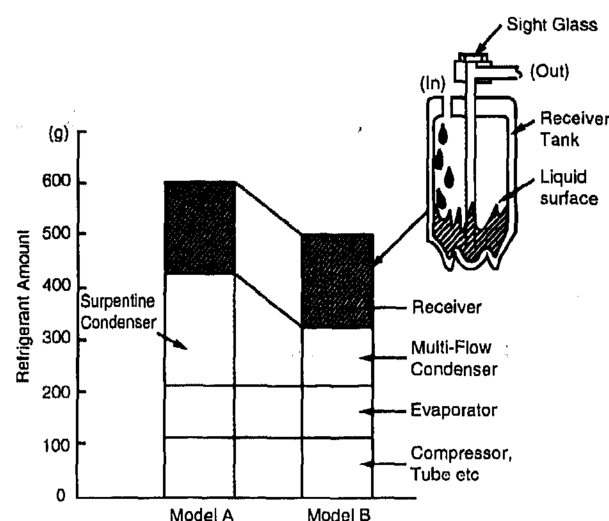

Fig. 3 The Location and Composition of the Refrigerant Amount for point (A)

In normal operation, liquid refrigerant supplied to the expansion valve is a saturated liquid having nearly zero sub-cooling, since liquid surface is always formed so that both liquid and gas exist inside the receiver. When this high-temperature saturated liquid is decompressed by the expansion valve, part of the liquid remains as gas, cooling down the liquid refrigerant. Thus, gas (approx. 40%) which does not contribute to cooling is generated and flows into the evaporator (Fig. 4).

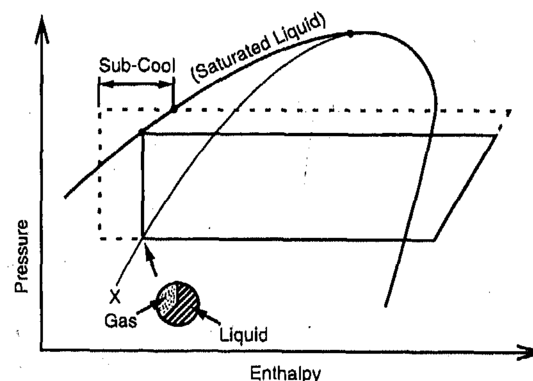

Fig. 4 The flows into the evaporator

If this high-temperature liquid refrigerant is cooled in advance, a smaller amount of gas will be generated, thus improving cooling performance. For instance, the amount of refrigerant can be increased to cause the liquid inside the receiver to overflow, thus making the downstream side of the condenser a liquid region. This region is then cooled by ambient air to cause sub-cooling. Fig. 2 shows this performance characteristic. Adding a further 50 to 100 g of refrigerant in addition to the refrigerant which has overflowed from the receiver can maintain sub-cooling

between 8 and 15°C, thus improving cooling performance by approximately 5% due to reduction of gas generated during decompression (Fig. 2 (B)).

However, it is still difficult to guarantee performance against fluctuation in refrigerant amount caused by changes in operation conditions and leakage of refrigerant. Furthermore, an increase in refrigerant amount is not preferable from the view point of environmental protection.

CONCEPT OF SUB-COOL SYSTEM

A receiver, which guarantees stable performance and quality, is installed in the passage of the refrigerant flow in the condenser, not at the exit of the condenser. Refrigerant is then supplied until a liquid region is developed inside the receiver, and the cooling section located downstream of the receiver is used as a sub-cool section where the liquid is cooled. Apart from that, this cooling section guarantees stable performance and also maintains quality since it liquefies gas which happen to flow from the receiver. The amount of refrigerant (150g) required at least to prevent the escape of gas from the receiver of the conventional system is no longer necessary. This results in the saving of refrigerant, even if an increase in refrigerant amount (50~100g) is expected in the sub-cool section. As a result, the sub-cool system not only helps in both improvement of performance and saving of refrigerant, but also reduces costs and weight, furthermore improving ease of installation by utilizing one of the headers of the multi-flow condenser to integrate a receiver with the header as shown in Fig. 5.

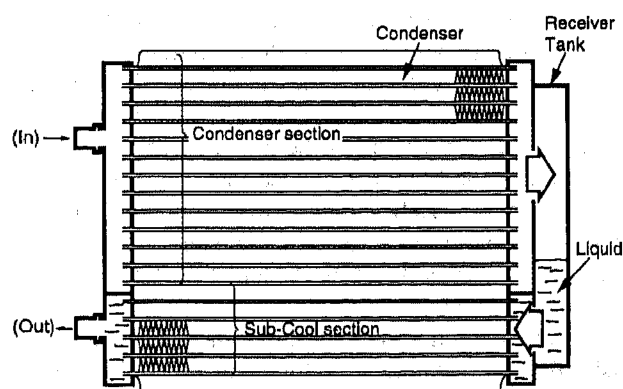

Fig. 5 Concept of Sub-Cool System

EXAMINATION OF OPTIMUM SUB-COOL SECTION RATIO

We now examine the optimum sub-cool section ratio for the multi-flow condenser.

Computer simulation was performed, and the results are shown in Fig. 6. From the point view of cooling performance and efficiency, the figure shows a wide range of the optimum sub-cool section ratio. Taking various operation conditions into account, it can be from 15% to 20%.

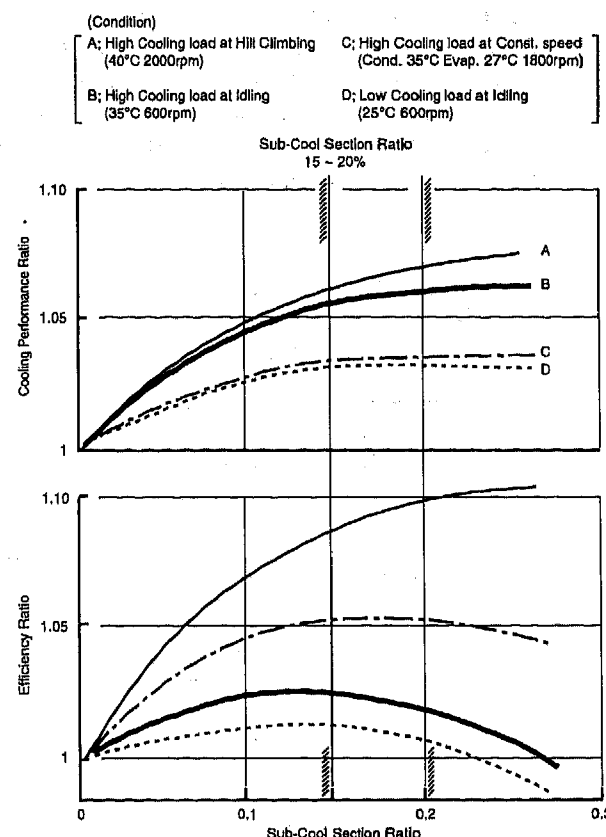

Fig. 6 Ultimate Sub-Cool Section Ratio

EXAMINATION OF LIQUID STORAGE FUNCTION

To integrate a liquid tank with the condenser's header and facilitate installation of the tank, the tank must be long and thin. If refrigerant flows into the receiver from the top of the tank and flows out from the bottom as in the conventional receiver, no liquid surface will be developed, thus liquid and gas will be mixed if the tank is thin. As a result, sub-cooling cannot be constant irrespective of the refrigerant amount, as shown in Fig. 7.

We therefore examined a method in which a liquid storage function is provided in upper space of refrigerant flow. Fig. 8 shows its operating principle.

(1) Some of the gas flowing into the entrance enters the gas region inside the tank due to buoyancy, but the gas condenses on the cooled inner surface, thus resulting in a balanced liquid surface. (Fig. 8-b)

(2) Accordingly, when more gas flows into the entrance, more gas enters the gas region, causing the liquid level to drop, thus supplying refrigerant into the refrigeration cycle. (Fig. 8-a) Supply of refrigerant

continues until state (1) is reached.

(3) When refrigerant no longer contains gas and sub-cool is developed, liquid refrigerant inside the tank also cools down. This causes gas in upper space to condense. As a result, inner pressure decreases, liquid surface rises, and finally extra refrigerant in the refrigeration cycle is stored. (Fig. 8-c) This continues until state (1) is reached.

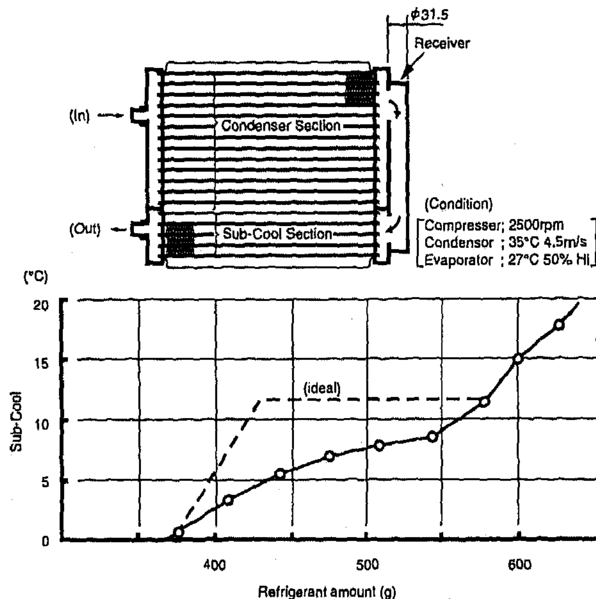

Fig. 7 The Behavior of Sub-Cool vs Refrigerant Amount

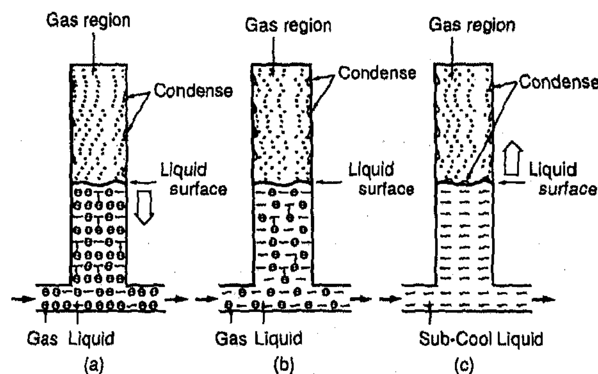

Fig. 8 The behavior of Liquid Storage Function

Fig. 9 shows the characteristic of the refrigerant storage which employs the above principle. From the figure, development of the liquid surface can be observed. It can also be observed that the more the refrigerant amount increases, the more refrigerant is stored in the tank.
Furthermore, stable sub-cooling is maintained at the exit of the sub-cool section as long as the liquid surface exists.

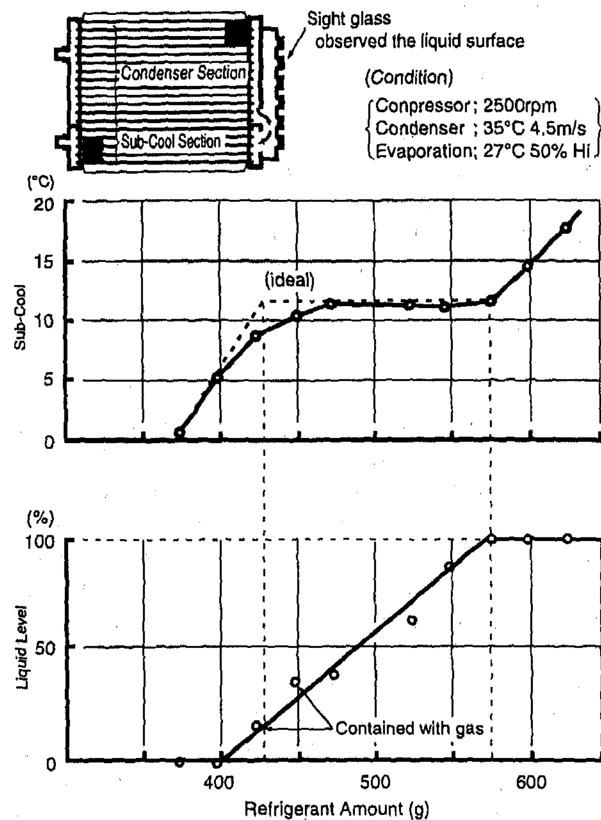

Fig. 9 The behavior of Sub-Cool vs Refrigerant Amount

STRUCTURE OF THE DEVELOPED SYSTEM

Fig. 10 shows a detailed structure of the developed system and its external view. A multi-flow condenser is used and a receiver tank with an inner diameter of 31.5 mm is integrated in one of the headers. To use approximately 20% of the lower section of the heat exchanger as the sub-cool section, the header is divided into condenser and sub-cool sections. Refrigerant flows from the condenser section into the receiver tank and then out into the sub-cool section. Liquid is stored on the top of the tank.

A dryer enclosed in a felt bag is installed inside the tank, and a filter is installed at both the entrance and exit at the bottom of the tank.
As with the conventional receiver, functions other than the liquid storage function are also provided. Like the conventional system, the sight glass located in the liquid line is used to check for shortage of refrigerant.

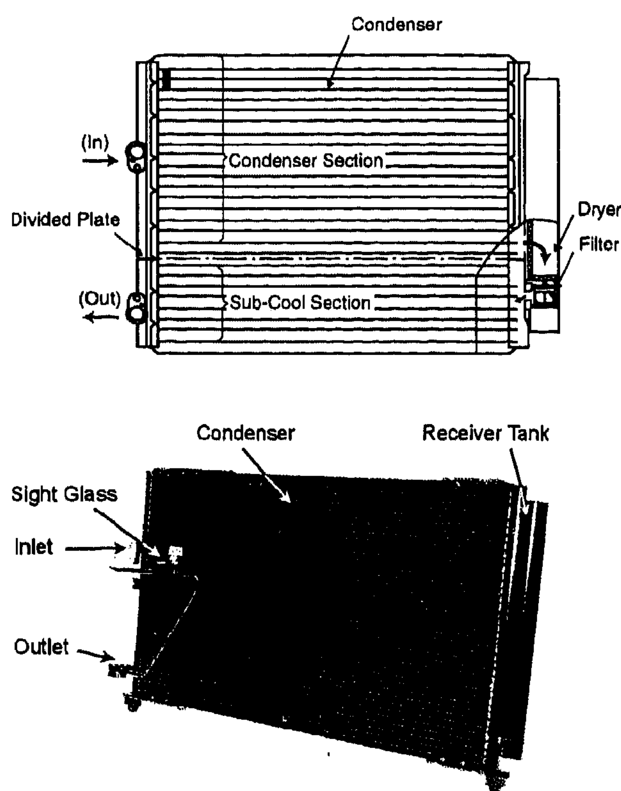

Fig.10 Structure of Sub-Cool System

EFFECTS

Evaluation results for effects of the developed sub-cool system are given below.

Fig. 11 shows comparison of refrigerant amount characteristic between the systems using the conventional receiver and the developed sub-cool system, in which the same size condenser used. The conventional system is stable in the range where no sub-cooling exists, whilst the developed system is stable at approximately 13°C of sub-cool.

This sub-cool has improved the cooling performance by 5% as shown in Fig. 12. This means that outlet air temperature can be reduced by 1.5°C and room temperature reduced by 1°C in the case of cool-down performance of an actual vehicle. Reducing the discharge displacement of compressor to provide the same cooling performance results in a saving of power by 10%.

In addition, when compared to a system using the conventional receiver which requires extra refrigerant to prevent the escape of gas, the developed system saves an average of 100 g of refrigerant as shown in Fig. 11.

CONCLUSION

We have developed a sub-cool system which can improve the efficiency of car air conditioning system and reduce the amount of refrigerant. The system employs a liquid storage function in the passage of the refrigerant flow in the condenser, and cools down the liquid in the cooling section to cause sub-cool.

Since the liquid storage function is provided as a long thin receiver tank integrated into the multi-flow condenser' s header by welding, the function can be installed easily. This was made possible since it was found that a long thin tank can be provided in upper space of the refrigerant flow to store liquid.

This system has a power saving of 10% whilst maintaining the same cooling performance and a reduction in refrigerant amount of 100 g.

Determination of Adsorption Parameters of Active Carbon Filters Measuring Only the Beginning of the Breakthrough Curve

Thomas Wolff

Wix-Helsa Filtration Products, Inc.

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

The adsorbed mass is an important parameter for the characterization of adsorptive filters. For its calculation it is necessary to determine the breakthrough versus time for a given upstream concentration. In order to reduce testing time, emissions and the amount of contaminants required, an evaluation method was developed that allow prediction of the breakthrough curve by extrapolating an aborted measurement. This new method reduces the amount of contaminants by more than 80%. Two additional parameters, which describe the characteristics of an adsorptive filter, result from the evaluation procedure.

INTRODUCTION

The total adsorbed mass and the breakthrough after a few seconds are parameters used to characterize an adsorptive filter. They have to be determined, for example, during the production procedure to ensure the quality of the produced filters. To determine the adsorbed mass, the integral over the breakthrough curve $P(t)$ has to be calculated. Using the ideal gas equation, the adsorbed mass is derived by calculating the difference between the whole amount of agent which the filter has been exposed to and the amount of gas having penetrated the filter (i.e. the integral over the downstream concentration vs. time). All these calculation steps are summarized in equation (1).

$$M_{ads} = M_{tot} - \frac{p\dot{V}}{RT} M_{mol} \int_0^{t_E} P(t)dt \qquad (1)$$

where M_{ads} is the adsorbed mass, M_{tot} the whole mass and M_{mol} the mol mass of the contaminant in g, p the ambient preassure in Pa, $\dot{V}$ the flow rate in m^3/min,

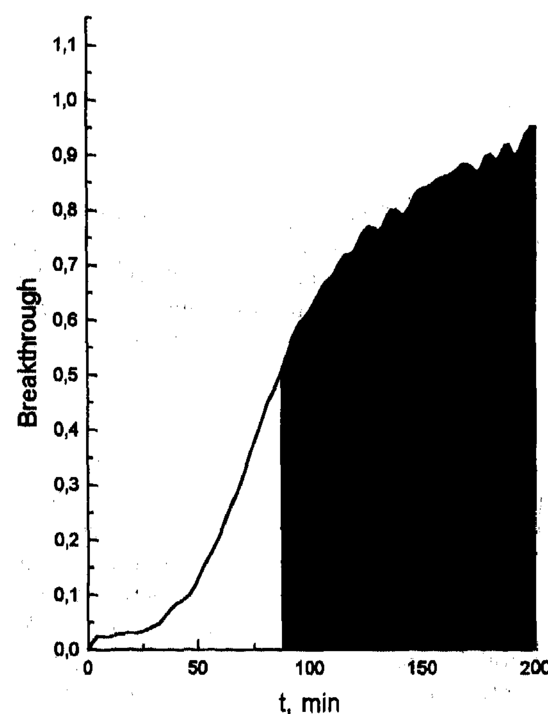

Figure 1: Typical breakthrough curve of an activated carbon filter using toluene as the contaminant. The shaded area under the curve represents the amount of gas, which, starting from the point at about 90 minutes, is not adsorbed by the filter.

a reasonable evaluation method with sufficient accuracy which reduces the required test time and the amount of contaminant by at least 50%. The emissions can be reduced by approximately 80%.

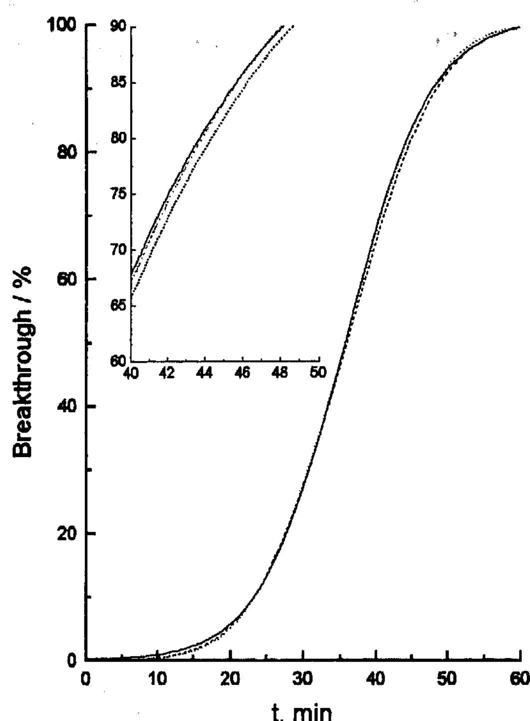

Figure 2: Two fits of equation (2) to a set of measured data (solid curve). The dotted curve is a fit to the whole dataset and the dashed curve is a fit to the first half portion of the same data. The inset shows an enlarged portion to demonstrate the difference between the two fitted curves.

$R = 8,3144 J/mol\,K$ the gas constant and T the ambient temperature in Kelvin. Equation (1) shows, that if $P(t)$ is known, the adsorbed mass can be determined. In figure 1 a typical breakthrough curve of an activated carbon filter, using toluene as the contaminant, is shown. The measurement time for such a curve takes up to several hours, depending on the filter type and contaminant. During the later phase of the test the major amount of the agent penetrates through the filter. The shaded area under the curve in figure 1 represents the amount of gas, which, starting from the point at about 90 minutes, is not adsorbed by the filter. This area is much larger than that one under the first section of the curve. It is therefore of major importance to find an evaluation procedure which enables us to determine the adsorbed mass from the data of an incomplete breakthrough curve.

It is the aim of this paper to demonstrate that a fit of the data of the initial section of a measured breakthrough curve to an appropriate function provides a reasonable evaluation method with sufficient accuracy which reduces the required test time and the amount of contaminant by at least 50%. The emissions can be reduced by approximately 80%.

EVALUATION PROCEDURE

The easiest way to derive $P(t)$ from the data of an initial fragment of a breakthrough curve is fitting the data to a function that describes exact the curvature of $P(t)$. In the example shown in figure 1 and in all other cases where $P(t)$ is given by a symmetrical S-curve, which begins at a given offset P_0 and reaches 100 %, the appropriate function is the error function $\mathrm{erf}(t) = 2\pi^{-1/2}\int_0^x \exp(-t^2)dt$. The complete form of the function, which can be taken for the fit is given by equation (2):

$$P(t) = \frac{P_s}{2}\left\{1 + \mathrm{erf}\left(\frac{t-t_b}{t_w}\right)\right\} + P_0 \qquad (2)$$

where P_s is a scaling factor and P_0 represents an offset. t_b and t_w are two additional parameters for the characterization of an adsorptive filter. The subscript b stands for breakthrough and the subscript w for width. The larger t_b, the longer is the "lifetime" of the filter. t_w describes the kinetics of the adsorption process. It can be compared to the width of a Gaussian distribution which leads into a convolution with a Heaviside function $\theta(t-t_d)$ to the error function in (2).

$$\mathrm{erf}(t-t_d)/t_w) = 2\pi^{-1/2}\exp(-(t/t_w)^2) * \theta(t-t_d)$$

The unit of t_b and t_w is *minutes*. The integral over the function in equation (2) is easy to solve and we get the following expression for the total adsorbed mass

$$M_{ads} = M_{tot} - \frac{p\dot{V}}{RT} M_{mol}\, P_s\,(\mathrm{F}(t_b, t_w, t_E) - \mathrm{F}(t_b, t_w, 0)) + P_0\, t_E \qquad (3)$$

with

$$\mathrm{F}(x,y,t) = \frac{y}{2\sqrt{\pi}}\exp\left(-\frac{(t-x)^2}{y^2}\right) + \frac{1}{2}(t-x) + \frac{1}{2}(t-x)\,\mathrm{erf}\left(\frac{t-x}{y}\right)$$

Using an appropriate method for a non linear fit, e.g. a Gauss-Newton or a Marquart-Levenberg method, with the four fit parameters P_s, P_0, t_b, and t_w, equation (2) can be fit to a set of measured data. In figure 2 two fits of (2) to a data set, derived from actual carbon filter media using n-butane as the contaminant, are shown. The dotted curve is a fit to the whole data set (solid

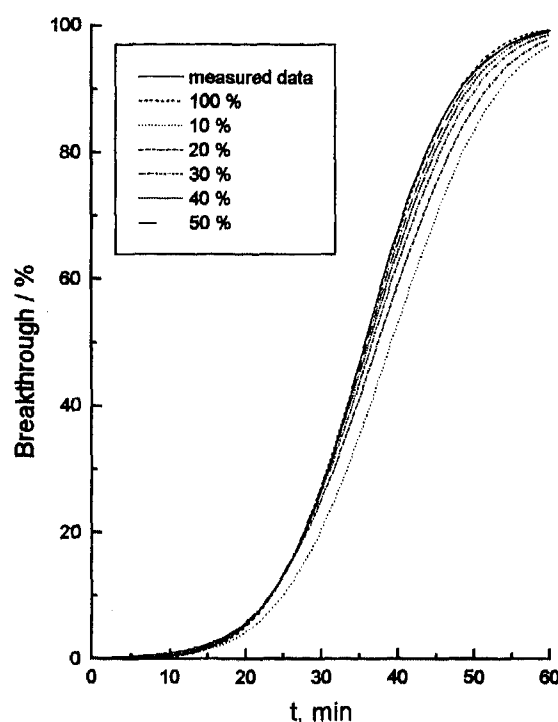

Figure 3: Fits of equation (2) to datapoints (solid line), which were cut off at six different levels (corresponding to table 1).

curve) and the dashed curve is a fit to the first half portion of the same data. The plot demonstrates, that both fits are in good agreement with the measured data (similar to the one shown in the example).

This indicates that measurements can be aborted whenever a breakthrough of about 50% is reached and the rest of the curve can be determined by fitting $P(t)$ to the real test data.

EVALUATION OF THE NEW METHOD

Figure 3 shows six different fits to the data of the last example. Each of the six curves corresponds to a value for the breakthrough, which represents the last point of the dataset used for the non-linear fit.

In table 1 the values of the breakthrough of the last datapoint are listed together with the corresponding error, which results from the difference of the real adsorbed mass to the value calculated from the fitted curve using equation (3). The values in table 1 indicate that the deviation from the actual value for M_{ads} is less than 1% if we interrupt the measurement at 50% breakthrough. This point represents the point of inflection of the curve. If the test is aborted close to this point the error will be less than 1%. Deviation increases as testing time is reduced.

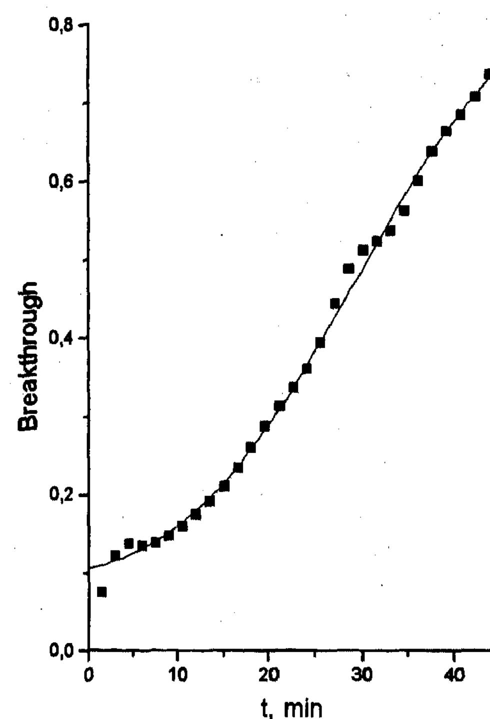

Figure 4: Fit of equation (2) to a breakthrough curve of a combination (thin bed) filter. The contaminant was toluene. The initial penetration (spontaneity) can be determined from the value of the fitted curve at $t = 0$.

Table 1

$P(t_e)$ / %	error / %
100	0.17
50	0.8
40	1.52
30	2.7
20	4.8
10	9.2

The size of the error depends on how good the measured data fits to equation (2). An evaluation of a large amount of measured curves of two different active carbon systems has shown, that the error, which we get when we cut the data near the point of inflection, is in the range of 0.7 – 3.0 %.

CONCLUSIONS

With the present evaluation method it is possible to cut down the testing time to 50% or less and the emissions can be reduced by about 80%. These two results are very important, whenever the adsorbed mass of a large amount of samples has to be determined, e.g. quality control during the production of adsorptive filters. The whole production and testing process can be accelerated and environmental pollution problems related to testing can be reduced to a minimum. The reduction of the costs for one measurement is another important argument for the application of this method.

Another very useful effect of this method is, that we can determine the breakthrough of the filter at the initial time of the measurement. This value, which we call the spontaneity of the filter, can normally be determined by extrapolation from the first datapoints to $t = 0$. If a fit to equation (2) was made, the spontaneity is directly represented by the value of $P(0)$. In figure 4 a fit to the breakthrough curve of a combination filter using toluene as a test agent is shown. The spontaneity according to the above mentioned proposal would read 10.5%. In this example the fluctuation of the first datapoints would have made an extrapolation inaccurate and difficult.

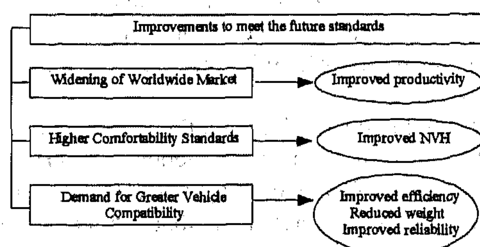
Improvement of Scroll Compressor for Vehicle Air Conditioning Systems

Jiro Iizuka, Norio Kitano, Shigeru Ito, and Shinichi Otake
Sanden Corp.

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

Mobile Air Conditioning Compressors with the scroll mechanism design are superior in noise, vibration and harshness (NVH) levels, and in efficiency.



For further NVH improvements; for improved comfortability; to enhance the manufacturability to meet the increasing market volumes; and to give better vehicle compatibility in weight reduction and increased durability, the New Type TR Compressor is presented.

INTRODUCTION

BACKGROUND - Fifteen years has passed since mass production of the TR compressor started in 1981. During this period, four models of different displacements were developed, TR60, TR70, TR90, TR105. Additionally the controlled capacity compressor TRC model was developed and improvements were implemented to make the TR compressor line compatible with the new refrigerant HFC 134a.

DEVELOPMENT OF THE NEW TR MODEL

To meet the future performance standards for automobile air conditioners the New Type TR Compressor was developed.

PRODUCTIVITY

Improved productivity is gained by simplifying the parts structure.

EM BEARING - The current TR has a ball coupling as an anti rotation mechanism for the orbiting scroll member, and it serves as a thrust bearing. This ball coupling consists of a pair of races, a pair of retainer rings with beveled holes to retain the ball bearings and a set of ball bearings. This will be replaced by an Eccentric Motion Bearing (EMB) and will include only a pair of integrated races which constrain the ball travel, and a set of ball bearings.

Parts manufacturing and assembly operations are simplified and reduced with the EM Bearing and the quantity of parts is decreased.

BALANCING METHOD - The balance weight shown in Figures 1 & 2 must be offset with a clutch armature plate weight. The mass times distance of the counterweight, that is next to the scroll, is offset by the orbiting scroll centroid times the orbiting radius, and this couple alone provides adequate balance.

In the new TR compressor, the balance weight and armature weight are eliminated thus giving substantial productivity improvement and reduction in parts and weight.

Not only is weight reduced by the elimination of the balance weight and clutch armature counterweight, Figure 1 and cross-hatched section of Figure 2, but some mass is eliminated from the housing as well.

SEALING METHOD BETWEEN SUCTION AND DISCHARGE CHAMBER - In the current TR compressor the suction and discharge chambers are sealed off with an O-ring. In the New Type TR Compressor both chambers are sealed from each other by metal contact. This method improves assembly productivity. Figure 3.

SHAFT HOLDING METHOD - In the current TR the shaft position is held by the rear ball bearing on the crankshaft flange which butts against the shaft balance weight and the crankshaft flange. In the New Type TR Compressor, this ball bearing is replaced by a lighter weight, efficient needle bearing. Figures 4 & 5.

The shaft is held in position by the front bearing races being retained between the clutch armature hub and the snap ring. Figures 5 & 6.

These changes improve productivity of parts manufacturing and assembly.

HIGHER COMFORTABILITY STANDARDS

IMPROVEMENT OF NVH - In the current TR the radii of the beveled holes in the retainer rings are the same as the orbiting radius. The ball bearings, of smaller diameter than the beveled holes, then travel around the holes on the bevels as the scroll is traveling in an orbit.

The amount of bevel and the thickness of the retainer rings dictate the ball travel radius. The ball bearings can move off of the bevels at any change of condition because their travel is not constrained. Thus, a kind of ball bearing "backlash", occurs at many condition changes, particularly load changes. This degrades the NVH characteristics.

The New Type TR Compressor consists of an integral race and ball retainer which gives actual paths for the ball to travel in and thus the ball travel becomes constrained and true and backlash does not occur. Figure 7.

Also, the compressor moment of inertia becomes smaller due to the elimination of the clutch armature balance weight and the drive shaft balance weight. This then reduces the starting torque which improves the NVH characteristic at the numerous cycling events.

Figure 8 compares the sound pressure level in DBA between the standard TR and the New Type TR Compressor.

DEMAND FOR GREATER VEHICLE COMPATIBILITY

EFFICIENCY AND RELIABILITY - To meet the ever increasing A/C loads, the market demands an even greater capacity of the scroll compressor. The engine compartment packaging limitations, however, prevent the application of a larger compressor with a larger diameter to satisfy the needed increase in capacity.

Due to the cantilever aspect of the scroll wall at the discharge end, any increase in scroll wall height to increase displacement should be accompanied by a stronger root at the end wall section.

To gain toughness at the root center in the current design, the wall would have to be thickened and this would cause the starting points of the involute to be delayed, or in other words moved away from the center.

This would cause a shorter and more rapid compression process, and as a result, the gas leakage to the suction side at the center would be increased and this would degrade compressor efficiency (COP), and this would be unsatisfactory. Therefore, to increase efficiency and to give extra root strength for even taller scroll walls, the New TR will provide a new concept two step scroll wall. See Figure 9.

To improve efficiency the involute curve length has been increased by decreasing the angle from the center of the generating circle, A degrees and B degrees - current TR; to $A-\alpha$ degrees and $B-\beta$ degrees - New Type TR. The length increase of the involute curve is shown by comparing the involutes of Figure 9a with Figure 9b.

Figure 10 shows a Finite Element Analysis comparison between the current TR90 (Base Design) and the New TR design. The two step design shows a significant reduction in maximum stress and a 34% increase in the safety factor.

Figure 11 shows the crank angle vs. gas pressure. The two step center wall method gives a longer compression process at the final compression stage.

This method comes closest to reaching the ideal scroll compression cycle which has never been attained due to the difficulty in achieving sufficient strength at the scroll center wall.

By this improvement, a smoother torque, higher efficiency and lower pressure variations are achieved.

WEIGHT - Cars are becoming more efficient year by year as the demand increases for better fuel economy and lower emissions. Weight reduction at every area of an automobile carries the highest priority.

As discussed in the preceding paragraphs, the weight of the New Type TR Compressor is reduced by eliminating certain counterweight parts, redesigning of certain parts and by simplifying the structure.

The quantity of parts has been reduced by 18%. The weight of the compressor has been reduced by 10% from 5.9Kg to 5.3Kg.

RELIABILITY - The overall reliability has been improved by replacing the ball bearing with a needle bearing and by reducing the starting moment of inertia. This also reduces weight and size.

Included is a newly designed shaft lip seal with a rubber coated edge face that replaces the O-ring.

The seal reliability is the same as the O-ring type, but the structure and assembly is simplified giving an overall reliability improvement. See Figure 12.

COMPARISON OF ANTI-ROTATION MECHANISMS

The EM bearing has been compared to other anti-rotation mechanisms such as the Oldham Coupling, which is constructed of a crossed sliding apparatus, and the Pin and Ring Coupling which is constructed of a pair of pins and guide rings.

The Oldham Coupling and the Pin and Ring Coupling have low mechanical efficiency due to frictional forces. Also, the Oldham Coupling has a fundamental limitation in inertia force balancing that results from its reciprocal motion. Both designs, however, have good noise characteristics, thus they were evaluated.

The Ball Coupling of the current TR and the EM Bearing have the best mechanical efficiency due to the use of ball bearings located between the orbiting scroll and the base.

The EM Bearing gives better productivity than the Ball Coupling due to a decrease in the number of parts. Further, the EM Bearing gives a big advantage in noise reduction compared to the Ball Coupling. See Table 1, which shows the ranking of these characteristics among the four designs. From this comparison, the EM Bearing was designed as the most suitable coupling for the advanced scroll compressor.

CONCLUSION

The scroll compressor is a superior design because it has the highest volumetric and isentropic efficiency and has the lowest NVH characteristics of all types of vehicle A/C compressor mechanisms.

The New Type TR Scroll Compressor has been developed to further improve the NVH characteristics, to improve efficiency, and improve reliability.

By this design, the productivity and vehicle compatibility were greatly improved, thus meeting the widening market demands and acceptance.

In-Vehicle Adsorptive Filters Efficiency

Nathalie Lemaitre
Valeo Thermal Systems

Yves Godet
INERIS

ABSTRACT

This paper presents the Valeo approach to qualifying adsorptive filters in real conditions in vehicle. The first part describes the choice of air quality indicators and the adapted methods used to measure them. The second part presents the application in vehicle and the results. The last part compares results to laboratory characterizations.

INTRODUCTION

Adsorptive filters are recently developed to improve air quality in the passenger compartment. Valeo is interested in integrating such filters in heating and air conditioning systems to provide a better air quality in vehicle for drivers and passengers. These filters contain activated carbon and non-woven material to treat gases and particles present in ambient air. They are generally called « combined filters ».

The common characterization test of adsorptive filters is based on DIN 71640 part 2, proposed for ISO standard. It can give the main features for adsorptive filters : efficiency and capacity of adsorption. This procedure is adapted to laboratory conditions and uses high concentrations of test gases. These concentrations are still much higher than those met in the atmosphere around the vehicle.

Also it is essential to know how these filters react in real conditions in vehicle. As well, it is important to compare laboratory characterization and real tests results.

In this objective, this paper will attempt to evaluate different filters in real conditions of use.

AIR QUALITY INDICATORS AND MEASUREMENT METHODS

AIR QUALITY INDICATORS - The indicators of air quality are chosen according to atmospheric pollutants found in the cabin and the ability to measure them in a vehicle.

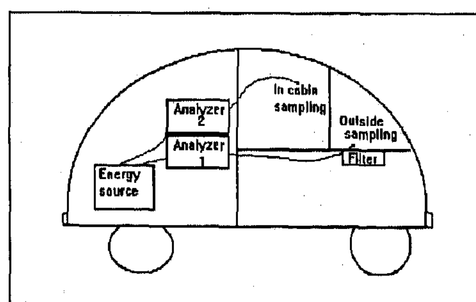
Atmospheric pollutants - Main atmospheric pollutants are regulated because of their effect on health and are continuously monitored in ambient air by registered laboratories. These are sulfur dioxide (SO_2), nitrogen oxides (NO_2, NO), carbon monoxide (CO), ozone (O_3), volatile organic compounds (V.O.C) including hydrocarbons. The major sources are industry, heating and transportation. It is possible to measure these gases by direct or indirect methods. For in-vehicle tests, 6 indicator gases are selected:

- 3 gases used in DIN test : SO_2 - NO_2 - toluene,
- 2 gases to complete : benzene - xylene
- and 1 gas for traffic indicator : CO

MEASUREMENT METHODS - Specific methods are applied to measure the different gases.

Sulfur dioxide (SO_2) - In ambient air, SO_2 molecules are stable. Ultraviolet rays can transform them to excited state. The return to the stable state creates a fluorescent radiation emission. The fluorescence intensity is proportional to SO_2 concentration. Direct analyzers can be used in the vehicle to measure SO_2.

Nitrogen dioxide NO_2) - To be measured by chemiluminescence, NO_2 is first converted into NO by reduction in a molybdenum oven. Then chemiluminescence corresponds to the oxidation of NO molecules by O_3 molecules : $NO + O_3 \Rightarrow NO_2^* + O_2$. The return to a stable state creates a light radiation emission : $NO_2^* \Rightarrow NO_2 + h\nu$ the radiation is proportional to NO_x concentration. Without conversion, the radiation is only proportional to NO. The difference between NO_x and NO gives NO_2 concentration. Direct analyzers measuring both NOx and NO can be used in the vehicle to determine NO_2 concentration.



Carbon monoxide (CO) - CO molecules, absorb in infrared rays. This absorption, follows Beer-Lambert law and is proportional to CO concentration. Direct analyzers can be used in the vehicle to measure CO.

Volatile Organic Compounds (V.O.C) - To obtain specific hydrocarbon measurements, the method used is first a sampling on adsorptive tubes and then analysis in the laboratory by gas phase chromatography phase and mass spectrometry. A first sampling in the vehicle shows the main hydrocarbons found in the cabin come typically from urban pollution (3). Many compounds are identified : benzene, toluene, octane, tetrachloroethylene, ethylbenzene, p xylene, styrene, o-xylene, nonane... Majority compounds are : toluene, benzene, xylene. This indirect method can be used in vehicle.

VEHICLE APPLICATION AND RESULTS

VEHICLE APPLICATION - A vehicle is dedicated to the tests with a driver and a responsible of measurement.

Measurement on board - For each air quality indicator, two measurements are necessary to evaluate outdoor and indoor concentrations simultaneously. Each gas concentration measurement needs an analyzer or a sampler. Because of the size of the analyzers chosen, only one gas is measured during a test. However, the 3 hydrocarbons can be sampled at the same time with pumps. 2 identical analyzers are placed on the back seat and connected to the energy source. Sampling tubes are joined to analyzers (or pumps for V.O.C) : one from the outside air inlet, the other from the cabin at passengers head. For direct measurement, analyzers are linked to a portable computer which can display the results graphically.

Filters equipment - An adapted box is placed on the external air inlet of the air conditioning system on the vehicle. Filters can be easily replaced in this box during the trial. The filter surface is 5dm^2 with 35mm depth, and less than 200 grams of activated carbon to reduce the pressure drop. 3 filters were tested :

- 2 combined filters including non-woven fibers and activated carbon granules for particles and gases filtration, coming from 2 different manufacturers.
- 1 filter without activated carbon called a placebo.

The tests distribution is presented below in table 1 :

	Filter A	Filter B	Placebo
SO_2	❶	❶	❶
NO_2	❷	❷	❷
CO	❸	❸	❸
toluene	❹	❹	❹
benzene	❹	❹	❹
xylene	❹	❹	❹

❹ : concentrations with test day numbering

Trials organization - A loop of 17 kilometers was defined in Paris, mixing periphery and center town, needing 30 to 50 minutes depending on traffic intensity. The loop was repeated for each couple « indicator/filter », that is to say, 12 loops in all. The campaign is realized in 4 days for all measurements.

Relative humidity and temperature are monitored during the trials, and the air conditioning system preserves a constant temperature of 22 to 25°c in the cabin.

The airflow with the filter in place is fixed at 245m^3/h, in full cold mode.

RESULTS - Results are expressed directly in part per billion (ppb) or million (ppm), or converted in microgram per cubic meter (µg/m^3)

Loops concentrations profile - For direct measurement, it is possible to obtain the profile of concentrations during the loop.

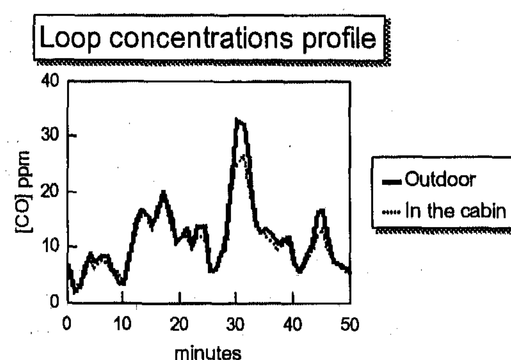


Figure 1 : example of a loop concentrations profile

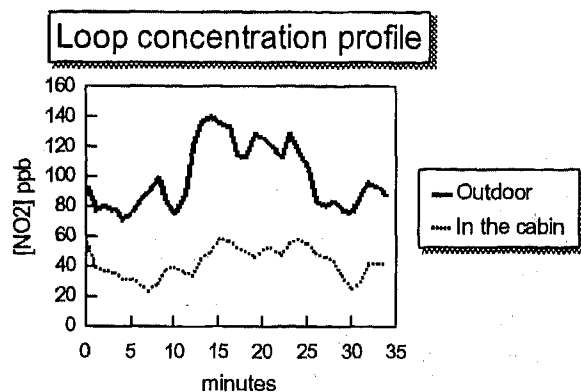

Figure 2 : example of a loop concentrations profile

The same type of profile is observed for SO_2. The concentration changes very rapidly around the vehicle according to the traffic environment. During a loop, the variation can reach a factor of 3 in 5 minutes. The concentration in the cabin follows the same variation, but at a lower level when the gas is adsorbed on a filter (figure 2). Driver and passengers are subjected to pollution peaks.

Trials concentrations profile - Results can be expressed in average of concentration for each loop.

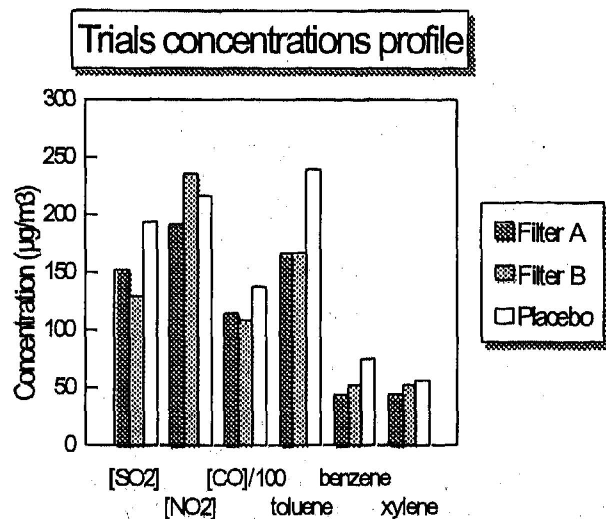

Figure 2 : Trials concentrations profile

The concentrations are quite homogeneous between the loops for a same indicator, measured the same day. The variations can only reach a factor 1,2 to 1,4.

The results can be compared to standards (1) for limit value of 1 hour exposure in ambient air. No standards are defined for 1 hour exposure for toluene, benzene and xylene.

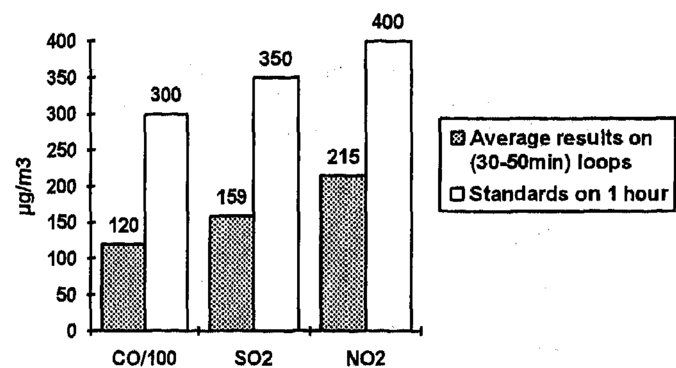

Figure 2 : Indicators concentrations

The concentrations obtained during this campaign are lower than standard values.

Air quality indicators results - The concentrations profile is presented for each indicator

• CO is not adsorbed on filter. To have an idea about the validity of the measurement, the lack of influence of this gas can be illustrated figure 4. The small difference measured between outside and in the cabin, could be attributed to the inertia time of both samples, or to the air modification in sampling tubes or air conditioning system.

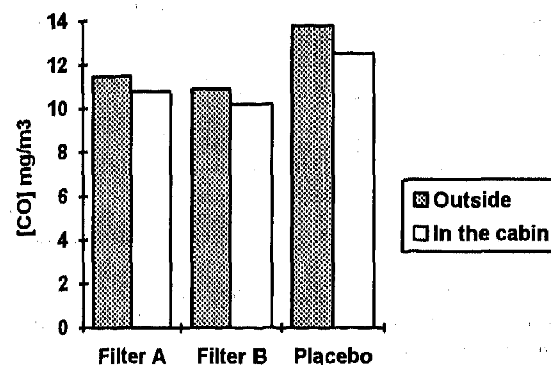

Figure 4 : CO concentrations measurement.

• SO_2 is adsorbed on filters. The high difference between outside and in the cabin for filters A and B, and the lack of difference for the placebo are shown in figure 5.

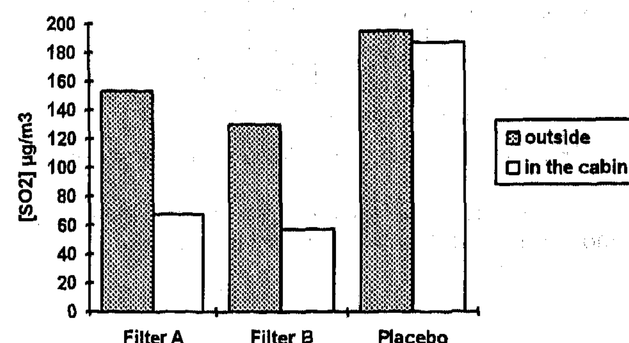

Figure 5 : SO2 concentrations measurement.

• NO_2 presents the same behaviour as SO_2, but with the placebo the highest concentration is for this case, in the cabin with the same explanation than for CO measurement.

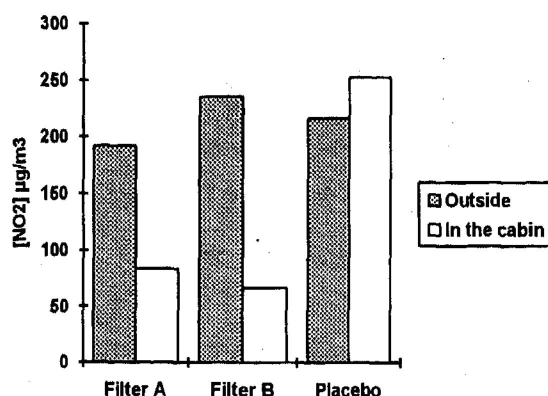

Figure 6 : NO2 concentrations measurement.

• Toluene is adsorbed on filters A and B, and not adsorbed with the placebo.

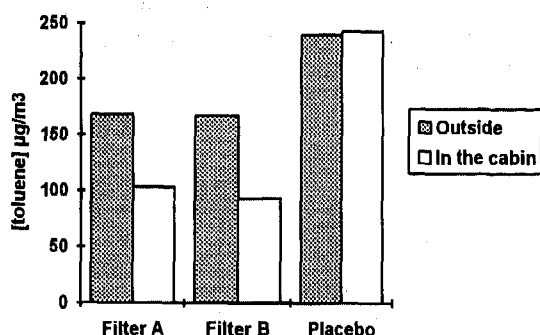

Figure 7 : Toluene concentrations measurement.

• Benzene concentrations are always lower in the cabin than outside, but more with filters A and B than with the placebo.

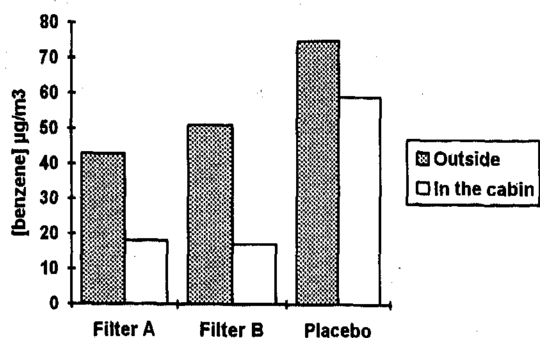

Figure 8 : Benzene concentrations measurement.

• Xylene concentrations are lower in the cabin, more with filters A and B than with the placebo.

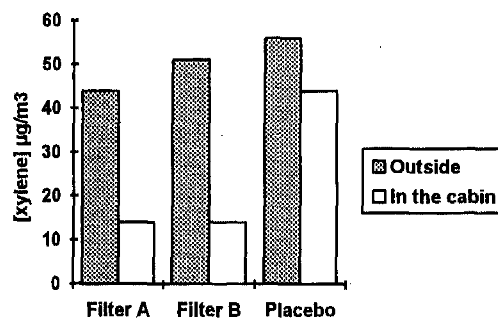

Figure 9 : Xylene concentrations measurement.

Filters efficiency - The efficiency is calculated according to the formula :

$$E\ (\%) = 1 - \frac{\text{Concentration in the cabin}}{\text{Concentration outside}}$$

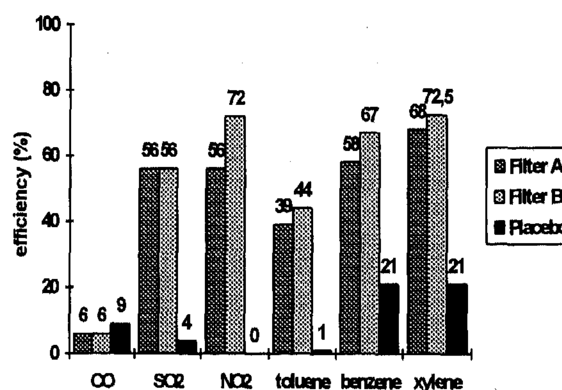

Figure 10 : Efficiency values

The efficiency of filters A and B is demonstrated in vehicle for SO_2, NO_2 and toluene. The efficiency is significant for indicators present in large concentrations. This is confirmed by the results of no efficiency obtained with the placebo. But for benzene and xylene, the level of concentration is too low to permit a precised efficiency calculation because the placebo shows 21% efficiency and this is not the true.

If a global efficiency is calculated on the 3 significant indicators, filter A is associated with a value of 48% and filter B with 57%. Filter B seems to be a little more efficient than filter A.

LABORATORY AND VEHICLE EFFICIENCY COMPARISON

TEST CONDITIONS COMPARISON - The following test parameters can be considered : temperature, relative humidity, airflow, gas concentration.

	VEHICLE	LABORATORY
Temperature	14 to 33°c	23°c
Humidity	30 to 50%	45%
Airflow	245m³/h	200m³/h
Concentration of		
toluene	80ppb	80ppm
SO_2	61ppb	30ppm
NO_2	113ppb	30ppm

The biggest difference comes from a factor 1000 between the gas concentrations. The gas feeding in laboratory is homogenous while it is more turbulent in vehicle. On top of that, the sample points are placed in a stable zone of the bench, that does not exist in vehicle.

RESULTS COMPARISON - Results of filter A and B characterization in the laboratory exist only for toluene.

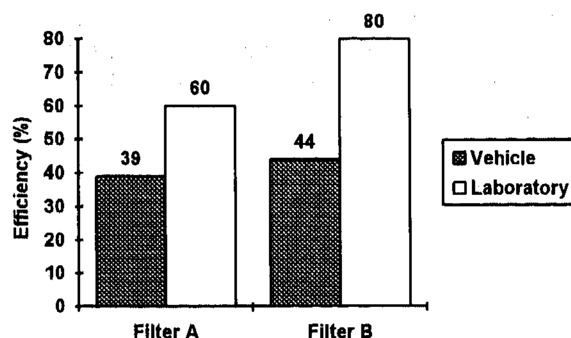

Figure 11 : Toluene effciency comparison

On this particular comparison, the laboratory characterization is more optimistic than the real evaluation. The efficiency is multiplied by 1,5 for filter A, and by 1,8 for filter B.

Obviously, conditions of tests are very different and can affect the results. Only a second campaign would confirm these first results.

CONCLUSION

This study shows that it is possible to evaluate filter efficiency in the vehicle. However, the necessary methods employed are heavy to implement and difficult to use systematically.

But it is clear that absorptive filters improve distinctly air quality in the vehicle. The tested filters reduce disturbing gases concentrations like SO_2, NO_2 and toluene by 40 to 70%. A little difference can be noticed between the two filters tested, A and B, but they are quite similar.

In this example and for toluene, the efficiency evaluation in vehicle is lower than the laboratory characterization. The conditions are very different but it would be interesting to confirm this comparison in a next campaign.

The other parameter which could be interesting to test, would be the real life time of adsorptive filters. Compare the capacity of adsorption measured in laboratory to real aging filters, could help to know the correlation between gram of test gases and filters life time. A next study could try to evaluate this feature.

ABSTRACT

This paper investigated the characteristics of the magnetic field and the attractive magnetic force in a magnetic clutch of the automotive air conditioner. The magnetic force was calculated by using the finite element method, the principle of virtual work and the Maxwell stress tensor, and it was measured by experiment. Magnetic field is not affected by the pulley groove and the attractive magnetic force is also not significantly affected by the bearing because the total magnetic field in the airgap is not changed. The magnetic force increases rapidly as the airgap decreases. The bridges in the disk and the pulley decrease the magnetic force because they create the radial flux to saturation and reduce the effective axial magnetic flux in the airgap to the amount of the radial magnetic flux flowing in the bridges. Also the magnetic force is decreased proportionally as the increase of the cross-sectional area of bridge.

INTRODUCTION

The magnetic clutch is widely used as a device to transmit the power of an engine to a compressor to drive the automotive air conditioner. Figure 1 shows the magnetic clutch with four poles. The current in the coil produces the closed magnetic flux path along the pulley, the airgap and the clutch disk, which results in the attractive magnetic force in the air gap between the rotary pulley and the stationary disk in order to engage the clutch disk to the rotary pulley. The excessive magnetic force results in the high impact force when the disk is engaged, and too little force does not allow the engagement of the disk.

This paper investigated the magnetic field and the attractive magnetic force, and the performance of magnetic clutch due to the variation of design parameters of the magnetic clutch. A finite element method (FEM) was used to analyze the magnetic field in the magnetic clutch. Magnetic nonlinearity was included by using the BH curves of the disk and the pulley measured by the Hysteresisgraph system. The attractive magnetic force was calculated by the principle of virtual work or the Maxwell stress tensor, as needed. Also an experimental setup was built and the attractive magnetic force was measured in the universal tension machine to verify the result of FEM. Finally, the design parameters of the magnetic clutch were thoroughly investigated in order to see how they affect the magnetic field and the magnetic force.

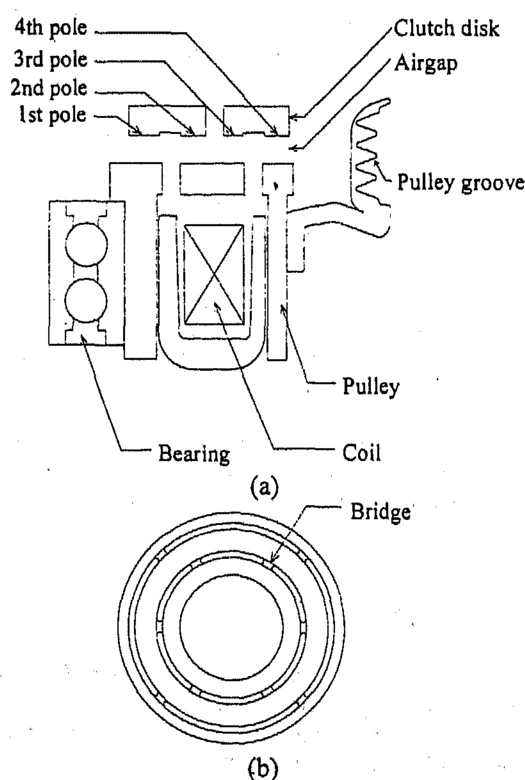

Figure 1: (a) Cross-section of the magnetic clutch with four poles
(b) Top view of the pulley

METHOD OF ANALYSIS

MAGNETIC FIELD AND MAGNETIC FORCE - The magnetic field generated by a magnetic clutch is described by the set of Maxwell's equations. Introducing the scalar potential into the Maxwell's equations, with some mathematics, gives a single partial differential equation for the scalar potential Φ.

$$\nabla^{T}\cdot\mu\nabla\Phi - \nabla^{T}\cdot\mu\mathbf{H}_s = 0 \qquad (1)$$

In this equation, μ is the permeability and $\mathbf{H}_s$, the field intensity due to the current in the coil may always be calculated directly by the Biot-Savart law.

$$\mathbf{H}_s = \frac{1}{4\pi}\int_{\Omega}\frac{J \times R}{|R|^3}d\Omega \qquad (2)$$

The governing equation, like the Poisson's equation for electrostatic fields, can be solved using the finite element method. ANSYS, a FEM solver for magnetic field, was used to calculate the scalar potential Φ and the magnetic field intensity, H.

A non-uniform distributed force per unit area at the interface between two materials is calculated by introducing the Maxwell stress tensor. Since the strain imposed on the material due to magnetostriction is small enough to neglect changes in the density, it can be assumed that the change of permeability is negligible. Thus, in tensor notation,

$$\sigma_{ij} = \frac{1}{\mu}\left(B_i B_j - \frac{1}{2}\delta_{ij}B_k B_k\right) \qquad (3)$$

where σ_{ij} is the Maxwell stress tensor. B_i is the magnetic flux density which is obtained by the multiplication of permeability to the magnetic field intensity. From the expression given by Woodson and Melcher(1985) for an interface between two materials a and b, the traction, f_i, is given by :

$$f_i = (\sigma_{ij}^{a} - \sigma_{ij}^{b})n_j \qquad (4)$$

The normal and the tangential traction can be decomposed.

$$f_n = (\sigma_{ij}^{a} - \sigma_{ij}^{b})n_i n_j \qquad (5)$$

$$f_t = \sqrt{|f_i|^2 - |f_n|^2} = |\mathbf{n} \times \mathbf{f} \times \mathbf{n}| \qquad (6)$$

Since $\mu_{air} << \mu_{iron}$, the magnetic traction can be simplified by the introduction of the cylindrical coordinate. Along the air gap, the normal and the tangential traction are as follows:

$$f_z \approx \sigma_{zz}^{a} = \frac{1}{2\mu_{air}}(B_z^2 - B_x^2 - B_y^2) \qquad (7)$$

$$f_x = f_y \approx \sigma_{xy}^{a} = \frac{1}{\mu_{air}}B_x B_y \qquad (8)$$

The magnetic force in the axial direction produced for one position can easily be derived from the integration of the normal force along the small air gap.

$$F_z = \int_S f_z \, dS \qquad (9)$$

The concept of virtual work may also be used to obtain the magnetic force. The stored energy in a magnetic field is as follows.

$$W = \int_{\Omega} B\cdot H \, d\Omega \qquad (10)$$

If the disk is moved by an infinitesimal distance δz, the work done is the product of the component of force in that direction F_z and δz. This work must come from the stored energy W of the system with the fact that the field distribution inside a closed surface in air remain unchanged if the external sources are not removed and replaced by currents and poles on the surface:

$$F_z = -\frac{\delta W}{\delta z} \qquad (11)$$

The magnetic force calculated by the virtual work has higher accuracy than that by the Maxwell stress tensor, because the energy computation is of an order of accuracy higher than the potential. However, the virtual work method does not produce the distribution of magnetic force.

FINITE ELEMENT MODEL - The magnetic clutch without bridges has the rotationally symmetric geometry with respect to z-axis, i.e. axisymmetry. Axisymmetric 2-dimensional FEM model was constructed as shown in Figure 2. 4 nodes quadrilateral and 3 nodes triangular elements are used, and it has fine mesh in the airgap. The total number of node and element are 12,149 and 12,107 respectively.

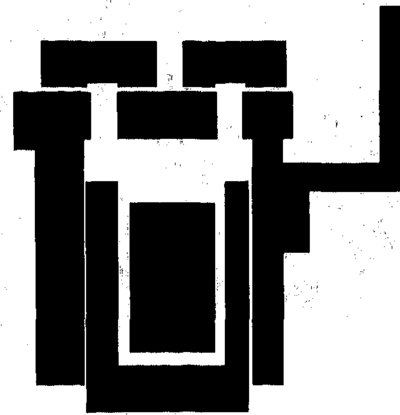

Figure 2: Axisymmetric 2-dimensional FEM Model

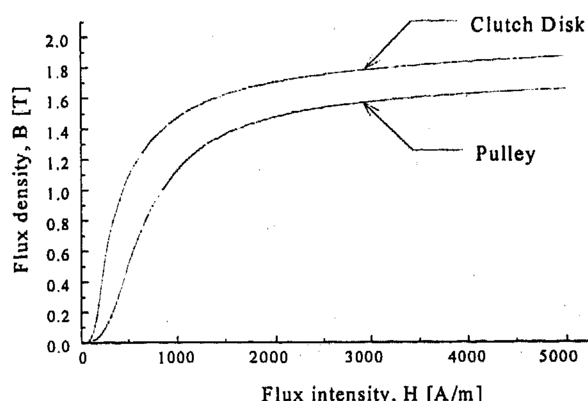

Figure 3: BH curves of the clutch disk and the pulley

The applied current of coil is assumed to be 2.9 A x 273 turns, and Figure 3 shows the BH curves of disk and pulley measured by the Hysteresisgraph system. ANSYS, a FEM solver was used to analyze the magnetic field of the magnetic clutch. Because it is relatively easier to construct than 3-dimensional model, this model was first investigated to see the role of each component and then 3-dimensional model was constructed without including the pulley groove and the bearing which do not affect the magnetic field in the airgap.

Because the magnetic flux flows within every quarter when the bridges of the disk face the bridge of the pulley exactly, the magnetic field of the whole magnetic clutch can be obtained by analyzing only one-quarter of the magnetic clutch as shown in Figure 4, with Neumman boundary condition at each cross-section. It was built with 8 nodes brick element and the total number of elements and nodes are 12,976 and 49,101 respectively. Again, ANSYS was used to analyze the magnetic field with the generalized scalar potential method. It takes about 4500 CPU sec with Cray YMP 4E for one position to solve the nonlinear magnetic field and to calculate the magnetic force by the principle of virtual work.

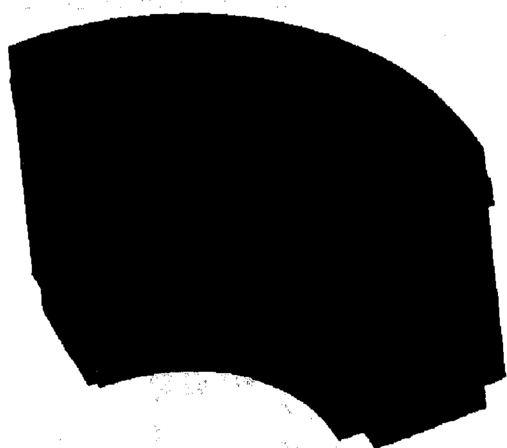

Figure 4: 3-dimensional FEM model of the magnetic clutch

EXPERIMENTAL SETUP - Figure 5 shows the experimental jig to measure the magnetic force of the magnetic clutch with the universal tension machine (UTM). The jig was made by aluminum to prevent the magnetic flux leakage. The pulley and the disk are attached to the jig and the aluminum sheets (0.3-0.7mm) are inserted between the disk and the pulley to measure the magnetic force for the different thickness of the airgap existing between the disk and the pulley, because the permeability of aluminum is almost same as that of air.

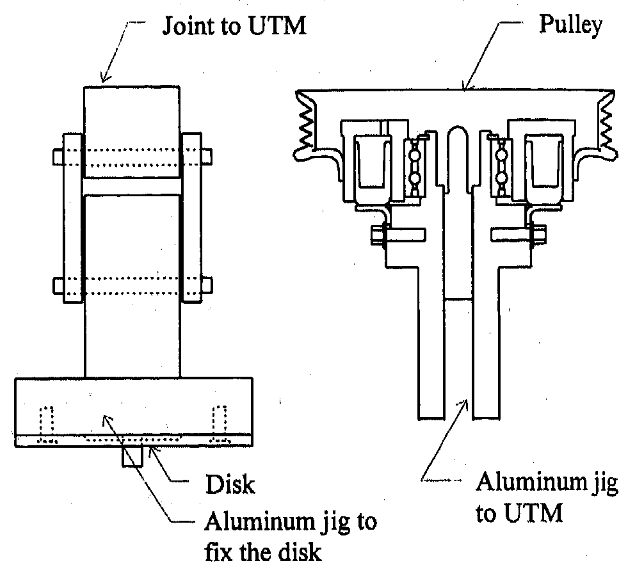

Figure 5: Experimental setup

RESULTS AND DISCUSSION

The geometry of magnetic clutch is so complicated that it must be simplified for the construction of a FEM model. The effect of pulley groove was investigated by analyzing the axisymmetric 2-dimensional FEM models for a case with a pulley groove and another case without it, when it has 0.6mm airgap. Both cases resulted in the same magnetic field in the airgap and the same magnetic force of 246.3 N, because the pulley groove plays the role of a magnetic open circuit which does not affect the total magnetic field along the airgap.

Figure 6 shows the variation of the magnetic force due to the existence of the bearing. The magnetic force was measured in the experimental setup as shown in Figure 5. The magnetic force with the bearing is almost the same as the force without it, because the total magnetic flux in the airgap is not significantly affected even though there may be minor change of the magnetic flux near the bearing. Based on the above observation, the pulley groove and the bearing were eliminated in the FEM model.

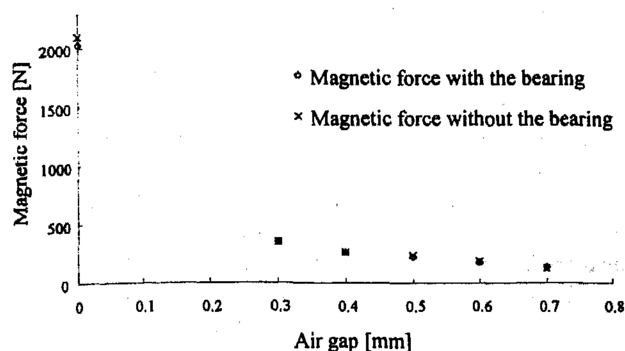

Figure 6: The variation of the magnetic forces due to the existence of the bearing

Figure 7 shows the calculated magnetic force and the measured magnetic force due to the different airgap thickness. The magnetic force is increased rapidly as the airgap is decreased. The discrepancy between the simulation and the experiment becomes larger as the airgap is decreased. The discrepancy between the axisymmetric 2-dimensional simulation and the experiment is relatively larger. But 3-dimensional model fairly decreases this discrepancy. The main difference between the axisymmetric 2-dimensional and 3-dimensional model is the bridges which connect poles in the pulley and the clutch disk as shown in Figure 1. The remaining discrepancy would be from the factors which are not included in 3-dimensional FEM model such as the rivet holes in the disk bridges, convexity of disk and surface roughness.

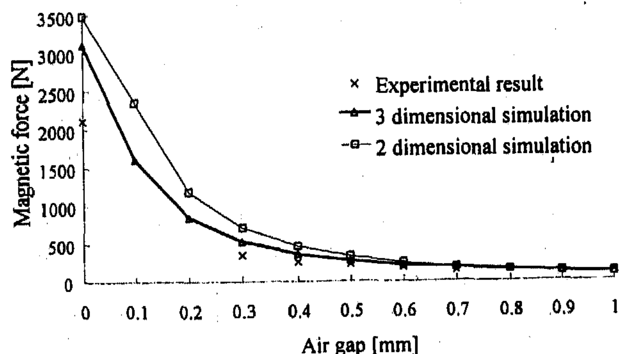

Figure 7: The calculated and the measured magnetic force

Figure 8 shows the contour plot of magnetic flux density in the pulley and the disk (0.6 mm airgap). High magnetic saturation is observed in the bridges of the pulley and the disk. Magnetic flux easily flows through the bridges not across the airgap because the permeability of iron is several hundred times greater than that of air. This results in the reduction of magnetic force because the bridges reduce the effective axial magnetic flux.

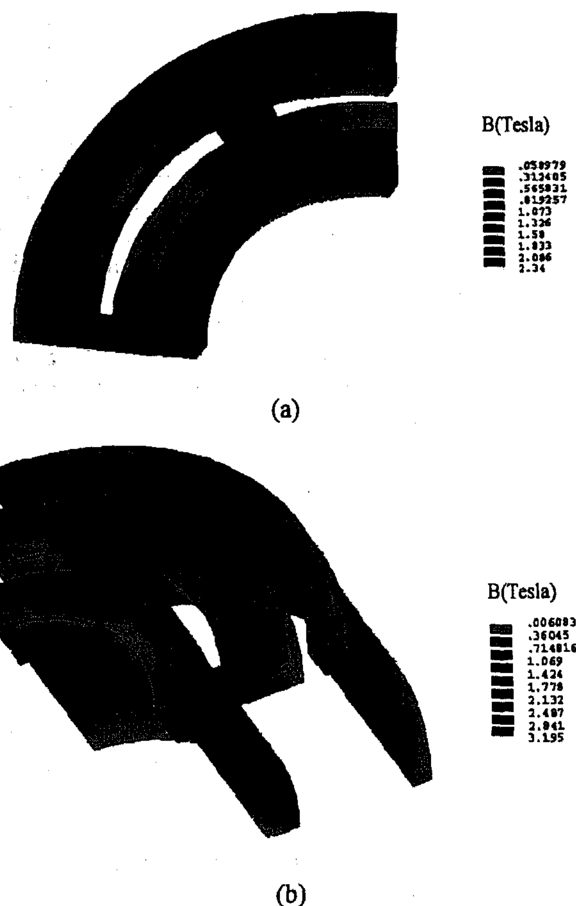

Figure 8: (a) The contour plot of the magnetic flux density in the disk
(b) The contour plot of the magnetic flux density in the pulley

Figure 9 shows the variation of the magnetic flux density in the bridges as the variation of the airgap. Even though the magnetic flux in the bridge is slightly decreased as the airgap is decreased, there are still high saturation of magnetic flux due to the large permeability of iron.

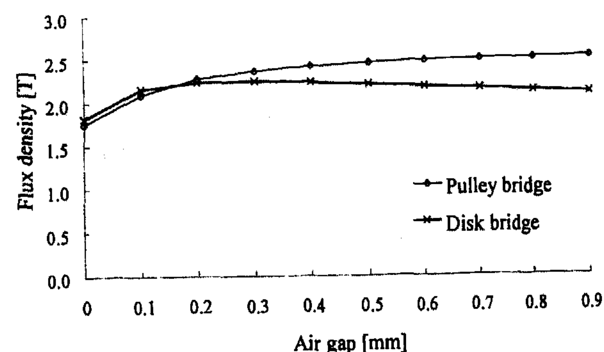

Figure 9: The variation of the magnetic flux density in the bridges

Figure 10 shows the variation of the magnetic force due to the variation of the cross-sectional area of the bridge. The magnitudes of the magnetic force are decreased as the cross-sectional area of the bridge is increased in the order of no bridge, bridge with 0.25 mm undercut, and bridge without undercut. The undercut in the bridge is defined as the axial removal of bridge from the disk and pulley surface. 0.25 mm undercut of the bridge reduces the effective cross-sectional area by 5 % and reduces the magnetic force by 8-17%. In the bridge, the magnetic flux flows radially until the bridge is saturated. The effective axial magnetic flux across the airgap is decreased to the amount of the radial magnetic flux flowing in the bridge, so that the attractive magnetic force is decreased.

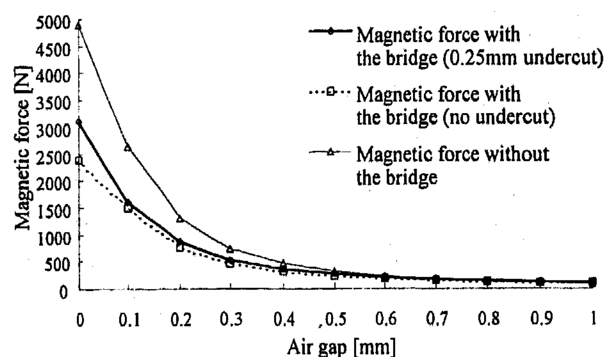

Figure 10: The variation of the magnetic force due to the area of bridge

The pulley of the magnetic clutch has six bridges inside (between the 1st and the 2nd pole) and four bridges outside (between the 3rd and the 4th pole). The effect of the location of bridges is investigated by analyzing another design of pulley with four bridges inside and six bridges outside. Figure 11 shows the magnetic force for both models. They produce almost the same magnetic force irrespective of the location of bridges, because they have the same effective cross-sectional area of bridge.

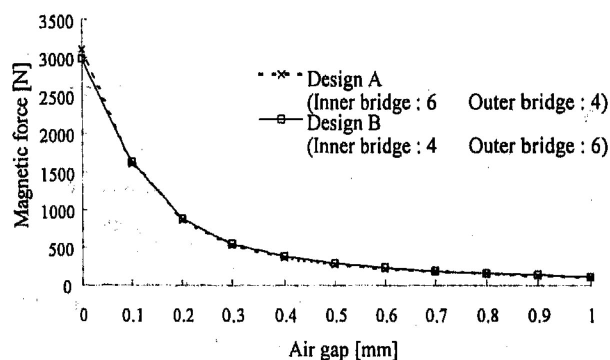

Figure 11: The variation of the magnetic force due to the location of bridges

CONCLUDING REMARKS

A method of analysis of the magnetic field and the magnetic force in the magnetic clutch has been presented from FEM, Maxwell stress tensor, the principle of virtual work and some experiments. Magnetic field is not affected by the pulley groove and the attractive magnetic force is also not significantly affected by the bearing because the total magnetic field in the airgap is not changed. The magnetic force is increased rapidly as the decrease of the airgap. The bridges in the disk and the pulley decrease the magnetic force because they are easily saturated and reduce the effective magnetic flux in the axial direction to the amount of the radial magnetic flux flowing in the bridges. Also the magnetic force is decreased proportionally as the increase of the cross-sectional area of bridge.

While the magnetic force allows the clutch disk to be engaged with the rotary pulley, the engagement occurs in a very short time, followed by impact with enormous impact force, and slipping between the disk and the pulley before firm engagement. Because the operation of the magnetic clutch is determined by the dynamic phenomena of the impact and the slipping as well as the characteristics of the attractive magnetic force, they should be thoroughly investigated in order to produce the magnetic clutch of high quality.

Simulation and Modeling of an A/C Rotary Vane Compressor

S. Takeshita
Zexel USA

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

A simulation model and code suitable for rotary vane compressor are developed. The simulation features are the compression algorithm that makes extensive use of entropy tracking and the real R134a properties in the form of look-up table rather than a polytropic equation. Compression process is modeled as an isentropic process with mass flow into and out of the compression chamber due to leaks between compression chambers and flow through the valves. It was found, during the course of algorithm development, that valve back flow has a significant influence. The simulation output including torque, torque variance, heat capacity, coefficient of performance compare quite favorably with experimental measurements. To demonstrate how the simulation may provide useful insight for design and parts optimization, two simulation examples, one dealing with the effect of varying aspect ratio and the other with cylinder profile characteristics, are presented.

1. INTRODUCTION

It has become common practice to utilize computer simulation of a new product in order to reduce the development time. The simulation model of the product should contain the essential features that are important to the designer and often requires the incorporation of highly nonlinear behavior in order to be useful. This code is written to provide a simulation realistic enough to be a useful design tool, yet is easy and "light" enough even for a lap-top.

In previous simulations, particularly the ones with simplified algorithms, the compression process is described by a polytropic relationship between volume and pressure with a single polytropic coefficient [1]. The polytropic relation is derived from the treatment of working fluid as an ideal gas and the compression process as completely isentropic and leak-free compression. In other words, the property of the working fluid and the description of the compression process are coupled to yield the polytropic description.

Other simulation models are based on energy conservation, and require input of empirical parameters such efficiency. It is quite justifiable since the focus of the simulation is not the compression per se, but related phenomena such as heat transfer between working fluid, lubricant and components [2], and acoustic interaction between chambers or valve dynamics [3].

In this simulation, the compression process is treated as a combination of isentropic compression of the gas inside of the compression chamber and flow of gas into and out of the chamber with irreversible mixing. The thermodynamic property of the working fluid is given by the use of look-up table. Unlike the polytropic description of the process, the behavior of gas and compression process are encapsulated rather than interwound. The description of the compression becomes canonical through tracking of entropy and the addition of mass flow through gaps and valves.

Some of the parameters that are necessary as simulation input were not obtained, thus the simulation code is used to determine them by best-fitting a number of experimentally obtained pressure profiles. The code is then verified by comparison of output with measurement data other than those used in computing the parameters. Examples of how the simulation can be used in predicting the influence of design parameter are introduced to provide some insights into cylinder design.

2. DESCRIPTION OF PHYSICAL MODELING

The simulation code is written for rotary vane compressor with five vanes and cylinder with two fold point symmetry, namely Zexel KC_XX type compressors. The compressor is of variable capacity type. A brief cross-section diagram is shown in Figure 1.

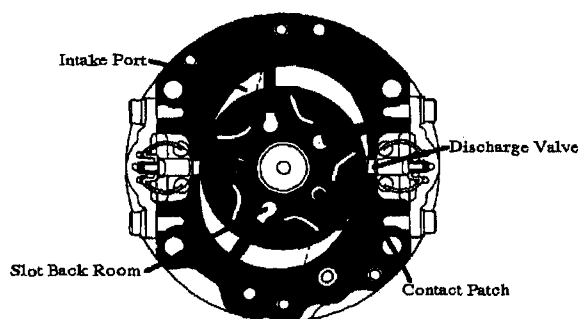

Figure 1. Cross-section of Zexel KC_XX Compressor

2.1. WORKING FLUID

A look-up table for R134a thermodynamic properties was constructed in an encapsulated subroutine form. It accepts any two of the seven state functions (T, P, x, v, u, h and s) and computes the other by interpolation and/or reverse interpolation. It also computes dependent properties such as heat capacities, acoustic speed, and viscosity. It provides encapsulated description of refrigerant behavior over a very wide region, including compressed liquid and saturated mixture. The table can be used in simulations of heat exchangers and of the entire system. The values of thermodynamic functions were taken out of Makita, et. al. [4]

It has been customary to model the refrigerant gas as a polyatomic ideal gas, that is, it obeys the ideal gas law, but its heat capacity is a function of temperature. In many works, this model is further simplified by assuming a constant ratio of specific heats, typically around 1.1, which is much more realistic than the specific heat ratio for monatomic ideal gas of 5/3. Nevertheless, in such scheme, the property of refrigerant and the characteristics of the compression path are intertwined.

The compression process is modeled as an approximately isentropic process, more precisely, an isentropic process with corrections due to gas flow in and out of compression chamber. The isolation of the gas property and compression process itself is a desirable feature to properly incorporate the corrections.

A good measure of the validity of the ideal gas approximation is the compressibility. If it is close to unity throughout the compression path, the ideal gas is a good approximation. In our preliminary investigation, we found out that this may not always be the case. In Temperature-Entropy diagram, a typical compression process shows itself to be very near the saturated gas line. While the compressibility stays close to unity when the discharge pressure is relatively low, the compressibility starts deviating from unity as the pressure becomes higher. The designed compression path may be in approximately ideal region, but the simulation must also be able to analyze operating conditions that are out of designed scope.

2.2. COMPRESSION

The compression process is modeled in two parts. Consider the compression process between time t_0 and $t_1=t_0+\Delta t$. The compression of the gas that is in the chamber at time t_0 is modeled by isentropic compression. The other part is the leak into and out of the chamber that takes place between time t_0 and t_1. The leak and flow through valve are described in the next section. For now, it is a certain amount of gas in a certain state that enters the chamber. The heat transfer, including that due to friction, is not yet accounted for this version of simulation.

The state of chamber at t_1 is computed from the state at t_0. The mass in the chamber increases by the amount of the net flow into the chamber.

$$m_1=m_0+\Delta m_{in}-\Delta m_{out} \qquad (1)$$

where $\Delta m_{in}=\Delta m_{in}$ (origin state, chamber state; flow geometry)
$\Delta m_{out}=\Delta m_{out}$ (destination state, chamber state; flow geometry)

The internal energy in the chamber can be approached in two ways. The first is the use of the first law of thermodynamics exclusively, and the second is the incorporation of the second law for the compression process.

The first law treatment is simple energy balance.

$$U_{1P}=U_0 + \Delta Q - \Delta W + \Delta m_{in}h_{in} - \Delta m_{out}h_{out} \qquad (2)$$

where U_{1P} is the total internal energy in the chamber at t_1,
$= m_1u_1$,
U_0 at t_0, $= m_0u_0$,
ΔQ is the heat flow,
$=0$ for this analysis,
ΔW is the work done,
$=$ P(chamber state)ΔV,
h_{ini} is enthalpy of the incoming gas,
$= h$ (origin state),
h_{out} is enthalpy of the outgoing gas,
$= h$ (chamber state)

This model is used in predictor part of the calculation.

The other treatment arises from the model of compression part per se being isentropic. The work to compress the gas comes mostly from the change in the chamber volume but also, in small part, comes from the gas that is entering the chamber through the leak. This formulation allows the removal of work variables.

$U_{1C}=U_{0C} + \Delta Q + \Delta m_{in}u_{in} - \Delta m_{out}u_{out}$ (3)

where U_{1C} is the total internal energy in the chamber at t_1,
$= m_1u_1$,
U_{0C} is the energy of the isentropically compressed gas,
$= m_0u(P_1, s_0)$,
$\Delta Q = 0$, as before,
u_{in} is internal energy of the incoming gas,
$= u$(origin state),
u_{out} is internal energy of the outgoing gas,
$= u$(chamber state)

This model is used in corrector calculation.

The derivation of corrector equation (3) arises from the modeling of compression process to be isentropic to gas present in the chamber from t0 to t1. The work done onto the gas present in chamber comes from the work of the chamber and the net of the work done by the gas incoming and outgoing.

$$\Delta W_{chamber} = P\Delta V = \Delta W(\text{gas compression}) - \Delta m_{in}P_{in}v_{in} + \Delta m_{out}P_{out}v_{out} \quad (4)$$

Noting that, for the isentropic compression, the energy relationship for the gas present in the chamber is

$$U_{1C}=U_{0C} + \Delta W(\text{gas compression}) \quad (5)$$

Combining equations (2), (4) and (5) yields equation (3) representing the second scheme. The second method automatically incorporates assumptions (4) and (5). As stated earlier, the compression is modeled as fundamentally an isentropic compression with flows from leaks and valves. The second scheme follows more closely this canonical description of the process.

2.3. LEAK

For rotary vane and scroll type compressors, the leakage plays a major role in determining the compressor thermodynamic characteristics. In modeling this characteristics, leakage through the contact patch into the suction plenum and sides of the vane into the following chamber are considered, as they are the dominant leak mechanism.

The model employed is Fanno flow with possible (and probable) choking at the exit of the gap. The model is further explained with Figure 2, which shows various ranges of Fanno flow. Typical Fanno flow without choking starts out with isentropic acceleration from the initial stagnation state. The gas then enters the gap, which provides friction resulting in the increase of entropy as well as drop of pressure. The gas isentropically decelerates to stagnation after exiting from the gap. This process is shown in the Figure as path 00->0->1->10.

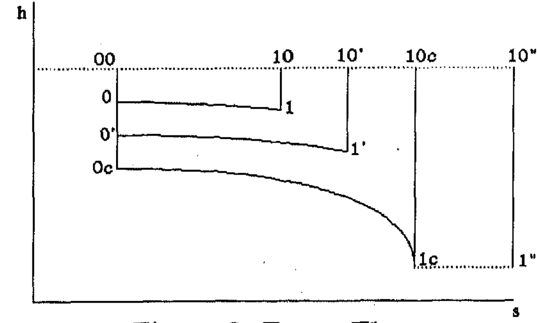

Figure 2. Fanno Flow

When the pressure difference is increased, a similar path is taken, but for higher flow density, it is shown in the figure as 00->0'->1'->10'. If the pressure difference is further increased, the flow will become critical at the exit of the gap This path is shown as $00\text{->}0_C\text{->}1_C\text{->}10_C$. The exit state 1_C is the point of maximum entropy on Fanno curve. If the pressure difference further increases, the flow up to the gap exit will remain the same and choking, which is the abrupt increase in entropy associated with abrupt drop in pressure, at the exit of the gap will occur. This is shown as $00\text{>}0_C\text{->}1_C\text{->}1''\text{->}10''$. For the most of flow across the contact patch of vane sides, the pressure difference is high enough for choking to occur. Thus, the flow density of the critical flow will be the flow quantity of the gap. The following relationship exists between the exit stagnation state and the flow density G, because the sum of enthalpy and kinetic energy is conserved.

$$h_{10C} = h_1 + \frac{1}{2}c_{s1}^2 = h_1 + \frac{1}{2}G^2v_1^2 \quad (6)$$

where c_{s1} is the acoustic speed at state 1,
v_1 is the specific volume at state 1.

An iteration scheme to obtain G from s_1 or vice versa is easily constructed from Equation (6).

While the energy conservation of Fanno flow provides a relationship between the flow density and entropy increment, we need yet another relationship to solve this problem with two unknown - the flow density and one of the state variables for the exit state. The other relationship is provided by examining how entropy increases by generation of lost work due to the friction with the gap walls. The entropy increase of the gas is associated with the generation of lost work due to the friction between the wall and the flowing gas. The lost work over the Δx segment of the gap is computed from the shear stress at the gap walls, as shown in Figure 3.

$$fdx=w_{Gap}(\tau(x, y=\frac{h_{Gap}}{2}) - \tau(x, y=-\frac{h_{Gap}}{2}))\, dx \quad (7)$$

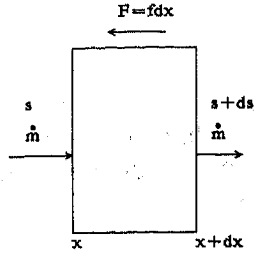

Figure 3. Entropy Increase in a Control Volume

where fdx is the frictional force generated within the differential segment
w_{Gap} is the width of the gap
τ is the shear stress, = μ ($\partial u/\partial y$)
μ is the viscosity

The lost work generation rate due to this friction force is

$$d\dot{L}W = fdx\ Vel = fdx\ vG \quad (8)$$

where $\dot{L}W$ is the total lost work generation rate,
$d\dot{L}W$ is that due to the differential segment,
Vel is the average velocity of the flow

Since the lost work generated contributes to increment of entropy equal to that divided by the temperature, the entropy increase that occur in the differential segment of the gap is given by the following.

$$dS = AG\ ds = d\dot{L}W/T = (fvG/T)\ dx$$
$$= AG\ (fv/AT)\ dx \quad (9)$$

where dS is the infinitesimal increase in the total entropy the segment,
A is the cross-sectional area of the gap $= h_{Gap}w_{Gap}$,
G is the flow density,
ds is the infinitesimal change in specific entropy

Thus, the increase in entropy over the length of the gap is

$$\Delta s = \int_0^{l_{Gap}} (fv/AT)\ dx \quad (10)$$

where l_{Gap} is the length of the gap

The relationship between entropy increase and flow density is derived from this equation. The following velocity profile is assumed for the derivation.

$$u(y)=u_{max}(1-(\frac{2y}{h_{Gap}})^{2n}) \quad (11)$$

where u(y) is the flow component along the gap,
y is the position within the gap,
y=0 being at the center of the gap,
h_{Gap} is the height of the gap,
n is the shape parameter,
4 to 5 for turbulent flow.

n=5 is used for this calculation. The entropy increase associated with the increment of lost work is the lost work divided by the temperature. The gap cross-section is also assumed to be constant through the length of the gap. Furthermore, the pressure profile is assumed to be linear. Finally, the relationship between the exit stagnation state (entropy) and the flow density G is given by

$$G= \frac{\Delta s\ h_{Gap}^2 SF(n)}{l_{Gap} < \frac{\mu v^2}{T} >_L} \quad (12)$$

where SF(n) is shape factor dependent on n,
$= (2n+1)/8n^2$
$<>_L$ indicates the average over the gap

The two relationships between the flow density G and entropy increase shown in Equations (6) and (12) are shown in Figure 4. Computations based on standard fixed point iteration can be performed to find out what the flow would be given the source state, gap dimensions, and sink pressure.

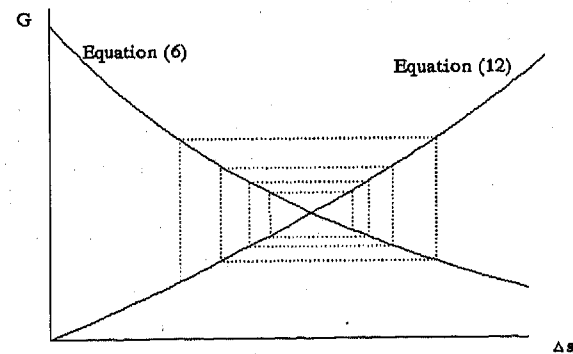

Figure 4. Relationship between G and Δs

The computations indicate that the choking would occur in most gap flow we are considering, that is, the pressure drop is quite small within the gap and the most of the pressure drop occurs at the exit of the gap. The gap flow density, therefore, is mostly a function of the flow origin state and the gap geometry. This also may provide an explanation for the findings that gap flow is better described using incompressible fluid model than compressible model without choking [5].

Unfortunately, this model still has two major flaws at the time of the writing. One is that the computation time is excessive; it costs as much computation time to compute one instance of gap flow as to compute the

entire cycle of compression chamber (with less sophisticated gap flow model). The other is that the computation is unstable in some regions on Δs-G map. To circumvent these problems, the computation is carried out for various combination of flow origin state and gap geometry for Freon 134a. An empirical formula created from the calculation results using linear regression in logarithm domain is used in the compressor simulation itself.

$$\ln G = a_0 + a_1 \ln l_{Gap} + a_2 \ln h_{Gap} + a_3 \ln P_{00} + a_4 \ln T_{00} \qquad (13)$$

where G is the flow density in kg/m²-sec
l_{Gap} is the gap length in m
h_{Gap} is the gap height in m
P_{00} is the origin stagnation pressure in MPa
T_{00} is the origin stagnation temperature in K
$a_0 = 20.69511$
$a_1 = -0.28968$
$a_2 = 0.659064$
$a_3 = 1.362197$
$a_4 = -1.22644$

2.4. VALVE

Valve characteristics that are important to the simulation are: (1) the forward flow from the compression chamber into the discharge plenum, and (2) the back flow. The forward flow characteristics determines the amount of excess compression and lost work, and is quite extensively studied. Back flow also plays an important role. During the preliminary investigation, it was found to be the most prominent correction to isentropic compression.

At this stage, the dynamic aspect of the valve behavior is not dealt with, since the simulation itself is that of steady state or constant rpm. Full dynamic response from the valve will be incorporated in the future for dynamic simulation with transient behavior. For both the forward and backward flow, the valve is modeled as a simple relationship between the mass flow rate and the pressure difference between the compression chamber and the discharge plenum.

The forward flow is modeled to be proportional to the 3/2 power of the pressure difference. The flow quantity is proportional to flow area and flow speed. The area is proportional to the lift of the valve, which is proportional to the pressure difference, and the flow speed is roughly proportional to the square root of the pressure difference. If the change in specific volume due to the pressure drop is not significant, these assumption correspond to the simplest model implied in Soedel [6].

$$dm/dt = C_F(\Delta P)^{3/2} \qquad (14)$$

where C_F is the constant for each valve

This hypothesis is confirmed by calculating the forward flow from the measured pressure data and plotting it against the pressure difference. Data from different operating condition (i.e. different rpm and discharge pressure) seem to line up the best for the power of 3/2. Of course, the coefficient can be derived from direct measurement.

The back flow is modeled differently, as the mechanism is quite different. The flow is assumed to be similar to the gap flow, where the gap closes as the pressure difference increases.

$$dm/dt = C_B(1-\Delta P/P_{CL})\ \Delta P^{1/2} \qquad (15)$$

where C_B and P_{CL} are valve dependent constants

The flow speed, again, is assumed to be proportional to the square root of the pressure difference. The better sealing of valve under higher pressure difference is represented by the term $(1-\Delta P/P_{CL})$. The coefficients can be based on actual measurement. In this simulation, these coefficient are determined by best fitting to the actual pressure data.

Another dynamic effect of the valve is the inertial delay of the closure, which causes the back flow as the vane crosses the discharge port. This is simulated by one time mass dump.

2.5. VANE AND ROTOR FORCE AND TORQUE LOADING

The vane loading is shown in Figure 5. The pressure in the back room of the vane is assumed to be the average of the two chambers adjacent to the vane. The friction between the vane and the rotor, or the friction between the vane and the cylinder wall are assumed to be dry friction characterized by one coefficient of friction.

The torque is computed by loading on the rotor

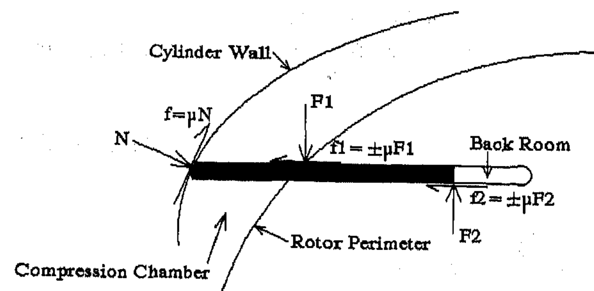

Figure 5. Vane Loading
(Pressure loading not shown)

coming from the vane and the pressure in the back room.

2.6. CYCLE EFFICIENCIES

Efficiency values that are of interest are volumetric efficiency of the compressor and coefficient of performance (COP) or the beta value for the entire cycle.

The volumetric efficiency is defined to be net mass flow rate divided by the product of compressor speed, compression chamber volume at the end of suction process and the density of the gas. In our case where there is no significant suction loss between the suction plenum and compression chamber, it is computed as the net mass that is discharged into the discharge plenum during one cycle of compression divided by the mass of gas that is present in the compression chamber at the start of compression, that is, when the compression chamber is physically separated from the suction plenum.

COP is the ratio of the heat absorbed in the evaporator divided and the work consumed by the compressor. A typical refrigeration cycle is shown on P-h diagram in Figure 6. Let subscript 1 denote the compressor inlet and evaporator outlet, 2 the compressor outlet and condenser inlet, 3 the condenser outlet and throttle valve inlet, and 4 the throttle valve outlet and evaporator inlet. Then, COP should be given by the following formula.

$$COP_{Experiment} = q_L/w_C = (h_1-h_4)/(h_2-h_1) = (h_1-h_3)/(h_2-h_1) \quad (16)$$

where q_L is heat absorbed per unit mass of refrigerant

w_C is the compressor work per unit mass of refrigerant flow

Rather than use the exact formula above, which involves the simulation and measurement of the entire cycle, we have chosen to use an approximate version in which the effect of pressure drop of the condenser is approximated by 5°C of subcooling. Thus, the cycle on which our COP calculation is based on is shown in the Figure as 1-2-3'-4'-1. Thus, the COP of our calculation is given by the following equation.

$$COP_{Simulation} = q'_L/w_C = (h_1-h_{4'})/w_{C'} = (h_1-h_{3'})/w_{C'} \quad (17)$$

where q'_L is the estimate of heat per unit mass of refrigerant based on 5°C subcooling

$w_{C'}$ is work required on the part of compressor per kg of discharged refrigerant, from the computation

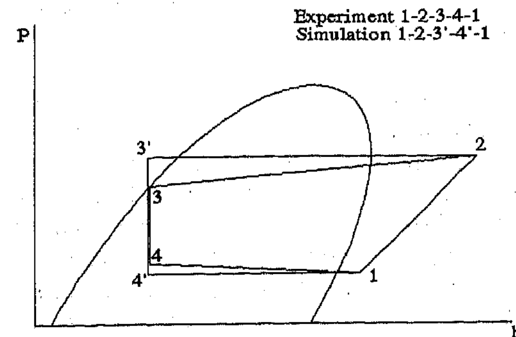

Figure 6. P-h Diagram for Refrigeration Cycle

3. DESCRIPTION OF NUMERICAL MODELING

3.1. INPUT AND OUTPUT

Two versions of the simulation were written; interactive and batch. In the interactive version, the input procedure is menu driven and the input data file for the batch version is organized in a fashion closely resembling the interactive menu. There are four menus for entering Design Parameters, Tolerance Parameters, Operation Parameters, and Computational Parameters. The Design Parameters menu contain items such as geometry of the cylinder and valve characteristics. The Tolerance Parameter menu contains various gap dimensions. The Operation Parameters menu contains such items as speed (in rpm), discharge pressure, and suction state. The Computational Parameter menu contains such items as the size of discretization of angular position, iteration repetition number and error criteria for convergence, and name of output file. Further details of each of the input variables are given in the appendix.

An operator can readily change the design variable through the menu. The batch version is used for computing multiple instances, and utility to create the batch input files through menu driven procedure was also written.

Each instance of simulation creates three files. The first is the header file, which is a duplicate copy of what the input parameters are. The second file is the pressure profile file, listing the chamber volume, pressure, temperature, mass, and mass flows through contact patch, vane sides, and discharge valve as a function of angular position. The third is the torque output. The first table contains the force loading on a vane and torque due to the loading on the vane as functions of angular position. At the end of the file, the overall thermodynamic performance parameters such as discharge temperature, volumetric efficiency and COP are also listed. The second set contains the torque loading from all five vanes (staggered by 72 degrees) and the combined torque as a function of angular position. At the end of the file, the total average torque and peak-to-peak variance is listed. Sample of each type of output files is given in Appendix.

3.2. PREDICTOR-CORRECTOR FOR PRESSURE CALCULATION

Predictor-Corrector scheme is used to compute the state of compression chamber. The canonical description of the compression process, i.e. the scheme represented in equation (3) is put in implicit form. The explicit form of the first law description represented in equation (2) is used to provide the initial guess to start the iteration loop. For the $\Delta\theta$ of 3 degrees and error ceiling of 0.001, in most part, the iteration converges within two tries.

The iterative method was chosen over an explicit scheme such as Runge-Kutta because of the computational instability that may develops shortly after the maximum pressure is reached. When the iterative computation becomes unstable, the bisection method is used. With the implicit iterative method, one can easily detect whether the iteration is converging or not, therefore, can judge whether to use bisection method for the next calculation.

3.3. ITERATIVE LOOP FOR OVERALL PROCESS

In order to compute the state at the next angular position, one needs to know the state of the chamber that is 72 degrees ahead and that of the discharge plenum, i.e. the source of leak and back flow into the chamber as shown in Figure 7a. But in the pressure calculation sequence, these are calculated later. To simultaneously solve for the chamber for every angle and discharge plenum state requires large computational power, and is inefficient.

This simulation uses iterative approach here as well. The state of chamber ahead and discharge plenum from the ith iteration loop is used to compute the state of chamber in the i+1st iteration loop. In the very first loop, all of the leaks are treated as if they are coming from the discharge plenum, whose state is estimated from the initial guess of the discharge temperature. This scheme is briefly represented in Figure 7b.

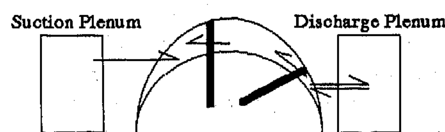

Figure 7a. Material Exchange between Chambers

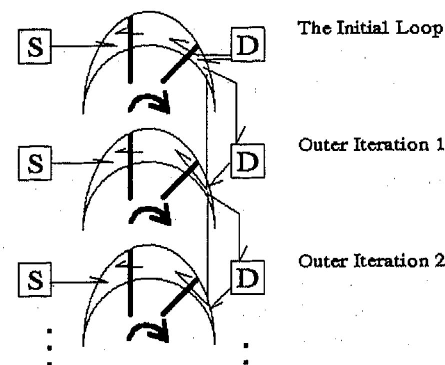

Figure 7b. Outer Iteration Loop

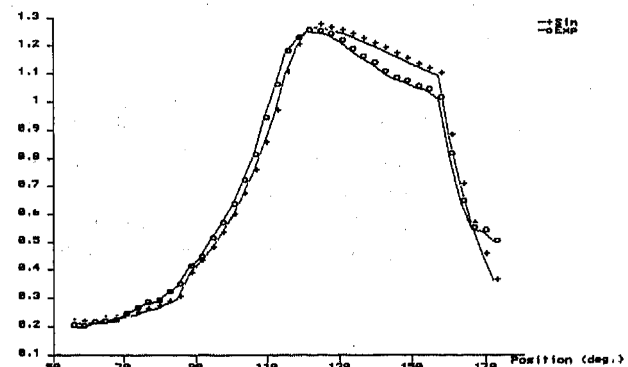
3.4. PARAMETER MATCHING AND VERIFICATION OF THE SIMULATION CODE

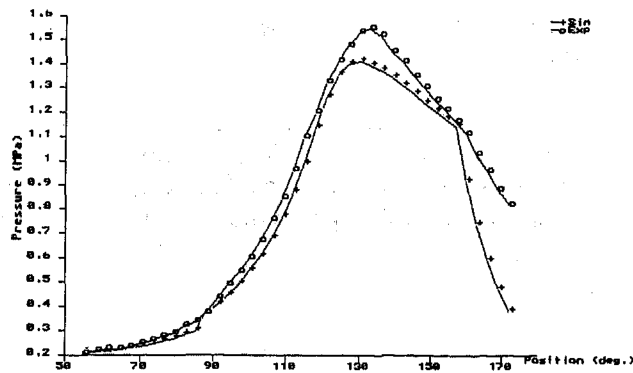
The important characteristic, such as the forward flow coefficient and back flow coefficients were not independently available. As a result, the technique of experimental design was used to find the values for these coefficients to best fit the compression chamber pressure profile data. The values determined by the method are used in subsequent calculations.

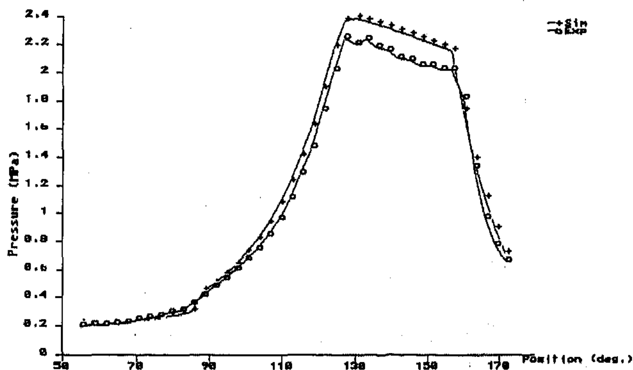
The operating conditions for the pressure profile data are given in Table 1 below. Figures 8a through d show the pressure profiles from the data set.

Table 1. Operating conditions for pressure profiles used in tuning.

Data Name	Speed (rpm)	Suction Pressure (Mpa)	Discharge Pressure (Mpa)
CV_10	800	0.2	1.05
CV_12	1800	0.2	1.05
CV_15	800	0.2	2.0
CV_17	1800	0.2	2.0







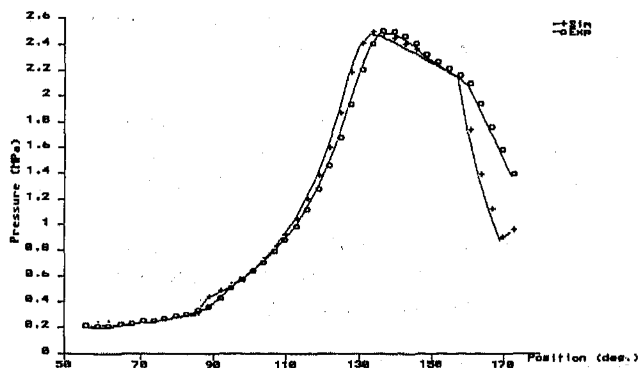


Figure 8a. Pressure Profile for CV_10

Figure 8b. Pressure Profile for CV_12

Figure 8c. Pressure Profile for CV_15

Figure 8d. Pressure Profile for CV_17

4. COMPUTATIONAL RESULTS

With the model now verified, design parameters can now be examined for their influence. Two examples are presented. The first example is the effect of the aspect ratio to torque, torque variance and compressor efficiency. The second example is the cylinder shape where the manner of vane extension and retraction are altered.

4.1 EFFECT OF ASPECT RATIO OF THE CYLINDER

The space available in the engine compartment for A/C compressor continue to shrink in size. In particular, the emphasis is on a slimmer compressor. Therefore, it is important to find out what effect this change in the aspect ratio will have, and what range of aspect ratios are reasonable.

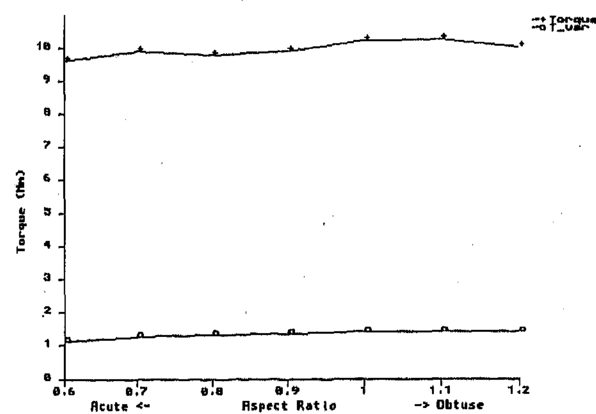
4.1.1. Description Of Design Parameter Varied

The aspect ratio of unity is given to the current design. The diameter of the compressor is increased by the aspect ratio a, while the length is reduced by the square of the aspect ratio to keep the nominal volume constant.

4.1.2. Results

There is very little change in torque and torque variance, as shown in Figure 9a. This agrees with a simple energy calculation. The efficiency of the compressor, however, decreases as the aspect ratio is reduced, because the effect of leak through contact patch grows as the aspect ratio is reduced. The effect of the leak is easily seen in the pressure profile. For the low aspect ratio, the right "shoulder" of the pressure profile is reduced, indicating the stronger presence of mechanism to reduce the pressure of compression chamber after it reaches high pressure state, as shown in Figure 9b.

Corresponding to the reduction in efficiency, the rise in temperature of the discharge state is also anticipated.



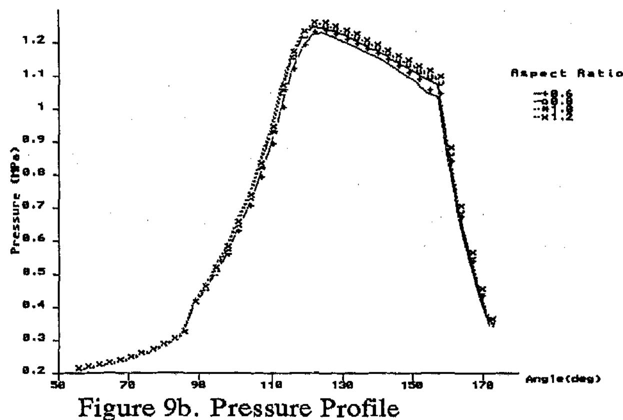


Figure 9a. Torque v. Aspect Ratio

Figure 9b. Pressure Profile

4.2 EFFECT OF VANE EXTENSION AND RETRACTION SCHEME

It is important to choose the cylinder shape rationally. To aid this, the cylinder shape is characterized by a number of parameters. The parameters then can be varied, according to design of experiment schemes, to estimate what combination of the parameters will yield the most desirable effect.

Here, the desired effect is the reduction of torque variance and improved efficiency.

4.2.1. Description of Design Parameters Varied

The cylinder shape is parametrized by the vane excursion as a function of rotor angular position. The excursion function is C^2, that is, its second derivative is continuous. The parameters that are varied are the beginning position of the maximum excursion of the vane, beginning position of the retraction of the vane, and the skew parameter for the extraction/retraction path. The maximum extension start position and the skew parameter determines how the vane extends, and the retraction start position and the skew parameter determines how the vane is retracted. Further description of the vane position is given in the appendix.

For the results in this paper, the maximum extension of the vane is held constant.

4.2.2. Results

The results indicate that the torque variance and efficiency are most greatly affected by how the vane retracts. The manner with which the vane extends does not have a major effect on torque variance, etc. Specifically, the position of vane retraction start has the greatest bearing on torque variance. The torque variance is determined by the height and width of torque profile from each vane. When the retraction starts later, the peak becomes higher and narrower, resulting in higher variance.

The simulation indicates that the vane can be extended rather quickly, giving the possibilities of increasing the length of the contact patch. Increasing the length of the contact patch may result in improved efficiency.

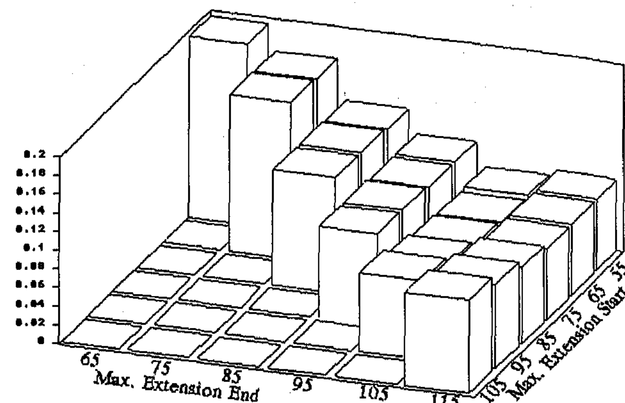

Figure 10. T_var/T_av v. Cylinder Profile Parameters

5. CONCLUSION

The compressor simulation code is constructed for steady state (constant rpm) operation. The simulation uses "real" R134a property and use of the first law with the emphasis on entropy accounting, rather than the conventional polytropic compression curve.

This simulation provides solid foundation for future expansion into dynamic and transient compressor simulation and overall cycle and system simulation.

Simulation results indicate that it is a useful tool in optimizing the compressor design parameter, such as aspect ratio and cylinder shape profile.

6. ACKNOWLEDGMENT

Author wishes to thank Mr. Shitara, Mr. Enokido and Zexel Compressor Design and Experiment Group for providing compressor design detail and performance test in formation; Mr. Butts, Mr. Sumikawa, Mr. Bearnt, Mr. Stricklen, Mr. Kato and Mr. Zhou at Zexel USA for valuable discussions over compressor engineering; Dr. Kobayashi and Dr. Miyamoto at Zexel R&D Center for guidance on fluid flow and leak mechanisms.

8. APPENDIX

8.1 SIMULATION INPUT VARIABLES

Design Parameters

1. Cylinder profile file
   Path and name of the cylinder profile data file. ASCII file with angle and r as a function of the angle. One pair of entry per line.
2. Rotor radius
3. Cylinder thickness
4. CP start angle
   Contact patch start
5. CP end angle
   Connect patch ends
6. Vane offset
   Distance between the center of the rotor and the line of vane motion
7. Vane Thickness
8. Vane off-center
   Distance between the center of the vane tip arc and the center of the vane.
9. Vane tip radius
10. Vane length
11. Vane mass
12. Vane-Cyl frict. coeff.
13. Vane-Rot frict. coeff.
14. Valve fwd. coeff.
    m_dot = CF x delta_P^3/2
15. Valve bwd. coeff.
    m_dot = CB x (1-delta_P/PCL) x delta_P^1/2
16. Valve bwd. P0
    PCL in the equation above.
17. Valve bwd. dump
    delta_m at port start position
18. Port Volume
19. Port Start

Tolerance Parameters
1. CP radial clearance
2. CP leak fudge   default 1.0
3. Vane length clearance
4. Vane tip gap width   Set to zero for this version
5. Vane side clearance
   Compression chamber to slot back room leak. Not addressed in this version
6. Vane Leak Fudge   default 1.0

Operation Parameters
1. Compressor RPM
2. Suction Port Closure   default max. intake position
3. Discharge Pressure   MPa
4. Discharge Temperature   K, Initial guess
5. Suction Pressure   MPa
6. Suction Temperature   K

Computation Parameters
1. Del_theta
   Angular step (3deg for the calculations shown in this paper)
2. Inner Iteration Max.   default 10
3. Inner Itr. Epsilon   default 0.001
4. Bisec Iteration   default 10
5. Bisec Search Bound   default 0.2.
   May need to be increased for high discharge pressure or high rpm calculation
6. Outer Iteration Max.   default 20
7. Outer Itr. Epsilon   default 0.01.
   Measures the convergence of the flow from a compression chamber to the following chamber when the latter has reached the discharge port position
8. Output File Name Stem
   Output file name. Default is based on the clock reading so that the output form the earlier calculation would not be overwritten

8.2 EQUATION OF VANE EXCURSION

The vane motion has five stages: retracted stage (prior to the end of the contact patch), where the position stays at the rotor radius, the extension stage where the vane moves from the rotor radius to maximum radius, maximum extension stage where the vane is at

the maximum radius, retraction stage, where the vane retracts from the maximum radius to rotor radius, and retracted stage (after the start of the contact patch). The first retracted stage ends when $\theta \leq \theta_a$, the extension stage is when θ is between θ_a and θ_b, the maximum extension stage is when θ is between θ_b and θ_c, the retraction stage is when θ is between θ_c and θ_d, and the second retracted stage starts when $\theta \geq \theta_d$. Let E_{max} be the maximum excursion,

$$\text{excursion}(\theta) = \begin{cases} 0, & \theta < \theta_a \\ E_{max}(f_0(\xi) + S \cdot f_1(\xi)), & \theta_a < \theta < \theta_b \quad \text{where } \xi=(\theta - \theta_a)/(\theta_b - \\ E_{max}, & \theta_b < \theta < \theta_c \\ E_{max}(f_0(\xi) + S \cdot f_1(\xi)), & \theta_c < \theta < \theta_d \quad \text{where } \xi=(\theta_d - \theta)/(\theta_d - \theta_c) \\ 0, & \theta > \theta_d \end{cases}$$

where

$$f_0(\xi)=10.0\xi^3 - 15.0\xi^4 + 6.0\xi^5$$
$$f_1(\xi)=-\xi^3 + 3.0\xi^4 - 3.0\xi^5 + \xi^6$$

For this calculation, E_{max} of 8.5mm, θ_a of 8 deg., and θ_d of 172 deg. were used, while θb, θc and the skew parameter S were varied.

Seat Belt Limitations in Collisions that Involve No Compromise of the Passenger Compartment

J. Hill and G. M. Mackay
Birmingham Accident Research Centre

S. Henderson
Rover Group Ltd.

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

This is a field study of cars that sustained very little passenger compartment intrusion in frontal crashes. It has been possible to define the key limits on seat belt effectiveness in these, the most common type of crash.

Data are taken from the in-depth investigations by the Co-operative Crash Injury Study and Rover Group in the U.K. Vehicle crashworthiness is assessed in detail and then matched with medical information from coroners reports, hospital records or questionnaires sent to survivors.

The study describes and compares important injury mechanisms such as driver head to steering wheel contacts, front passenger torso injuries caused by seat belt loads and front occupant leg injuries. 14% of occupants were rated two or above on the Maximum Abbreviated Injury Scale.

It is realistic to design seat belt systems for use in passenger compartments that can be expected not to deform in the more common frontal crashes. The discussion is concerned with the importance of these results when developing safety systems in that context.

INTRODUCTION

Looking to the near future we can expect new passenger cars to have ever increasing standards of structural front-crash performance. Present-day knowledge of design and testing can allow the passenger survival space to remain uncompromised in many crashes at impact speeds at least equal to current and proposed legislative impact tests.

Much research and development is presently concerned with making the most effective use of occupant interior space. This work focuses on seat belt supplementary technologies such as pretensioning devices and airbags. There is also a growing desire to develop dynamic, integrated restraint systems that will be effective over a wide variety of occupant characteristics and impact conditions. The specifications of these new technologies will draw heavily on field research into road traffic accidents.

This paper is a study of field cases where the crash effectiveness of seat belts was not compromised by any disruption of passenger interior-space. Results should then be directly relevant to restraint system design and modelling where the compartment is often considered undamaged.

In this paper the term "intrusion" refers to deformation of the passenger compartment measured inside towards the occupants. Vehicles chosen for this study did not have passenger compartment intrusion. They were often from "low-energy" crashes with injuries of relatively minor severity. There are, however, several good reasons to take interest in these cases. Trivial injuries caused by internal vehicle contacts provide information about occupant kinematics. Head strikes, for example, may only have caused external injuries, but they should be taken in to account because more severe impacts may cause internal injuries in otherwise similar conditions. Occasional, more severe, injuries can define important limitations to the effectiveness of current restraint systems, perhaps in terms of occupant or vehicle characteristics.

Horsch (1987) has shown that the relatively high frequency at which minor injuries occur relative to more serious or fatal crash outcomes, means that these injuries are the much more costly consequence to society as a whole. This is another reason why this study was considered important. Neck strains, for example, were one of the most numerous consequences of crashes in this study. The Abbreviated Injury Scale (AIS; AAAM, 1990) rates neck injuries as "minor" in terms of their relative severity, but these injuries are known to have both long-term and costly consequences.

ANALYSIS AND RESULTS

It is useful first to consider injuries occurring in frequent, "low-energy" impacts that involve current model cars. The Rover Group Accident Injury Study was commenced in August 1995 to examine vehicles involved in collisions that are owned and operated by Rover Group. The total fleet consists of approximately 20,000 vehicles, the majority of which are under 12 months old. The vehicles are driven by employees and families of employees of Rover Group and its associated companies. Medical details are obtained from

hospitals and questionnaires sent to the car occupants. All vehicles with significant damage (cost of labour to repair > £1000) are investigated.

The sample size is small at present (72 vehicles involved in frontal impacts with a total of 110 occupants), and mostly minor injuries have so-far been reported (33% of occupants rated AIS 1). In addition, two occupants were rated MAIS 2. One of these was an unrestrained driver who suffered loss of consciousness; the other was a restrained rear seat occupant who suffered two fractured ribs. Table 1 has been included to show the incidence of minor injuries in this accident sample that essentially represents typical, "every-day" crashes, involving current model vehicles. Injuries due to seat belt loads, neck strains and impacts by occupants on forward structures form the basis of this paper.

Injury Category	No Injuries	Seat Belt Bruising (AIS 1)	Neck Strain (AIS 1)	Impact Injuries (AIS 1)
Frequency	*71*	*9*	*22*	*24*
Rate	*65%*	*8%*	*20%*	*22%*

Table 1: Injuries sustained by 35 occupants from the Rover Study *Some occupants sustained more than one type of injury described above*

The Co-operative Crash Injury Study (CCIS) database was used for the rest of this study (Mackay, 1985; Hassan, 1996). The CCIS was very suitable for this purpose because it represents a full range of injury severities. It has been underway in the UK since December 1983. In-depth vehicle examinations are made at garages or scrap yards several days after road accidents occur. Medical details of car occupants are obtained from hospital records, coroners reports and questionnaires sent to survivors. Accidents are sampled according to a plan that ensures that a full range of accident injury severities are obtained equally from crashes occurring in rural and urban areas. The sample plan favours vehicles that contained fatal and seriously injured car occupants (rated according to the UK DoT system). Less-severe and non-injury cases are, however, very well represented. This was an important requirement of the present analysis requiring vehicles essentially from "low-energy" and low-injury severity crashes.

The current study makes use of records for accidents that occurred from April 1992 to December 1995. Accident records from before 1992 are not presently compatible with later cases.

For this study, a sub sample of seat-belted front occupants was selected from vehicles having sustained a front impact with no intrusion. Injuries of AIS 2 and above (AIS 2+) were initially studied. Secondly, all injury (AIS 1+) details were summarised to isolate the main types of injury. Occupant and crash characteristics were then compared.

FRONT IMPACTS WITH PASSENGER COMPARTMENTS UNCOMPROMISED - Occupants were only included for study if their vehicles met the following criteria:-

1. The most severe (or high energy) impact was frontal,
2. Secondary impacts, or roll-overs, were permitted if less severe than an initial front collision,
3. Zero intrusion of the passenger compartment measured inside the vehicle, towards the occupants, from any direction,
4. No steering wheel displacement.

Figure 1 shows that there were 1200 vehicles without any intrusion from front impacts.

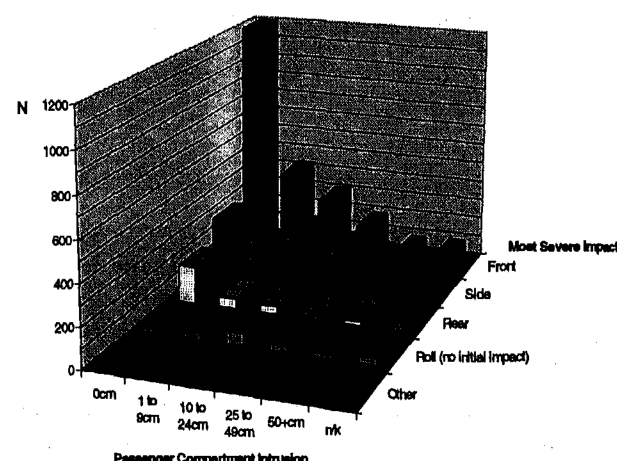

Figure 1: Intrusion vs. Impact Type for All Vehicles on the CCIS Database

FRONT SEAT OCCUPANTS - The major part of this study involves occupants selected according to the following criteria:-

Drivers and outboard-seated front seat passengers (FSPs),

Seat-belted using an emergency locking retractor, three-point (lap & diagonal) system,

Appropriately belted: occupants were excluded if known to be using belts in an inappropriate manner, if they were small children, or if a child restraint system was used. After consideration of work by Stalnaker (1993), small children were said to be occupants whose mass was < 35 kg, or if mass unknown < 13 years.

CCIS SUB-SAMPLE - Filtering occupants, as described above, on the CCIS database produced a sub-sample of 766 drivers and 188 FSPs. These can usefully be compared with all front occupants currently on the CCIS database. Crash severity was assessed from vehicle damage dimensions using the CRASH3 programme (NHTSA, 1982). It can be seen that a relatively "mild" sub-sample of cases has been selected, encompassing a less severe range of ETS (Figure 2, over) and occupant Maximum Abbreviated Injury Scale (MAIS, Figure 3). Two hundred and fifty nine occupants were not injured at all (MAIS 0). As might be expected, the sub-sample contained more females (Figure 4), FSPs, and older people (Figure 5).

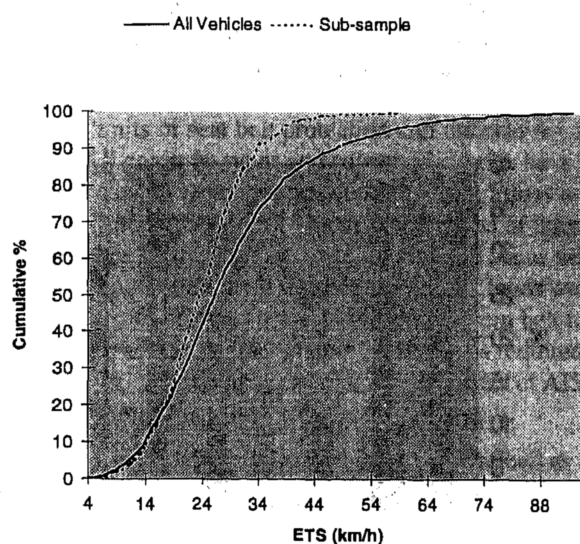

Figure 2: **ETS Distributions for All CCIS Vehicles vs. the Current Sub-sample**

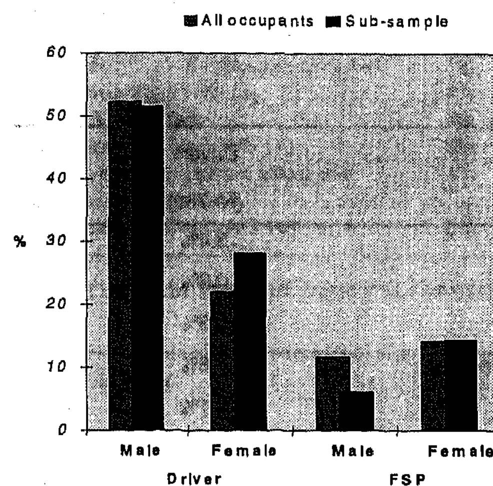

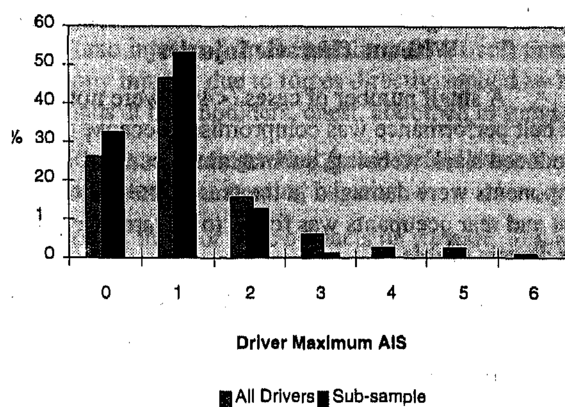

Figure 4: **Occupant Type Distributions Showing All CCIS Drivers and FSPs vs. the Current Sub-sample**

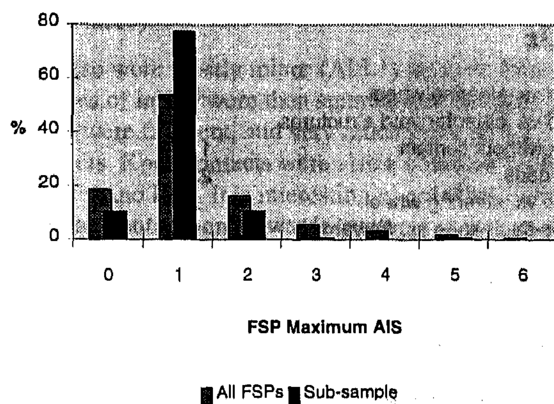

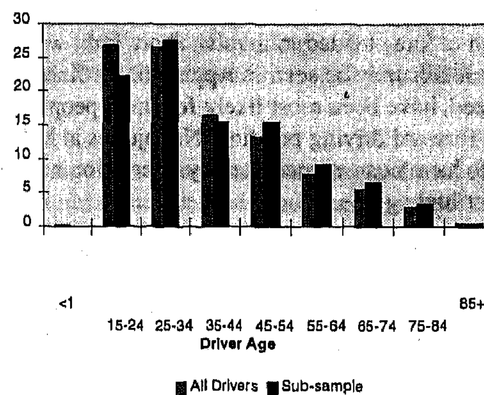

Figure 3: **Maximum AIS Distributions for All CCIS Occupants vs. the Current Sub-sample**

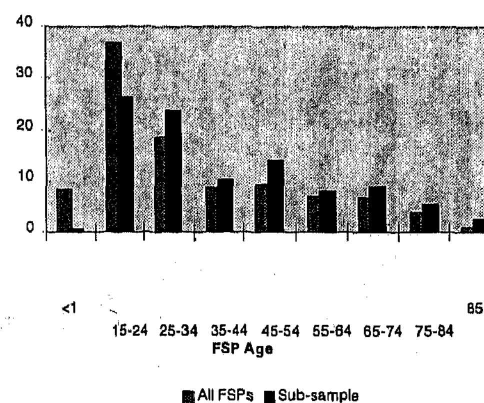

Figure 5: **Age Distributions for All CCIS Occupants vs. the Current Sub-sample**

Despite the relatively mild nature of these frontal impacts 13.8% of occupants were injured with MAIS 2+ and 1.6% (15 people) with MAIS 3+. The body regions injured at AIS 2+ are shown in Table 2. Main causes of concern are the thorax and, for drivers, the head.

	Drivers (N=766)	FSPs (N=188)
Head	3.4%	0.5%
Face	0.3%	
Neck	0.3%	
Upper Extremities	1.6%	1.1%
Thorax	6.1%	6.4%
Abdomen	-	1.1%
Spine (T & L)	0.3%	1.1%
Pelvis, Thigh & Knee	1.6%	1.6%
Lower Leg	1.2%	1.1%

Table 2: AIS 2+ Injury Rates

There were two neck injuries and several instances of thoracic/lumbar spine injuries. Injuries to female drivers at pelvis, thigh or knee tended to involve short, light-weight occupants (details may be seen in Appendix A). Knee contacts would, indeed, have been most likely for small people requiring a forward driving position. No injuries at MAIS 2+ were seen to have been exacerbated by interaction with other occupants or luggage.

It was possible to consider the interaction of various occupant and vehicle factors including occupant age, weight and height data together with seat belt performance and interaction between occupants. (Appendix A provides full details of occupant characteristics comparing all occupants (MAIS 0+) against AIS 2+ injuries at each body region.) Older occupants are more prone to an AIS of 2+ (Figure 6).

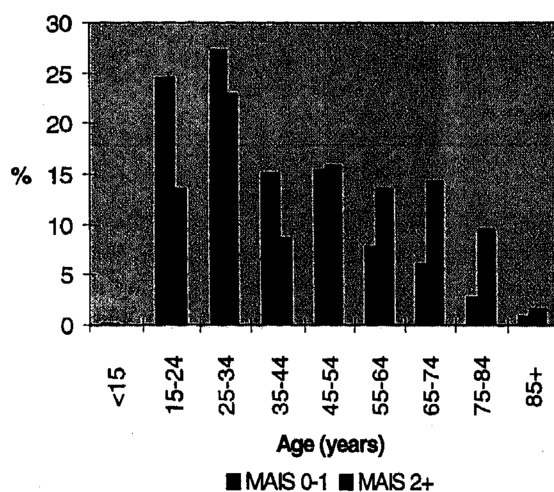

Figure 6: Age Distributions for All Front Seated Occupants With and Without Injuries Rated MAIS 2+

Advanced age was chiefly a factor affecting the thorax particularly considering female FSPs. Female FSPs were present over a very wide age range, but the majority (>75%) who suffered thoracic injuries were 65 years or older (Figure 7).

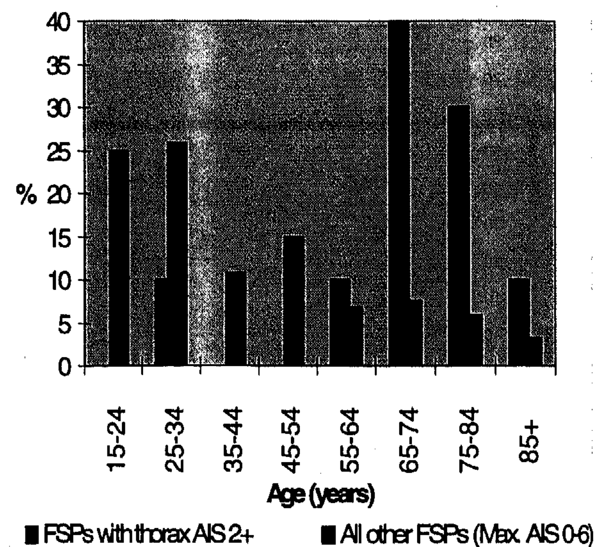

Figure 7: Age Distributions for Female FSPs With And Without Thoracic Injuries

A small number of cases (<4%) were noted where seat belt performance was compromised because clothing had introduced slack webbing, submarining occurred or seat belt components were damaged in the crash. Interaction between front and rear occupants was found to be rare affecting only four drivers (Table 3).

	Drivers (N= 766)	FSPs (N= 188)
Interaction between occupants/luggage	4	-
Seat belt compromised	30	8
AIS 1+		
Head vs. steering wheel	58	-
Head vs. other forward structures	6	8
Neck without contact	174	73
Belt loads	232	100
Torso vs. steering wheel	20	-
Pelvis-thigh-knee vs. forward structures	91	25
Legs vs. facia or footwell	43	15
AIS 2+		
Head vs. steering wheel	12	-
Head vs. other forward structures	1	1
Neck without contact	-	-
Belt loads	35	14
Torso vs. steering wheel	8	-
Pelvis-thigh-knee vs. forward structures	7	1
Legs vs. facia or footwell	7	1

Table 3: Types of Injury and other Factors

MAIN TYPES OF INJURY - The next objective of this study was to summarise common injurious occupant contacts on forward structures (AIS 1+), and other injury mechanisms. AIS 1 injuries arising from various forward contacts were worthy of detailed attention because they can describe the limits of seat belt protection and indicate occupant kinematics. All common types and causes of injuries have been described by several recent reports (ETSC, 1993; Fildes et al., 1991; Mackay and Hill, 1995). The principal types of injury and contributory factors that are widely known to occur were counted, as shown in Table 3. Injuries due to belt loads were extremely common. However, because injuries from belt loads are inevitable considering the magnitude of forces required to restrain people in frontal impacts, only such injuries at AIS 2+ were judged appropriate for further consideration.

Main types of injury were then briefly defined as follows:-

1. Head/face vs. steering wheel,
2. Head/face vs. other forward structures (includes contact on A pillars, windscreen, bonnet, header rail & facia),
3. Neck non-contact injuries, (includes soft tissue & bony injuries caused by decelerative forces),
4. Torso injuries form belt loads (AIS 2+ soft tissue or bony injuries due to forces directly applied by belt loads at the shoulders, chest, abdomen or pelvis),
5. Torso vs. steering wheel (some belted drivers contacted their steering wheels),
6. Pelvis, thigh or knee contacts on forward structures (caused by contacts on facia or steering column, but not steering wheel, and may also include indirect pelvic /thigh injuries due to knee contact on the facia),
7. Legs vs. facia or footwell (any injuries due to contact of extremities below the knee, on facia or footwell surfaces).

These were mostly minor (AIS 1) injuries. Rates for the main types of injury were then summarised in Table 4. Neck strains were frequent, and very much more so for front seat passengers. Knee contacts were also a common problem for both driver and FSP. It is interesting to note that FSPs sustained head contacts on forward structures at the same rate as drivers on steering wheels. It should be borne in mind that these results relate to a variety of frontal impacts some including multiple collisions or roll-overs. Accident reconstructions are carefully conducted and these results have been calculated where researchers concluded that occupant contacts occurred on frontal structures. Table 5 was produced to clarify this situation.

Table 5 shows injury rates for single frontal impacts from straight ahead of the vehicle (12 o'clock direction of force). Now the results suggest that drivers contacted their steering wheels more often than FSPs strike forward structures. Small increases in belt loading rates over results from Table 4 may well be significant as they indicate increased injury probability under more direct frontal loads.

Main Types of Injury	Drivers (N=440)	FSPs (N=109)
Head vs. steering wheel (AIS 1+)	8%	-
Head vs. other forward structures (AIS 1+)	1%	8%
Neck without contact (AIS 1+)	24%	40%
AIS 2+ due to belt loads	5%	5%
Torso vs. steering wheel (AIS 1+)	3%	-
Pelvis-thigh-knee vs. forward structures (AIS 1+)	13%	14%
Legs vs. facia or footwell (AIS 1+)	6%	8%

Table 4: The Main Types of Injury in Frontal Impacts

Main Types of Injury	Drivers (N=440)	FSPs (N=109)
Head vs. steering wheel (AIS 1+)	7%	-
Head vs. other forward structures (AIS 1+)	4%	4%
Neck without contact (AIS 1+)	21%	43%
AIS 2+ due to belt loads	6%	6%
Torso vs. steering wheel (AIS 1+)	3%	-
Pelvis-thigh-knee vs. forward structures (AIS 1+)	12%	13%
Legs vs. facia or footwell (AIS 1+)	5%	9%

Table 5: 12 O'clock Single Impacts No Belt-compromise or Occupant Interaction

Age was seen to be an important factor regarding torso injuries from belt loads and steering wheel contacts for all occupants. Typical results are shown in Figure 8 and Figure 9 for injuries caused by seat belt loads and steering wheels respectively.

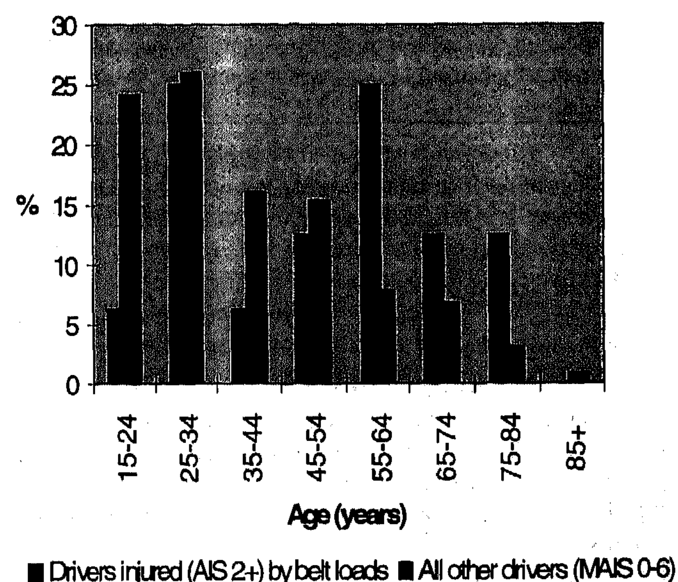

Figure 8: Age Distributions for Male Drivers With and Without Injuries to the Torso Caused by Seat Belt Loading

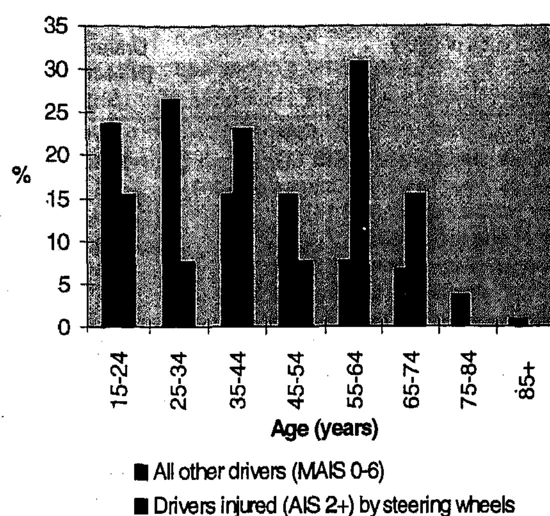

Figure 9: Age Distributions for Male Drivers With and Without Injuries to the Torso Caused by Contact with Steering Wheels

DISCUSSION

The main types of injuries to belted front seat occupants were identified for frontal crashes. These may be said to define limitations on seat belt effectiveness when the passenger compartment remains undeformed, and there is no steering wheel displacement.

The data gives a picture of car crashes on UK roads in the 1990s. All types of passenger car and years of registration are adequately represented, however the CCIS database is deliberately biased towards more severe impacts and many types of vehicles will be based on old designs. The Rover study, on the other hand, represents the "every-day" crash situation for current model cars often with supplementary restraint systems fitted. In the Rover subset the early data would suggest that minor injuries continue to occur and these are typically caused by forward contacts, belt loads and neck strains.

More frequent fitment of airbags may reduce the number of neck strains occurring to both drivers and FSPs in the future. It is hoped that future restraint systems will be tailored dynamically to occupant and crash characteristics, the objective being to make the best possible use of the occupant interior space (Mackay, 1994). Benefits should then extend to more severe impacts than those discussed here.

This paper is a first assessment of recent CCIS data. It is hoped that it will provide early clues for those designing restraint systems. A major challenge, and priority, could be to provide advanced load limiting, selectively for older people, without compromising protection through increased ride-down.

ACKNOWLEDGMENTS

The Co-operative Crash Injury Study is funded by the Department of Transport, Ford Motor Company Limited, Nissan Motor Company, Rover Group, Toyota Motor Company and Honda Motor Company. The project is managed by the Transport Research Laboratory. Grateful thanks are extended to Katie Stabler for her assistance in the preparation of this manuscript, and everyone involved with the CCIS data collection process.

Glazing Effects of Door or Frame Deformations in Crashes, Part 2

ABSTRACT:

The non-uniformity of temper of 27 motor vehicle door windows as measured by the polarization method is presented, illustrated by two photographs of windows between crossed polarizers. The tempered glass fracture characteristics of 11 Geo Prism door windows are illustrated by two video frames of the windows after fracturing by door deformation slowly applied at bumper level. The speed of some moderate sized fragments was measured to exceed 60 km/h, due to strain relief rather than contact by an intruding object. Glazing history is briefly summarized, with our support of the NHTSA conclusion that more than 1300 lives per year could be saved cost effectively by replacing tempered glass by an "advanced glazing."

INTRODUCTION:

In the first paper [1] of this continuing study, 12 front door windows for the 1990 Geo Prism, of tempered glass 3 mm thick, were slowly strained by a 12.7 cm diameter horizontal roller pressing on the outside of the glazing between two horizontal rollers 50 cm apart on the inside of the glazing. After counter-bending the glass to failure, the tempered glass shattered, with the pieces flying primarily in the direction of compression relief by the bending, "inside.". The cracks in the glazing were not in a square array, as occurs approximately when tempered glass is broken without being strained, but were angled, with some cracks not reaching the glass surface on the compression side. The consequence was that pieces with cracks not yet separated, called clusters, were larger and heavier and sharper, many with points, or many as slivers rather than the "cube-like" pieces of the unstrained shattered tempered glass.

In this Part 2, the non-uniformity of temper of glazing for a number of different vehicles, and the conditions of shattering of tempered glass windows when the deformation force was slowly applied at bumper level on the door, were studied, and the safety consequences of the "shatter and fly" characteristics of tempered glass as these affect laceration and ejection injuries are discussed.

MATERIALS AND METHODS:

This Part 2 study has two experimental sections. The first section deals with the variation of temper over the surface of 27 door windows of six make and model year vehicles, as determined by the birefringence method. Glass with a higher compression has a higher refractive index. The rapid cooling of the surfaces of the glass, in making tempered glass, puts the surfaces in greater compression (the glass shrinks), than the interior. Because of this the refractive index of light polarized parallel to the surface is greater than the refractive index of light polarized perpendicular to the surface. That is, the anisotropic compression of the glass produces an anisotropic refractive index or birefringence. The surface compression of the two sides of the glass is not perfectly uniform. As a result, looking at a piece of tempered glazing between crossed polarizers, or even looking through polaroid glasses at the glazing in sunlight reflected off a surface (and hence partially polarized) reveals the glazing to be light or birefringent in some areas (Figures 1 and 2). Indeed, this is the method to distinguish tempered glass, which is birefringent, from annealed glass, which is more nearly isotrophic or non-birefringent. Looking at a fragment of the glass on edge between crossed polarizers, as with a polarizing microscope, reveals the greatest birefringence of the glass, with the magnitude of the birefringence a measure of the compression level or extent of tempering of the surface. A laser beam Grazing Angle Surface Polarimeter (GASP) [2] was used to measure the birefringence along and perpendicular to the surface and so to measure the glass temper without having to examine only the edges of the glass. Three to five points were measured on each window using points that were brightest (most birefringent) and darkest (least birefringent) on the transmission views of the entire glazing between crossed polarizers.

The second experimental section of this study involved successively mounting 11 driver side doors of the 1989 Geo Prism on a frame. The hinges were attached to the frame, but the latch side of the door was not supported. The bottom of the door is supported by a box beam simulating the rocker panel, but the top of the door is supported with a steel

member that could pivot as the back of the door deformed. A rigid bumper was then pressed with a hydraulic ram against the door at a typical bumper height then advanced slowly until the tempered glass door window shattered, with the ram traveling up to 35 cm in more than 20 seconds. Different tests had different bumper horizontal angles with respect to the door (0 to 30 degrees), and different extent of overlap (left edge of the bumper at the front of the door to 30 cm rearward), simulating particularly side impacts with B pillar collapse. Two Super VHS video cameras were used, with shutter speeds of 0.008 seconds, at 30 frames per second. The views of the two cameras of the assembly and scatter patterns were from the top ("vertical view") and from the side ("horizontal view."), allowing parallax correction. High intensity lighting was used. White lines drawn six inches apart provide a scale in the camera views.

RESULTS

Using the GASP device, the variation of compression across the surfaces of 27 new original equipment manufacturer tempered door glasses from six different popular car models (Table I) was measured. The National Automotive Glass Specification (NAGS) catalog [3] number of the windows is given, along with the number of windows measured of each make/model. Also listed are the years that the same window part was utilized for the stated make/model. The highest and lowest temper of measurements within the make/model set of windows, and the highest and lowest temper measured within one window with the lowest temper value within the make/model set, are presented. Also given are other years for makes and models using the same window part number. The significant variation of temper over a single pane of glass, and the variation over different panes of glass, leads to a variation of strength of the glazing and a variation of the size of the particles and clusters when the glazing shatters.

For the door deformation tests, a selected frame of a top and of a side view are presented as Figure 3 and Figure 4, showing the diversity of sizes of the particles and clusters. Following some of the fastest single clusters that were big enough to be seen in successive frames at 30 frames per second allows an estimation of the speed of over 60 km/h, due not to the motion of the contacting bumper but to the abrupt release of the surface energy of the glazing. The smaller particles were moving faster, but a higher camera frame rate will be required to measure their speed. When the glass first shattered, more than half of the glass weight fell down on the outside of the window. In the different tests, from less than 20 % to about 40 % of the glass flew inward, with three tests with very little glass flying inward. We note the many road crashes with shattered tempered glass which have less door and window frame deformation than was required in these slow deformation tests. The significance of shock loading in dynamic crashes needs further study.

It is interesting to note that many of the larger clusters flying toward the inside break apart as they travel even 30 to 60 cm through the air, and so their size will not be judged by looking at particles of glass scattered throughout the vehicle after the crash. In other tests of shattered 6 mm tempered automotive glass, a cluster fragment weighing 62 grams was collected. Note that the head and body are typically less than 30 cm from the near side glazing. If the glazing is accelerated by an intruding object, its speed can be even higher. This combination of the greater weight than 4.25 grams of the uncracked fragment of a shattered tempered glazing specified in Federal Motor Vehicle Safety Standard 205 [4], and the high speeds, and the pointedness and sharpness of the fragments released under strained conditions [1], explains the observed penetration of tempered glass fragments not just into the skin but through the skull and into the brain [5]. In this case, Richard Johnson was found by computer tomography and an operation for removal to have a 6.2 by 2.5 cm triangular piece of tempered glass in the left parietotemporal region of the brain.

DISCUSSION:

In this section we discuss the death and injury consequences, involving laceration and ejection, of tempered glass characteristics, and the alternative glazings that can reduce these deaths and injuries.

A few years ago, the National Accident Sampling System data collection was modified to pay more attention to glazing injuries and their sources. A special request to NHTSA for 1995 data produced the following (rounded off) for occupant lacerations in crashes of light passenger vehicles in tow-away police reported crashes:

windshield contact	159,000
side window contacts	8,800
rear window contacts	903
flying glass	188,000

The lacerations due to flying glass are due to fragments of the shattered tempered glass flying throughout the occupant compartment, causing lacerations without the occupant moving onto the pre-crash glazing areas. Total lacerations were 1.1 million in 1995 crashes. About 35 % of these were due to glass, with the majority of the glass lacerations caused by flying tempered glass.

In most of the side and rear window glass contacts resulting in lacerations, the tempered glass shatters, leading to partial or complete ejections. Ejections also occur if the tempered glass is shattered by crash forces prior to the body reaching the window area. . On the other hand, contact with lacerations with the laminated glazing of the windshield typically involves cracking of the windshield, but with fewer ejections, and the windshield today is rarely opened out by crash forces prior to body contact, allowing ejection without glazing contact..

Ejection data was also requested, from NASS 1995, ratio-weighted. For the known ejections and routes:

	partial	complete
windshield	1,203	728
side windows	14,624	12,149
rear window	1,424	5,593

Partyka [6], correcting for the estimates by the police of partial ejections, low by about 50 %, concluded that the

deaths due to ejection were near 10,000 per year. Malliaris concluded from his studies that 75 % of ejections with death were through glazing areas, and 85 % of the ejections through glazing areas involved the shattering of the glazing by crash deformation forces prior to the occupants reaching the pre-crash glazing surface [7]. About 20 to 25 % of passenger car occupant deaths involve ejection, and about 40 percent of light truck, van, and sport/utility vehicle occupant deaths involve ejection, and this proportion has been almost the same for 15 years [8], while belt restraint use increased from a few percent to over 65 % [7]. Increased belt use over the years has not reduced ejection deaths. Although the belted occupant has a small percentage chance to fully eject, deaths and injuries result from partial ejections in side impacts and rollovers.

Laminated glazing was used for windshields and side and rear glazing from the early 1930's to 1962, with a transition to the use of the less expensive tempered glass for the side and rear glazing from the late 1930's, but particularly in the period of 1957 - 1962. The laminated windshield continued to be used, and was greatly improved in 1966 when the High Penetration Resistant (HPR) windshields, with 0.76 mm of polyvinyl butyral as the plastic interlayer, replaced the earlier windshields with 0.38 mm of PVB as the plastic interlayer [9], greatly reducing deaths with windshield ejection, and significantly reducing windshield lacerations.

The change from laminated to tempered side and rear windows (by 1962) and the change to HPR laminated windshields (1966) both occurred before the creation by Congress of the National Highway Safety Bureau (November 1966). This agency was created to require the vehicle manufacturers to provide certain specified minimum levels of safety in their products. The initial regulations primarily put the force of law behind the various industrial standards, with Federal Motor Vehicle Safety Standard 205 [4] adopting the American Standards Association (ASA) Z-26.1 Standard. This standard has remained essentially unchanged with regard to the absence of direct tests for laceration, head impact loads and ejection. Indeed, the initial drop tests of head penetration using a 22 pound headform and large glass pieces (2 x 3 feet) was replaced by drop tests with a 5 pound steel ball impacting on small (one foot square) glass pieces, based on correlation of results with tempered glass [8]. The correlation is less adequate with laminated (including glass plastic) glazings. The 22 pound headform provided some indication of ejection resistance, whereas the 5 pound steel ball test is primarily a test of glazing fracture characteristics.

Glass-plastic glazing, a form of advanced glazing, was invented in the United States in the 1960s but first commercialized in production motor vehicles in France [10 - 12]. This glazing is produced in two versions. The first is one or more layers of glass laminated with one or more layers of plastic, with one layer of plastic on the inside surface of the glazing in the vehicle. The most notable application of this system was the anti-laceration windshield, for which a plastic "layer" (which in different formulations may have differing plastics in multiple layers) was put on the inboard surface of an HPR windshield [13], used on a number of General Motors production vehicles between 1984 and 1987 [14]. The second type consists of an inboard plastic "layer" generally on a single layer of tempered glass [15]. The inboard plastic layer provides a smooth surface for body contact, and so essentially eliminates lacerations. With the two-ply tempered glass-plastic glazing, the inboard plastic layer will prevent shattered tempered glass pieces from flying into motor vehicle occupants, and will greatly reduce contact lacerations, and will provide a "safety net" over the window area with the potential to almost eliminate the ejection of children and significantly reduce the ejection of adults. This is particularly true when the plastic layer is bonded to the window frame or supported in an encapsulation trapped within the window channels for a moveable window, initially the "T-edge" concept [16, 17], with the glazing able to prevent ejection of an 18 kg headform moving at 32 km/h.

The NHTSA is responding to the injury reduction possibilities of the "advanced glazings" by extending the earlier research on glazing [18 - 22], with indications that more than 1300 lives per year could be save, in a cost-effective manner, with the replacement of tempered glass by advanced glazing. A regulation for the change has not yet been issued.

A number of European and Japanese manufacturers have or are about to change from the use of tempered glass to the use of laminated glazing in some of their side and rear and roof windows, including BMW, Audi (A-8 model), Volvo (1998 station wagon), Toyota, Nissan, and Honda. These changes are presented as improving noise or security characteristics, but they also improve occupant safety, and we hope to see this aspect advertised and prevailing throughout the industry. We note with great interest the Swedish effort to set a "zero goal" for motor vehicle safety [23], and recommend to them that glazing safety be part of this effort. We plan to continue our studies of the deformation conditions that shatter tempered glass, and their effect on glass-plastic glazing. We also plan to examine the change of stress to shatter tempered glass as it ages, particularly with the accumulating scratches and other surface damage with use, as reported earlier [24].

SUMMARY AND CONCLUSIONS

We have presented measurements of the non-uniformity of temper, as determined by the polarization method, of 27 door tempered glass windows. We have presented tempered glass fracture characteristics when 11 car doors were deformed at bumper height, with small fragments and large clusters flying into the occupant compartment, some with speeds above 60 km/h due to strain relief and not due to intruding object contact. We review the laceration injuries and ejection deaths with present vehicles with tempered glass side and rear windows, and means to reduce these injuries and deaths by laminated or glass-plastic glazing.

We conclude that tempered glass has dangerous characteristics of non-uniformity of temper, shattering under strain conditions into large and/or sharp fragments which

"fly" into the occupant compartment, and no ejection reduction capability once cracked.

ABSTRACT

Reducing the weight of vehicles could be a strong means of reducing fuel consumption in urban traffic. Published accident and injury statistics however show an inverse correlation of vehicle mass against injury severity in car to car collisions, above all in head-on collisions. This inverse correlation is in part caused by current crash test standards, where compatibility in collisions between cars of different size and weight is not a requirement. Compatibility in frontal collisions demands for significantly different deceleration-time curves in rigid barrier impacts for cars with different weight. Low mass vehicles (LMV) must meet compatibility criteria to comply with current injury criteria in real car to car collisions. Cars designed according to compatibility criteria can change future accident and injury statistics in a way that injury severity in LMVs can be reduced significantly.

This study shows, that head-on collisions at closing speeds of up to 100 km/h with a mass ratio of 1:2 of the collision opponents can be survived with occupant loads well below the limits of actual injury criteria (FMVSS 208), if compatibility requirements are met with regard to car structure as well as restraint systems.

INTRODUCTION

FOCUS - The research work described in this paper is focusing on frontal collisions between vehicles of different mass and size and the currently observed lack of compatibility therein. This lack of compatibility is considered to be the main reason for the infavourable appearance of small vehicles in accident statistics [1].

GENERAL - The reasons for the higher injury risk for occupants of small vehicles can be found in the low mass which results in a higher total change of velocity in car to car collisions, and, in comparison to heavier cars, in a usually lower stiffness of the crush zone and the cabin structure. Furthermore, the design of the car structure and the restraint systems are - according to current FMVSS and European standards - still being optimised for a head-on collision of a car against one of its kind (impact on rigid barrier), and not against the statistically most probable counterpart. These compatibility issues have been addressed by various authors in the past 25 years ([2], [3]).

CONSEQUENCES FOR THE LMV - The success of low mass vehicles, i.e. small vehicles (2.5 - 3.0-m overall length) with an energy-saving drivetrain, depends to a high degree on the level of passive safety they will offer. The safety deficits of the small cars mentioned above become even more apparent in LMVs with a curb weight less than 600 kg as compared to 800 - 1000 kg of current subcompact cars.

The basic principles for the structural design of such vehicles, as well as first results of crash tests, have been published earlier by our working group [4]. A curb weight for the LMV of 600 - 650 kg appears to be feasible. In frontal collisions, such a LMV should be compatible with 70 - 80% of the currently circulating cars. In Europe, the mass of collision opponents to be considered for the LMV (i.e. the European 'compact' class) ranges between 1300 - 1400 kg, which leads to a design mass ratio of about 1:2. In a frontal car to car collision with 100% overlap and 100 km/h closing speed, the LMV is subjected to a Δv of 20 m/s and a mean car deceleration level of 40 - 50 g. A highly optimised restraint system is needed to reach the same degree of occupant protection as encountered in conventional cars.

The results of mathematical modeling and sled tests of such an optimised restraint system have been presented at the 1996 STAPP conference [5]. They clearly indicate the feasibility of the procedure, in that the envisaged protection criteria could be met with ample margins.

Since the interior of LMV's dimensions are given by ergonomical constraints, the demand for a small overall length leads to a shorter, more densely packed frontal deformation zone. This lack of adequate crush space and the need to avoid car deceleration peaks higher than 60 g (approx.) demand for the frontal structure of the LMV being designed such that it generates an

almost ideal rectangular curve for deceleration versus time in frontal collisions (cf. Figure 1).

RESEARCH WORK - In 1991 our group started to design and test prototypes and experimental vehicles with respect to compatibility criteria. Crash tests at speeds up to 71 km/h were performed against rigid walls, deformable barriers and heavier cars to analyse the behaviour of car structures and restraint systems. Based on these preliminary results, the experimental LMV CRATCH for urban areas has been designed and built. Mathematical modelling, static and dynamic component tests as well as sled tests were used for the development of the restraint systems and of the car structure. The experimental LMV CRATCH has been successfully tested in a head-on car vs. car collision.

COLLISION MECHANICS

GENERAL - A small, light car will always experience a higher deceleration level in a real car versus car collision compared to its heavier opponent, as the deceleration for each of the colliding cars can be calculated with a simplified model from the crush load at the interface of the two cars. Both cars experience the same crush load vs. time curve with this simplified model.

$$(\text{deceleration}) = (\text{crush load}) / (\text{car mass})$$

Furthermore, this type of frontal collision will subject the lighter car to a higher total change of velocity. The velocity change of both cars can be calculated with the law of conservation of momentum. In real collisions the Δv is 5 - 10% above the theoretical value due to residual elasticity of the deformed structures.

$$\Delta v_1 = m_2 * (v_1 + v_2) / (m_1 + m_2)$$

$$\Delta v_2 = m_1 * (v_1 + v_2) / (m_1 + m_2)$$

As this study shows, the main reason for the higher injury risk for the occupants of currently circulating small cars in frontal collisions is not intrinsic in these two physical constraints. Instead, it is given by the lack of compatibility in frontal collisions among cars of different size and weight.

The restraint system of any car will only be able to deploy its effectiveness if the passenger compartment does not collapse in a collision. Intrusion of structural components into the cabin and deformation of the passenger compartment should be small. A extremely important parameter for the development of the restraint system is the mean deceleration level of the car cabin with its restraint system interface points and surfaces.

Furthermore, the design of the car structure and the restraint systems, are - according to current FMVSS and European standards - still being optimised for a collision of a car against one of its kind, and not against the statistically most likely counterpart. (A collision of a car against a rigid wall simulates, in an idealised way, a collision against the 'mirror image' of that car). Thus, the frontal stiffness is chosen such that most of the crush zone is deformed under the test conditions, resulting in the lowest mean deceleration level of the car and therefore normally in the lowest dummy loadings. In rigid wall tests at speeds of 50 km/h, mean decelerations of current cars range between 15 g and 25 g. Larger cars normally exhibit mean decelerations closer to 15 g, subcompact cars with short crush zones on the other hand show mean decelerations up to 25 g in collisions. A car with a high mass will thus be lead to exhibit a higher stiffness of the frontal structure, since the required force to induce a deformation at a given deceleration level is proportional to the mass.

A low mass vehicle, designed according to current crash test standards, will be doubly disadvantaged in case of a collision with a heavier vehicle. Not only will it experience a higher Δv due to the mass ratio, but its frontal deformation space, which is relatively soft (according to the reasons mentioned above), will be crushed before significant deformation of the heavier car even starts.

In conclusion - the frontal structural stiffness of a low mass vehicle must be at least equal or slightly *higher* than the stiffness of its heavier counterpart [6].

COMPATIBILITY - Structural compatibility in collisions means that the different cars should deform at the same load level, yielding a length of the deformation zone proportional to the mass of the car. This even helps to design a short and light LMV, e.g. with a total length of 2.5 - 3.0 m. Analysis of advanced restraint systems indicate, that such an 'universal' deformation load level should be defined in a way that mean deceleration levels of LMV's do not exceed 40 - 50 g. The maximum load level in a frontal collision at a given speed is experienced with 100% overlap, the load decreases with smaller overlap ratios. The length of the crushable zone is defined by the amount of energy that has to be absorbed. Since frontal crash tests against a rigid barrier are performed at the same speed with 100% and 50% overlap, the maximum required deformation length is determined by the 50% overlap condition. Under all conceivable conditions, the LMV's crush zone must be capable of absorbing the LMV's own kinetic energy. In a collision against a heavier car, some of the LMV's kinetic energy might also be dissipated through deformation of the heavier car if the front stiffness of the LMV is designed according to the considerations mentioned above. Such a concept is reasonable, since the heavier car experiences a considerably smaller change in velocity in this type of collision than in a test against a rigid barrier. Earlier tests with an ultrastiff lightweight structure crashed against an Audi 100 have confirmed this concept [4].

Figure 1 shows, schematically, deceleration pulses during an impact on a rigid barrier with an initial velocity of 15.5 m/s for a LMV designed according to compatibility criteria in comparison to a typical compact car. Deformations in this example would be in the range of 300 mm for the LMV vs. 800 mm for the Compact Car.

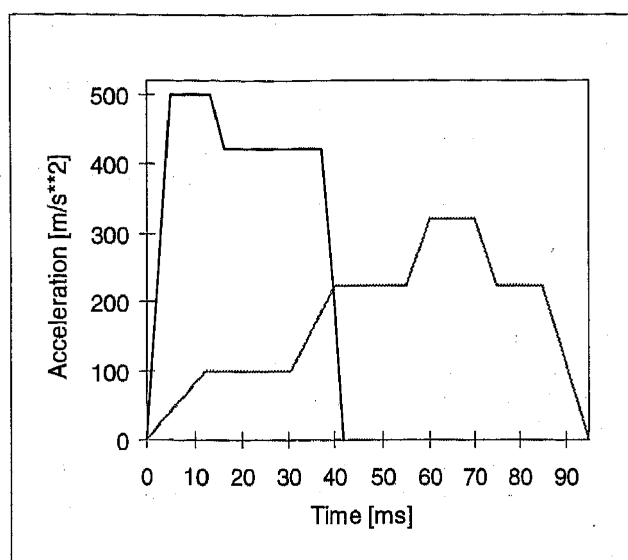

Figure 1: Schematic representation of the deceleration pulses of a typical Compact Car (gray) and a compatible LMV (black) against a rigid barrier at 15.5 m/s (56 km/h).

INTERIOR GEOMETRY

Low mass vehicles are intended primarily for use in urban areas and short ranges. A rather upright seating position is adept to this situation since it offers a better overview of the traffic situation for the driver and thus enhances active safety (cf. Figure 2). Such a seating position results in somewhat shorter ride-down distances for the upper body parts. On the other hand, given an adequate restraint system, the upright position will lead to less forward rotation of the upper body parts, thus reducing unnecessary decelerations especially of the head. Once the seating position is chosen, the position and angle of the steering wheel as well as the position of the feet and the knee bolster are determined by ergonomical considerations.

RESTRAINT SYSTEM CONCEPT

The restraint system of the experimental LMV CRATCH has been presented at the 1996 STAPP conference [5]. Here a short summary.

Restraint system simulations for the LMV with the pulse in Figure 1 and a Δv of 20 m/s clearly show that additional ride-down space in the car interior has to be provided, thereby compensating for the diminished crush zone. The effective use of the ride-down space must be ascertained, e.g. the restraint systems must become active as soon as possible and the components must deform ideally at a constant load level. Figure 2 illustrates the interior geometry and the restraint system components of the experimental low mass vehicle CRATCH.

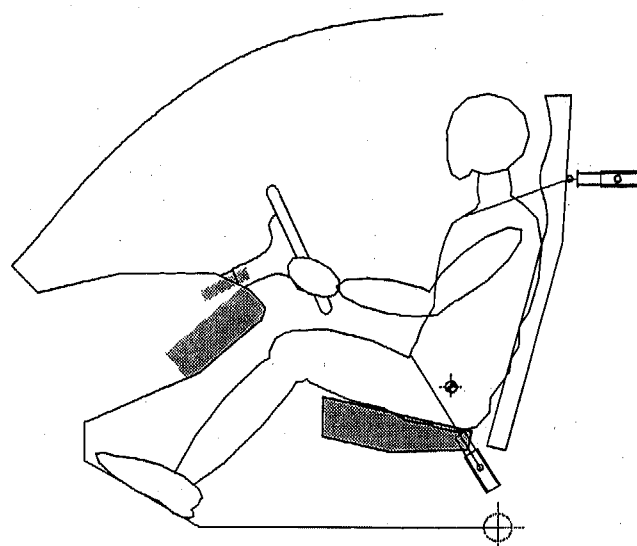

Figure 2: Interior geometry of the LMV. Additional energy absorbing components are marked in light gray.

Low mass vehicles are currently produced only in small quantities. Therefore, it is essential that generally available components are implemented in their restraint system. However, such components need adaptation to the specific LMV situation. The following components are integrated in the experimental LMV CRATCH.

AIRBAG - A full size airbag from a German midsize car is used, the exhaust orifices and the trigger time have been adapted.

STEERING COLUMN - A deformable retracting steering column has been developed, that must absorb energy and enlarge the ride down distance by 100 mm.

SEAT PAN - A hard, crushable foam material with a thin soft cushion on top is used. This provides better coupling of the pelvis and higher energy absorption.

KNEE BOLSTER - A bolster with an adequate thickness (~ 100 mm) and compressive strength is used as an energy absorbing component. The initial distance between knee and foam (50 - 100 mm) is a crucial parameter which should be minimised as far as comfort requirements permit.

BELT SYSTEM - The use of a belt system is essential if occupant protection criteria are to be met in a

collision as described above. A 3-point belt system with a stiff webbing (4 - 8 %) and belt load limiters with excessive belt extraction at the design load has been developed to provide the required ride down distance for the occupants and optimised energy absorption properties.

ABSORPTION OF COLLISION ENERGY

CONVENTIONAL CARS - A major part of the kinetic energy of conventional cars in frontal collisions is not absorbed through deformation of the front structure, but instead through direct contact of the wide, heavy engines and accessories and also the front wheels and suspension with the opponent or an obstacle. Deformation of engine and wheel suspensions as well as compression of these components contribute to energy absorption. This arrangement provides an important load path for various overlap conditions through engine and wheels into the cabin floor structure. The cabin floor structure usually absorbs energy through deformation, thereby allowing drivetrain and chassis to intrude into the cabin. Additionally, the very stiff and heavy elements of the drivetrain create a dynamic stiffness against lateral load components in frontal - side collisions.

LOW MASS VEHICLES - LMV's have small, light drive trains. The front structure must be capable to absorb most of the collision energy including lateral load components, since deformation of the cabin and intrusion of components into it should be avoided. An ideal design of a deformable front structure would allow to distribute energy absorption to all its structural elements even for a 50% overlap situation, thereby substituting the part of a heavier car's engine.

STRUCTURAL CONCEPT OF THE LMV CRATCH

GENERAL FUNCTION - A stiff transversal beam right behind the front bumper over the full width of the experimental LMV CRATCH can react various load conditions (point load or distributed load) and overlap situations in frontal and frontal-side collisions. The beam is located at the average bumper height of 440 mm above ground with a width of 120 mm. The beam transfers the load onto the deformation elements of the front structure. A deformation element inside each front wheel bay was selected chosen out of a selection of concepts (cf. figure 3). The two deformation elements are implemented as curved longitudinal beams. The cabin structure is stiff, it does not deform until the deformation elements are fully crushed. The structural interface between cabin and deformation elements is a second stiff transversal beam, connecting the two A-pillars in front of the floorpan.

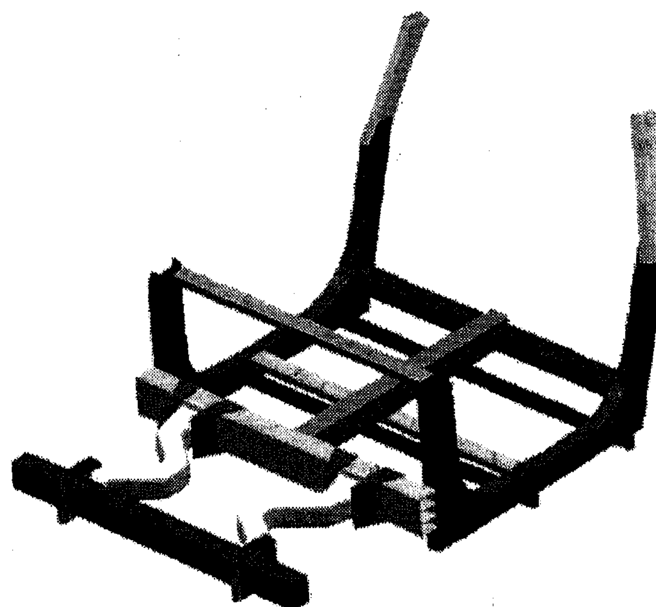

Figure 3: The CRATCH spaceframe

The deformation elements are thin-walled rectangular tubes. They are attached rigidly to the 'bumper' beam and the 'A-pillar' transversal beam, all together forming a stiff frame. This frame is designed to transfer longitudinal as well as transversal loads. In a 100% overlap situation, both deformation elements absorb energy through plastic bending and folding of the tube cross-section at three locations each (cf. figure 4), as opposed to a 50% overlap situation, where only one knee element bends at three locations and the other element bends at one location (cf. figure 5). This means that for 50% overlap, the near knee element accounts for 80 - 90 % and the far one for 10 - 20 % of the collision energy absorbed. The length of the deformation elements is determined by the average crush load and the amount of energy to be absorbed in the various collision situations.

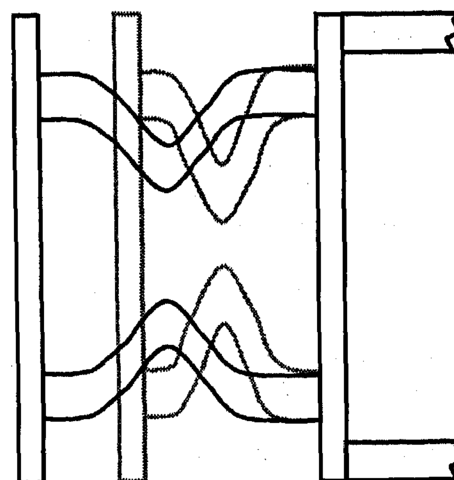

Figure 4: Deformation of front structure (100 % overlap)

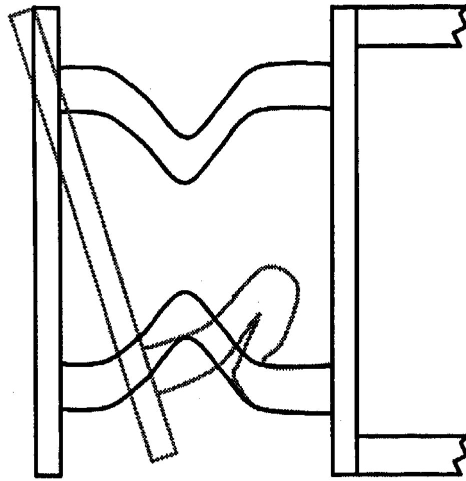

Figure 5: Deformation of front structure (50 % overlap)

TYPE OF STRUCTURE AND MATERIAL - For realization of the above described structural functions of an experimental LMV the design of a spaceframe was chosen. Most elements are tubes of rectangular cross section. Since buckling, rather than yield and rupture of the material is the failure criterion, aluminum was selected in place of steel. Using aluminum also helps to reduce the weight of this construction. The design is based upon single cell tubes without integrated stringers in the walls. The tubes are manufactured by welding U-profiles bent out of sheet metal. Most nodes of the spaceframe are welded, some special nodes had to be riveted.

DESIGN DATA OF THE STRUCTURE

The experimental LMV CRATCH is designed according to the following design requirements:

- cabin for 2 occupants plus luggage
- length 3.0 m
- width 1.65 m
- height 1.7 m
- space for a hybrid drivetrain
- space for 250 kg batteries
- max. curb weight 650 kg
- design frontal crash pulse for 50% and 100% overlap according to figure 6
- max. deceleration level for the cabin 60 g.
- collision angles maximum +20° and -20° to the longitudinal axis
- Stiff cabin structure, structural elements arranged such, that drivetrain or chassis components, bumpers and obstacles cannot intrude into the cabin in frontal and side collisions

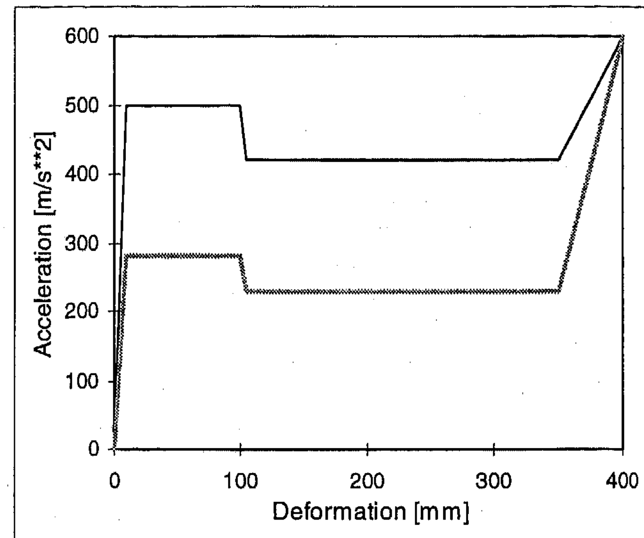

Figure 6: Frontal crash design pulses for the experimental LMV CRATCH, 100% (black) and 25% (gray) overlap against a rigid barrier. These 25% correspond to 50% overlap vs. a deformable barrier due to the nature of this structure.

ANALYSIS & OPTIMISATION OF THE STRUCTURE

ANALYSIS OF THE STRUCTURE - The static strength of the deformation frame was analysed using a simple FE model composed of beam elements and shear panels. The frame was analised for plastic deformations without folding of the cross sections. The load vs. deformation curve does not change for lateral load components up to a collision angle of 20°. As a result,

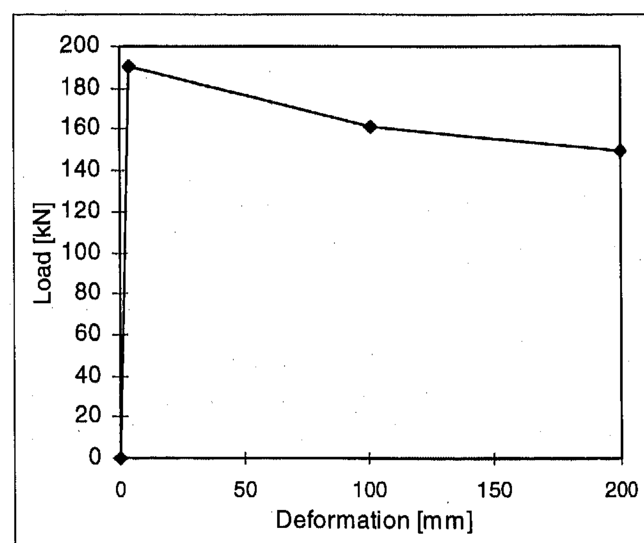

Figure 7: Theoretical crush load, 50% overlap, collision angle 0° - 20°

the crush zone should not be sensitive to lateral loads, e.g. as imposed in oblique impacts (cf. Figure 7).

STATIC TESTS - A test fixture to crush one deformation element according to the condition of a frontal collision with 100% overlap was set up. Four static tests were performed to develop a element with the specified load vs. deformation curve. The dynamic deformation curve was estimated to be 10% higher than the static curve (cf. figure 8).

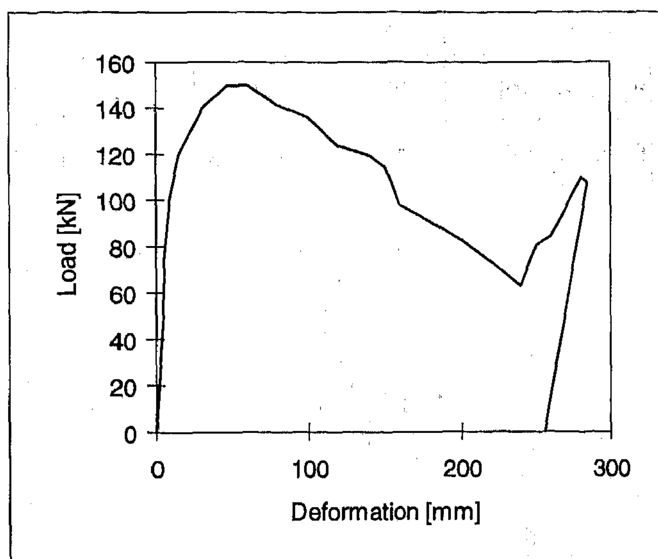

Figure 8: Static crush load of one deformation element, corresponding to a 100 % overlap impact. Load vector parallel to the longitudinal axis.

DYNAMIC TESTS - A preliminary dynamic test of the CRATCH spaceframe structure (without the costly hand-made body and without occupant surrogates and restraint systems) was deemed necessary in order to ascertain predictions and estimates of the dynamic behaviour of the two car structures. Such a test was performed in cooperation with the European car manufacturer Renault. The spaceframe of the experimental LMV CRATCH, equipped with hybrid drivetrain, suspensions and wheels, was tested against a production car (Renault LAGUNA). Ballast was added in order to match the design weight. Both vehicles collided with an initial velocity of 50 km/h, at 50 % overlap and a collision angle of 0°. Following the evaluation of this preliminary test, some modifications at the LMV were necessary. The crash pulse of the LMV was 15 % lower than the estimated pulse and the energy absorption was 25% lower than the kinetic energy of the CRATCH. As predicted, there was no intrusion of deformed components into the floorpan of neither car, and the total deformation of both occupant compartments was extremely small.

VERIFICATION OF THE THEORETICAL FINDINGS

Due to limited resources only one fully equipped experimental LMV CRATCH could be manufactured, i.e. only one frontal collision situation CRATCH vs. Renault LAGUNA could be tested. Therefore, it seemed adequate to use the estimated design pulse for a head-on collision with 100% overlap and a Δv of 20 m/s for the development of the restraint system and the subsequent sled tests, because this is the worst case for the restraint system. A frontal collision with 50 % overlap at 0° collision angle and a Δv of 20 m/s on the other hand is considered to be the critical load case for the crush zone, because only 50 - 60 % of the deformable structure is crushed and absorbs energy. This latter load case yields a lower and longer crash pulse but it shows the maximum deformations with a possible hardening of the structure at the end of the crushable zone, and an eventual intrusion of components into the foot space of the driver. Accordingly, this load case was selected to be tested in the final collision test CRATCH vs. LAGUNA.

FINAL COMPATIBILITY CRASH TEST

GENERAL - The French car manufacturer Renault was a highly welcome partner in the project, as this car manufacturer has a long tradition in offering a model range of largely different size and weight. Compatibility in collisions, at the very least among the currently circulating fleet of their own make, is a central issue for this manufacturer. Therefore, the LAGUNA already exhibits an adequate stiffness of the crush zone considering frontal collisions against small cars. Moreover, in terms of mass and exterior dimensions, the LAGUNA is representative for the current European 'compact' class cars.

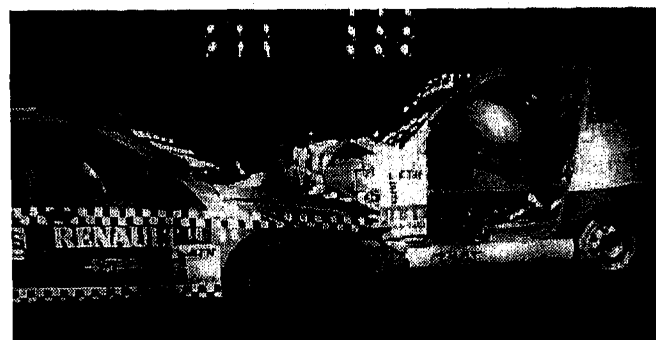

Figure 9: The collision opponents

The driver and passenger positions of the CRATCH as well as the driver position of the LAGUNA were occupied by instrumented 50th percentile Hybrid III dummies. A uninstrumented Hybrid II dummy was used for the passenger position of the LAGUNA, since occupant loads were expected to be well below actual protection criteria.

Table 1: Test parameters

		CRATCH	LAGUNA
Length width (without mirror) Height	[m]	3,05 1,65 1,7	4,508 1,752 1,433
Empty weight incl. measuring equipment, no fuel	[kg]	671,7	1356,6
Driver & passenger dummies	[kg]	160,3	153,4
Collision weight	[kg]	832	1510
Collision speed	[km/h]	50,5	50,5
Overlap (0° collision angle)	[%]	50	46,8
theoretical Δv (w/o rotation and elastic rebound)	[km/h]	65,12	35,88

The test was performed successfully. The high center of gravity of CRATCH caused a remarkable rotation about the lateral axis, i.e the rear bumper was lifted by 0,5 m approx. Both cars rotated about the vertical axis, the CRATCH by 140°, the LAGUNA by 80°.

As predicted, the CRATCH cabin showed no measurable deformation and no intrusion. The left deformation element was totally crushed and, after full deformation had occurred, the rear folding joint broke. Future improvements of the deformation elements should incorporate the elimination of such ruptures.

The LAGUNA cabin showed very small deformation and intrusion into the driver's floorpan (5 - 20 mm).

Table 2: Energy balance

		CRATCH	LAGUNA
measured Δv	[km/h]	71,6	32.76
kinetic energy	[kJ]	81,9	148,6
absorbed energy	[kJ]	65	140

The energy absorption capability for this type of collision of the CRATCH has been exhausted in the test. Further investigation is needed with respect to the energy absorption in other collision situations, e.g. against rigid barriers.

Table 3: Occupant loads

	CRATCH		LAGUNA	limit
	driver	pass.	driver	
HIC_{36}	632	546	257	1000
a_{3ms} head [g]	58,4	62,6	38	80
a_{3ms} chest [g]	39,7	33,3	35	60
F femur l/r [kN]	2,1 / 1.6	1,6 / 0.3	n.m	10.1

CONCLUSIONS

The safety deficits of small cars observed today in accident statistics can be alleviated if the structure and the restraint systems of these cars are designed and optimised for the situation they will most likely encounter in a real world situation, e.g. a collision against a heavier car.

For the extreme example of a low mass vehicle with a curb weight 25 % lower than current subcompact cars, it was shown that the development of a rigid lightweight structure with well defined properties of the crush zone is feasible and that a restraint system which can meet occupant protection criteria even at a Δv of 21.5 m/s (77.4 km/h) and car mean deceleration levels of 400 - 500 m/s^2 can also be conceived [5].

ACKNOWLEDGMENTS

The study presented here was in part supported by the Swiss Foundation for Traffic Safety and the Swiss Ministry of Energy.

We wish to thank ALUSUISSE (Neuhausen, Switzerland) for helping us to find an adequate technology and for building this experimental spaceframe, Renault (Paris, France) for the cooperation, for performing the preliminary crash test and for supplying two Laguna cars, PARS GmbH, Alzenau, Germany, for performing the sled tests, and MST GmbH, Aschaffenburg, Germany, for supplying the original and modified airbag modules and steering wheels.

The Relationship Between Car Size and Occupant Injury in Traffic Accidents in Japan

Koji Mizuno, Tetsuhiro Umeda, and Hideki Yonezawa
Traffic Safety and Nuisance Research Institute

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

The relationship between car size and occupant injury is examined using traffic accident data from all over Japan. For head-on collisions, the occupant injury rate is formulated based on the approximation of occupant injury by delta-V. The effects on occupant injury of the sizes of the striking and struck vehicles, as well as the effects of seat belt use and vehicle velocity, are examined in head-on, side-impact and single-car collisions.

As occupant injuries are also influenced by the other car or cars involved in a collision, the number and size distribution of vehicles is important. Sensitivity analysis shows that the effect of the number of lighter cars is greater in head-on collisions and that the effect of the number of heavier cars is greater in side-impact collisions, relative to the total number of fatalities.

INTRODUCTION

It is well known that the injury risk to the occupant is higher in lighter vehicles in head-on collisions. The effect of vehicle mass on occupant injury has been examined in detail by Evans.[1] He claims from the data of FARS that when 900-kg and 1800-kg cars collide head-on, the risk of fatality in the smaller car is 13 times higher than that in the larger car.

The higher injury risk due to the difference of mass between two vehicles is defined as the aggressiveness of the heavier vehicle. The aggressiveness of vehicle mass increases when combined with high vehicle rigidity, such as is found in light trucks and vans.[2] The compatibility between small car and large car is investigated and low mass vehicle is proposed with an optimized restraint system.[3]

In single-car accidents, the injury rate does not vary as much as in head-on collisions, though it has been shown by comparison to pedestrian fatalities that the risk of fatal injury increases as the mass of the vehicle decreases.[1] The analysis was carried out not only with respect to vehicle mass, but also the power/weight ratio of the car.[3] The risk of fatality increases in proportion to the power/weight ratio of the car. This is related to the fact that sports and specialty cars with high power/weight ratios and which are driven by younger drivers are frequently involved in high-speed single-car accidents.[5]

The automotive traffic environment varies from country to country according to the vehicle population, road conditions, and traffic laws. The average mass of a passenger car in Japan is 1131 kg (1994), which is smaller than that of cars in the United States. One reason the average mass is so small is the existence in Japan of mini-passenger cars, which average only 639 kg and the size of which is defined by Japanese law. Therefore, since occupant injury is affected by car size, the question must be examined in the context of the Japanese traffic environment to know what occurs in collisions with different car sizes.

This research focuses on the relationship between occupant injury and car size, especially vehicle mass, in traffic accidents in Japan. We mainly used the law enforcement data on traffic accident and analyzed statistically the size effect of the car.

METHODOLOGY

As law enforcement data on traffic accidents belongs to the National Police Agency and vehicle data belongs to the Ministry of Transport (MOT), in the past accident data was not correlated to vehicle design factors, such as mass, body dimensions, and engine displacement. Therefore the relationship between occupant injuries and vehicle designs was difficult to analyze. In 1993, the

Institute of Traffic Accident Research and Data Analysis (ITARDA) was established by the National Police Agency, the Ministry of Transport and the Ministry of Construction. ITARDA aims to reduce road accidents and injuries through comprehensive investigation and research on traffic accidents. Data on traffic accidents, drivers, roads and vehicles are integrated by ITARDA, so that it is now possible to correlate accident data with vehicle design factors such as body dimensions, mass, wheelbase or engine displacement.

The National Police Agency collects data only on accidents where at least one occupant suffered injury or death. Accordingly, in this paper the probability of injury means the fraction of injuries to occupants involved in such accidents. As the number of vehicle occupants killed in traffic accidents is about 4,500 per year and accident data for the four years from 1992 to 1995 was used, the total number of fatalities alone was insufficient for statistical analysis. Therefore, the broader classification of serious or fatal injury was examined. As no injured passengers are not included in the accident data, only driver injuries were examined in order to simplify the analysis.

Occupant injuries are examined in accident configurations such as head-on, side-impact, and single-car collisions, which are in turn classified according to location of impact. In this paper, a head-on collision is defined as one in which the impact location on both vehicles is on the front, including a frontal oblique collision. Side-impact collisions are defined as those in which the front of one vehicle collides with the side of another vehicle. Note that in the accident data, only eight locations of deformation are defined: front, right front, left front, right side, left side, rear, right rear and left rear.

Accidents between passenger cars and single-car accidents of passenger cars made up half (49.3%) of the total number of accidents involving 4-wheel vehicles in 1994. Since most passenger cars are bonnet types with similar mechanisms of injury, rather than cabover-types, this study deals with collisions between bonnet-type cars or single-vehicle accidents of bonnet-type cars.

Table 1 Categories of vehicles

	Dimensions			Engine
	Length (meters)	Width (meters)	Height (meters)	Displacement (liters)
Mini-size	3.3 or less	1.4 or less	2.0 or less	0.66 or less
Small-size	4.7 or less	1.7 or less	2.0 or less	2.0 or less
Ordinary-size	No limit	No limit	No limit	No limit

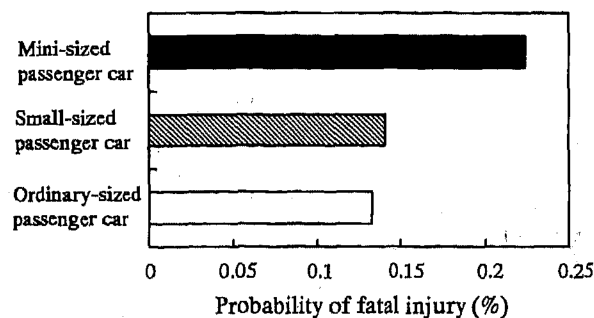

Fig. 3. Probability of fatal injury to driver involved in car-to-car collision (1994)[5]

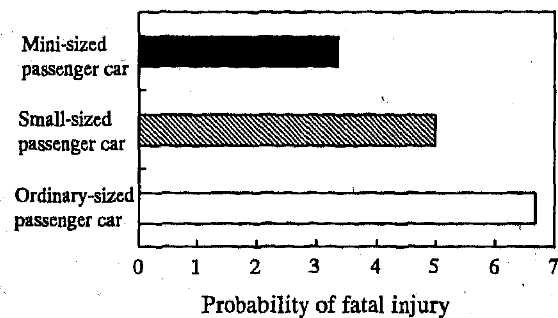

Fig. 4. Probability of fatal injury to driver involved in single car accident (1994)[5]

VEHICLE CATEGORY AND CLASSIFICATION

Vehicles are classified by their use, such as passenger vehicle, truck, bus and special-purpose motor vehicle. Fig. 1 shows the number of registered vehicles in Japan. The vehicles are categorized by their size and engine displacement, as mini-sized, small-sized and ordinary-sized vehicles (Table 1). The vehicle tax varies according to the vehicle's category and classification.

Fig. 2 shows the distribution of passenger vehicles according to mass. The mass of the vehicle is determined by its size and engine displacement, so the masses of mini-sized, small-sized and ordinary-sized cars cover different ranges. The mass of a mini-sized passenger vehicle is from 500 kg to 800 kg, that of a small-sized passenger vehicle is greater than 600 kg, and that of an ordinary-sized passenger vehicle is greater than 1100 kg. Many mini-sized cars are registered as trucks to take advantage of lower taxes, but they have almost the same structure and usage as a passenger car excluding the folding seats for goods loading facilities.

Bonnet-type passenger cars must be put through a front crash test against a fixed barrier, with the speed set at 50 km/h for small-sized and ordinary-sized cars, and at 40 km/h for mini-sized cars. In 1998, the legally defined minimum dimensions for a mini-size car will be changed to 3.4 meters long and 1.48 meters wide in order to meet the standards for a frontal crash test at 50 km/h.

As different drivers elect to use mini-sized, small-sized or ordinary-sized cars, the accident involvement rate and fatal accident rate are different for each category of cars. Fig. 3 shows the probability of injury to the drivers in car-to-car collisions including rear-end collisions, and Fig. 4 shows that of the drivers in single car accidents. In car-to-car collisions, it is shown that the probability of fatal injury to the driver in a smaller car is higher, especially in mini sized car. However, in single car accidents, the probability of fatal injury to the driver in a smaller car is lower. This is because the crash velocity of a smaller car is lower in a single car accident.

INJURY RATE

HEAD-ON COLLISION - The data on head-on collisions between bonnet-type cars for the years 1992 to 1995 include 950 driver fatalities, 11,634 serious injuries, 185,848 minor injuries and 167,034 cases of no injury to the driver. The percentage of fatally injured drivers wearing seat belts was 30.2%, which is far less than the 77.6% figure for all drivers involved in head-on collisions. According to the data, the percentage of drivers wearing seat belts does not vary much with vehicle mass.

Vehicle mass has a greater effect on the severity of occupant injuries in head-on collisions than in other accident configurations. Fig. 5 shows the probability of serious or fatal injury to the driver of car 1 in a head-on collision between car 1 and car 2. The probability of serious or fatal injury increases as the mass of car 1, m_1, decreases and that of car 2, m_2, increases. When m_1 is less than 700 kg and m_2 is greater than 1401 kg, the probability of serious or

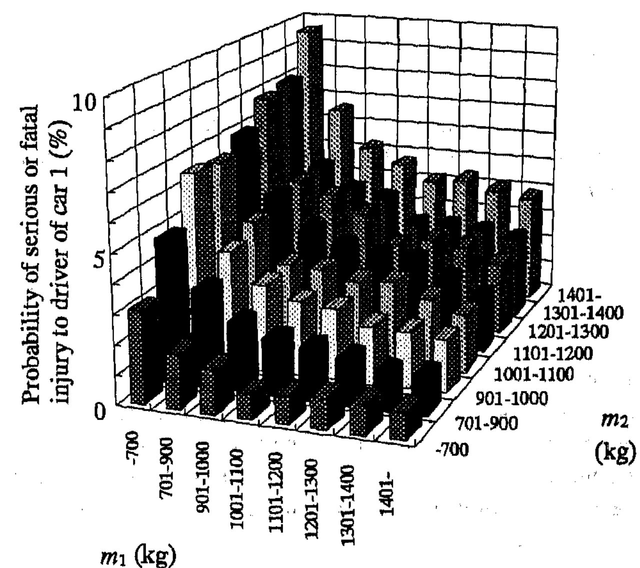

Fig. 5. Probability of serious or fatal injury to driver of car 1 in head-on collision

fatal injury to the driver of car 1 is 9.5%. By contrast, when m_1 is greater than 1401 kg and m_2 is less than 700 kg, the probability of serious or fatal injury to the driver of car 1 is 0.95%.

The probability of occupant injury depends not only on the mass of the car in which the occupant is traveling but also that of the other car. Thus, the probability of injury to the occupant in a car with a given mass is influenced by the numerical distribution of cars, and the travel and accident rates. Fig. 6 shows the probability of serious or fatal injury to the driver in a head-on collision relative to the mass of the driver's vehicle. Fig. 7 shows the same probability relative to the mass of the other vehicle. The probability of serious or fatal injury increases exponentially as the mass of the driver's car decreases, especially if the mass is less than 1000 kg. On the other hand, the probability of injury steadily increases as the other vehicle's mass increases.

The occupant injury rate versus car mass is estimated using delta-V. We define the probability of injury as

$R_i(m_i, m_j)$ = Probability of injury to occupant of car i, in collision with car j,

where m_i, m_j = masses of vehicles i and j. Delta-V is defined as the change in the car passenger compartment velocity during an impact and is used as an indicator of impact severity. As delta-V is the velocity change that the occupant experiences, it is potentially a factor for occupant injury. Thus the probability of occupant injury is approximated by delta-V to the power k, as[6]

$$R = r_0(\Delta v)^k , \quad (1)$$

where r_0 is the constant for injury severity.

Using Eq. (1) and Newton's third law, the relationship between delta-V and the probability of occupant injury can be expressed as

$$\frac{R_2}{R_1} = \left(\frac{\Delta v_2}{\Delta v_1}\right)^k = \left(\frac{m_1}{m_2}\right)^k , \quad (2)$$

where Δv_1, Δv_2 = delta-V of vehicles 1 and 2. The ratio of vehicle mass and probability of occupant injury is shown in Fig. 8 in the manner demonstrated by Evans.[6] The parameter k is obtained for serious or fatal injury, and for more than minor injury, according to the slope of the straight line.

$$\begin{cases} k = 2.67 \text{ (Serious or fatal injury)} \\ k = 1.07 \text{ (More than minor injury)} \end{cases} \quad (3)$$

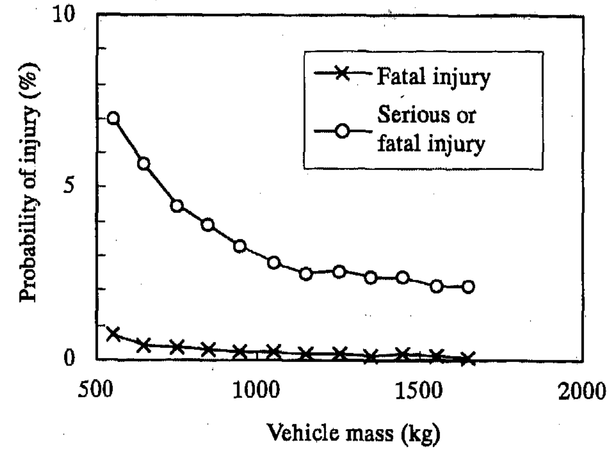

Fig. 6. Probability of injury to driver in head-on collision

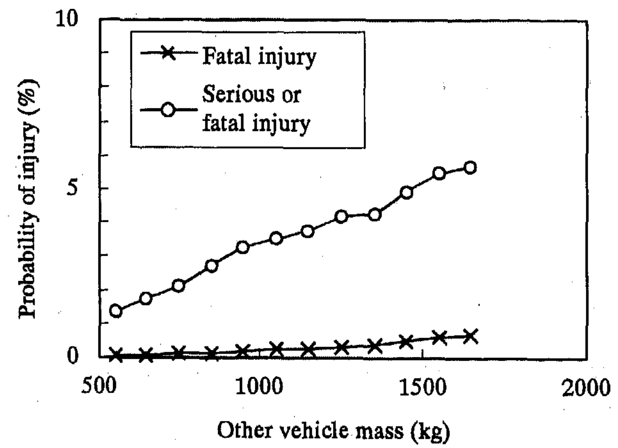

Fig. 7. Probability of injury to driver versus mass of other vehicle in head-on collision

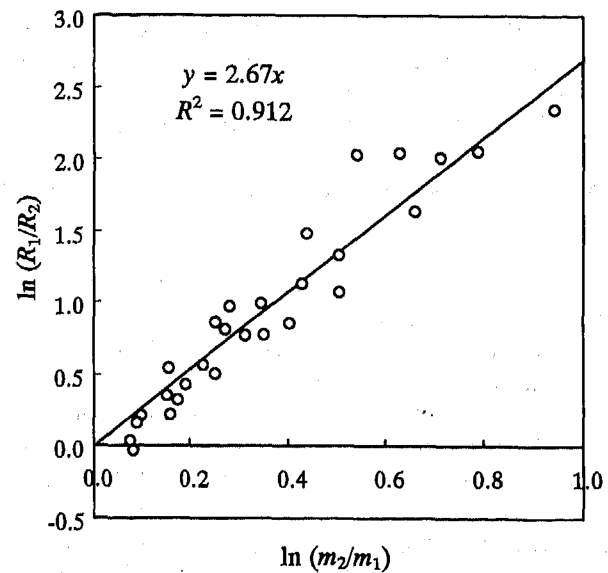

Fig. 8. Ratio of car mass and probability of serious or fatal injury in head-on collision

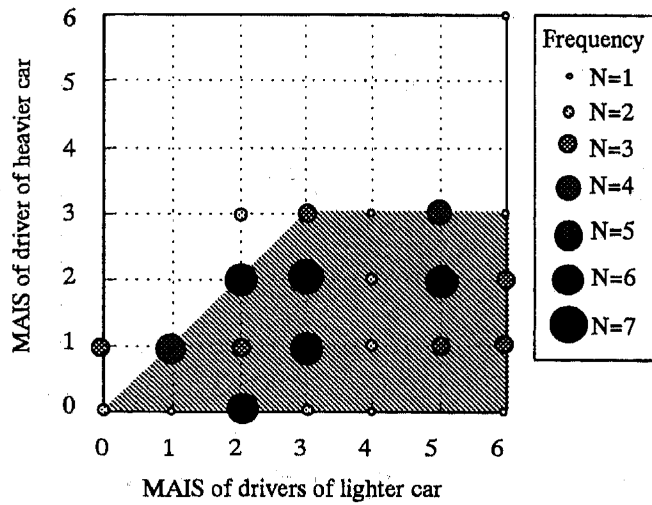

Fig. 9. Comparison of AIS of each driver in head-on collision (N=59)

It is well known that human head tolerance is proportional to $\alpha^{2.5}T$. Thus the probability of serious injury is expressed as

$$R \propto \alpha^{2.5}T \tag{4}$$

where α is acceleration and T is duration time. The ratio of probability of serious or fatal injury, R_2/R_1, is obtained as follows:

$$\frac{R_2}{R_1} = \left(\frac{\alpha_2}{\alpha_1}\right)^{2.5} = \left(\frac{m_1}{m_2}\right)^{2.5} \tag{5}$$

Comparing Eq. (2) with Eq. (5), the exponent value of 2.67 for serious injury or fatality derived from Eq. (2) is seen to be close to the posited value of 2.5, suggesting that the value 2.67 is appropriate for serious injury or fatality.

There is a tendency of higher risk to the driver of a lighter car. Fig. 9 shows the Abbreviated Injury Scale (AIS) for the driver of each car involved in head-on collisions investigated by the MOT. [7] In many cases the AIS for the driver of the lighter car is larger than that for the driver of the heavier car. Furthermore, in most of the head-on collisions investigated, the AIS for the heavier car is less than or equal to 3, whereas that for the driver of the lighter car is in the range 0 to 6. That is to say, the AIS for each driver is distributed in the region under the oblique line shown in Fig. 9.

For many head-on collisions, delta-V is approximated for a central collision. Assuming the restitution coefficient is zero, delta-V is obtained for a central collision as follows:

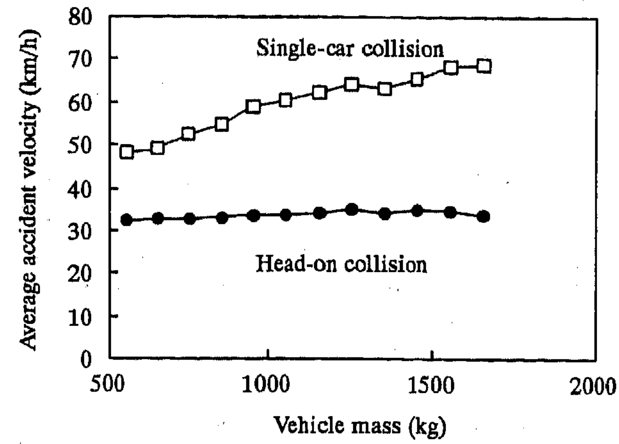

Fig. 10. Average accident velocity in head-on collision

$$\Delta v_1 = \frac{m_2}{m_1 + m_2} v_c \tag{6}$$

where v_c is closing speed. From Eq. (1) and Eq.(6), the probability of injury for the driver in car 1 is expressed as follows:

$$\begin{aligned} R_1 &= r_0 \left(\frac{m_2}{m_1 + m_2} v_c\right)^k \\ &= a \left(\frac{m_2}{m_1 + m_2}\right)^k \end{aligned} \tag{7}$$

where $a = r_0 v_c^k$.

Before discussing Eq. (7), the relationship between the coefficient a, closing speed and vehicle mass must be examined. Fig. 10 shows the average accident velocity versus vehicle mass in head-on and single-car collisions. The accident velocity is defined as the velocity at the moment the driver perceives the hazard of colliding with another vehicle, a pedestrian, or a parked car or other stationary object. Specifically, it indicates the velocity before the driver brakes or steers to avoid the accident, and is compiled mainly from drivers' testimony. For head-on collisions, the accident velocity does not change significantly with vehicle mass (32.5-35.2 km/h) as shown in Fig. 10. On the other hand, for single-car collision, the accident velocity increases from 48.4 to 68.6 km/h as the vehicle mass increases. It is possible that the characteristics of drivers who are involved in head-in collisions are different from those of drivers who are involved in single-car collision. The accident velocity is likely to be closely related to collision velocity. This fact suggests that the collision velocity should be considered in a single-car accident,

whereas it does not have to be considered in a head-on collision, when statistically evaluating the effect of vehicle mass on occupant injury. Thus, the coefficient a is thought to be independent of vehicle mass in head-on collisions in Eq. (7).

According to Eq. (7), there is a linear relationship between $\ln(R_1)$ which is natural logarithm of R_1 and $\ln\{m_2/(m_1+m_2)\}$. Fig. 11 demonstrates the strong relationship between $\ln\{m_2/(m_1+m_2)\}$ and $\ln(R_1)$ for serious and fatal injury. The coefficient a is obtained by an intercept of the straight line in Fig. 11 as follows:

$$\begin{cases} a = 20.6 & \text{(Serious or fatal injury)} \\ a = 112.2 & \text{(More than minor injury)} \end{cases} \quad (8)$$

The regression of the probability of injury due to vehicle mass in a head-on collision is obtained using Eq. (3), Eq. (7) and Eq. (8). According to Eq. (8), the probability of injury exceeds 100% when the mass of the other car, m_2, is infinite. This is because Eq. (8) applies only to bonnet-type cars under 2000 kg. Eq. (7) also suggests the probability of injury increases with the closing speed, which depends on v_c^k.

The effect of wearing a seat belt on the probability of serious or fatal injury versus vehicle mass is shown in Fig. 12. Wearing a seat belt reduces the risk of serious or fatal injury over the entire range of vehicle mass. The probability of fatal or serious injury for belted drivers is between 1.5 and 5.1%, whereas that for unbelted drivers is between 4.3 and 11.6%, which shows that the effect of vehicle mass is large for unbelted drivers. Thus, wearing a seat belt is more important for the occupant of a lighter car in order to mitigate the severity of injury.

The probability of serious or fatal injury versus mass ratio is compared for belted and unbelted drivers as shown in Fig. 13. The straight line for belted and unbelted drivers are parallel. When the slope of the line is fixed at 2.67 as obtained for all drivers in Eq.(8), a is estimated for serious or fatal injury as follows:

Table 2 The coefficient a and k

Injury severity	Seat belt	k	a
Serious or fatal injury	Belted	2.67	14.1
	Unbelted		37.9
More than minor injury	Belted	1.07	106.7
	Unbelted		133.7

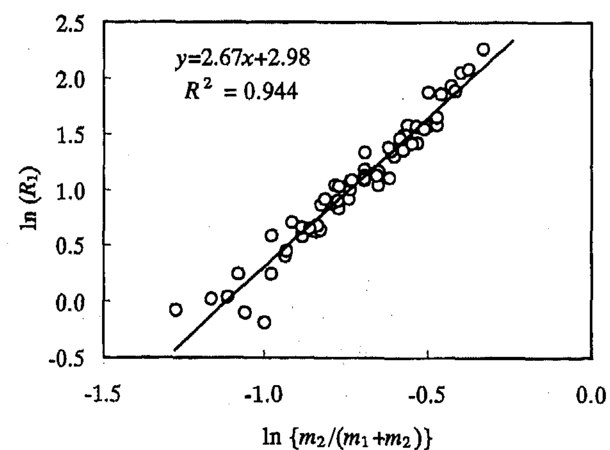

Fig. 11. Mass ratio and the probability of injury to driver in car 1 in head-on collision

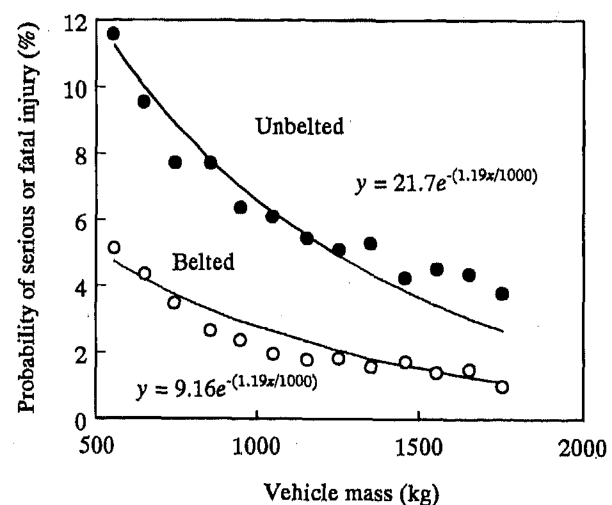

Fig. 12. Effect of seat belt on probability of serious or fatal injury to driver in head-on collision

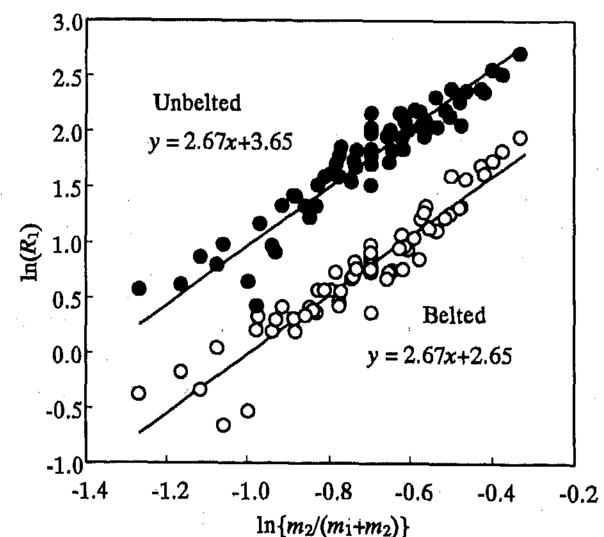

Fig. 13. The comparison of the probability of serious or fatal injury for belted and unbelted drivers in head-on collisions

$$\begin{cases} a_{Belted} = 14.1 & \text{(Belted driver)} \\ a_{Unbelted} = 37.9 & \text{(Unbelted driver)} \end{cases} \quad (9)$$

Table 2 summarizes a and k for restraint condition and injury severity.

When the combination of car mass (m_1, m_2) is equal for two head-on collisions, the probability of injury for belted and unbelted driver is obtained by Eq.(7) and Eq.(9) as:

$$\frac{R_{Unbelted}}{R_{Belted}} = \frac{a_{Unbelted}}{a_{Belted}} = 2.68 \text{ (Serious or fatal injury)} \quad (10)$$

Fig. 14 shows the average accident velocity classified by seat belt wearing. The accident velocity is higher for cars driven by unbelted drivers, which shows the risk involved in a severe accident is higher for unbelted drivers. In Eq.(7) a is dependent on crash velocity, however, in Eq.(10) the difference of the crash velocity between belted and unbelted drivers is not considered.

Thus, a double pair comparison method is used in order to compare the injury rate between belted and unbelted drivers. The ratio of seriously or fatal injury rate of the driver in car 1 to that of driver in car 2, R_1/R_2, is obtained by the ratio of the number of serious or fatal injuries of the drivers in car1 to that of the drivers in car 2. Using this method, injury rate is not affected by the difference of crash velocities between two cars driven by belted and unbelted drivers. Fig. 15 shows the ratio of injury rate classified by seat belt wearing of the driver in car 1 and car 2. When both drivers wear a seat belt or don't wear a seat belt in car 1 and car 2, R_1/R_2 is expressed using Eq.(2) and Eq.(3) as:

$$R_{1,Belted} / R_{2,Belted} = R_{1,Unbelted} / R_{2,Unbelted} = (m_2 / m_1)^{2.67} \quad (11)$$

where $R_{i,\,Belted}$ is the injury rate of the belted driver in car i and $R_{i,\,Unbelted}$ is that of the unbelted driver in car i. The data obtained by the double pair comparison method for belted/belted and unbelted/unbelted drivers is distributed along the approximate curve in Eq.(11). In the case where the driver in car 1 do not wear seat belt and the driver in car 2 wears a seat belt, the ratio of serious or fatal injury is approximated as:

$$R_{1,Unbelted} / R_{2,Belted} = 1.89(m_2 / m_1)^{2.67} = (1.27 m_2 / m_1)^{2.67} \quad (12)$$

This result shows when the combination of striking and struck car mass (m_1, m_2) is equal, the serious or fatal injury rate for unbelted drivers is 1.89 times higher than that for unbelted drivers. Eq. (12) also shows that in order to gain

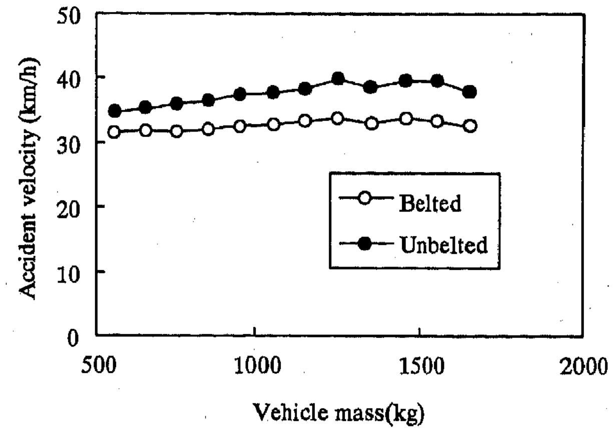

Fig. 14. Average accident velocity of cars with belted and unbelted drivers in head-on collisions

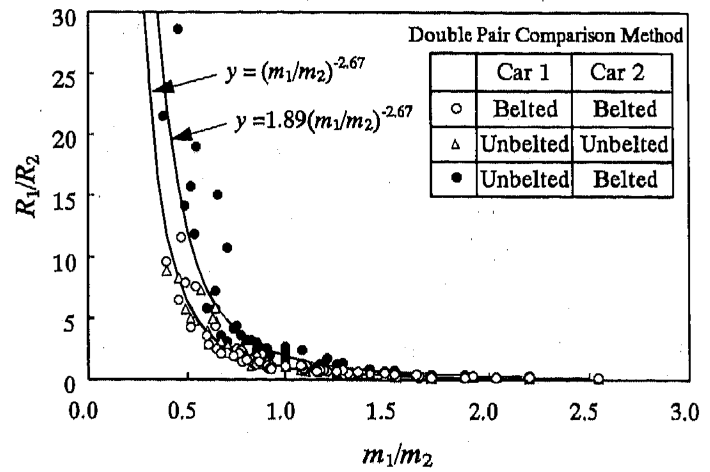

Fig. 15. Ratio of probability of serious or fatal injury for driver's restraint condition in car 1 and 2

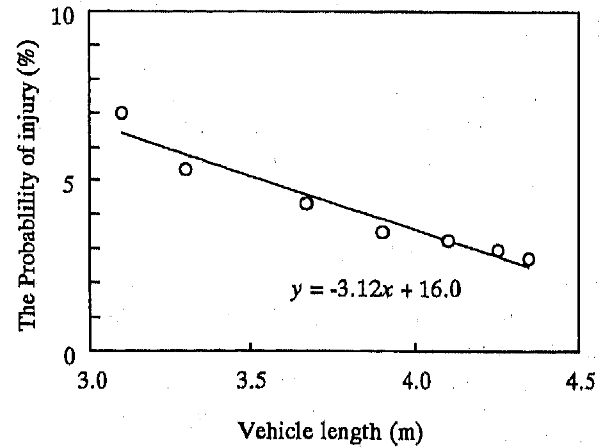

Fig. 16. Car length and probability of serious or fatal injury in head-on collision

the same probability of serious or fatal injury, the unbelted driver requires a vehicle mass 1.27 times that of vehicle mass driven by the belted driver.

The length as well as the mass of a car influences the severity of injury to the occupant. As the total length of the car increases, the hood is likely to be longer and to have a greater capacity to absorb impact. Fig. 16 shows the effect of car length on the probability of serious or fatal injury to the driver. The relation between length and the probability of serious or fatal injury can be described as straight line. However, since length is strongly linked to vehicle mass, it is difficult to identify the effect of length alone.

SIDE-IMPACT COLLISION - The data on side-impact collisions between bonnet-type cars for the years 1992 to 1995 includes 88,127 drivers struck from the right side (the driver's side in Japan) and 87,261 drivers struck from the left side. Among these, right-side collisions accounted for 296 deaths, 3,159 serious injuries, and 59,606 minor injuries, while left-side collisions resulted in 248 deaths, 2,199 serious injuries, and 49,859 minor injuries. Therefore, the number of deaths is larger in collisions on the driver's side, even though the number of side-impact collisions is almost the same for the right and left sides. In this section, the probability of injury to the driver when the other car strikes the right side is examined. Fig. 17 shows the probability of driver injury in a car struck from right side. The probability of injury to the driver increases as the mass of the struck vehicle decreases and that of the striking vehicle increases, although the effect of the struck vehicle mass on the probability of injury is somewhat smaller than it is in head-on collisions.

The effect of the mass of the struck and the striking vehicle on the probability of driver injury is shown in Fig. 18 and Fig. 19 respectively. As the mass of the struck vehicle decreases and the mass of the striking vehicle increases, the probability of injury increases. The probability of driver injury ranges from 3.0 to 6.3% relative to the struck vehicle mass, in contrast to the range from 2.1 to 7.0% for a head-on collision. Thus, the struck vehicle mass influences injury probability more significantly in a head-on collision than in a side-impact collision.

The relationship between the mass ratio of two vehicles in a side-impact collision and the probability of occupant injury is shown in Fig. 20. The correlation between mass ratio and probability of injury is small compared to a head-on collision (Fig. 11). Two reasons for this may be proposed. First, the impact direction diverges as the two cars travel in different directions, i.e., Eq. (6) does not hold for two-dimensional behavior in a side-impact collision. Second, the occupant injury rate is not fully correlated to delta-V. In a side impact, the interior of the struck side hits the occupant before the exchange of momentum between

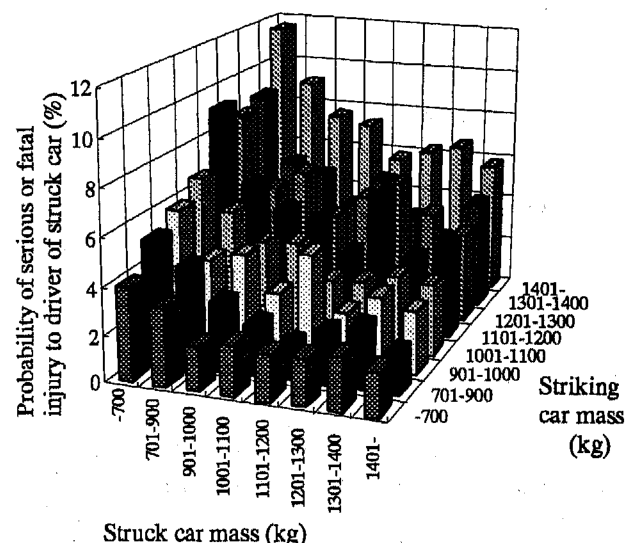

Fig. 17. Probability of injury to driver of car struck from right side

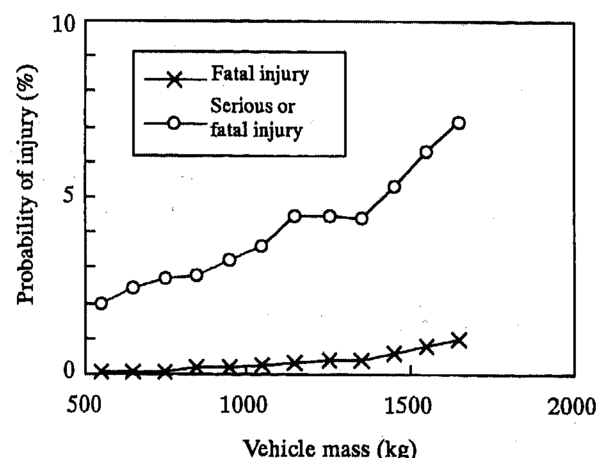

Fig. 19. Striking vehicle mass and probability of driver injury in side-impact collision. Location of impact is right side of car.

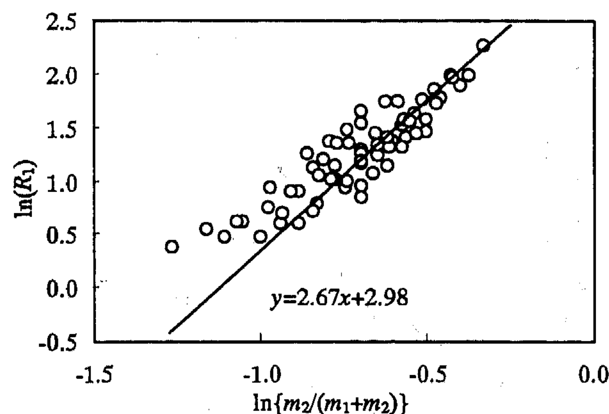

Fig. 20. Mass ratio and probability of serious or fatal injury to driver in struck vehicle in side-impact collision. Straight line is a regression line for head-on collision.

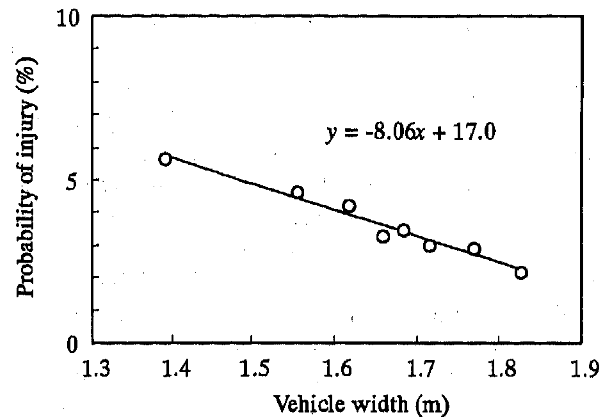

Fig. 21. Car width and probability of serious or fatal injury to driver in side-impact collision

two cars is over. The straight line in Fig. 20 is that for a head-on collision. The probability of injury in a side-impact collision can be seen to rise above this line when the mass ratio, $m_2/(m_1+m_2)$, is small, which demonstrates that the occupant on the struck side is likely to be seriously or fatally injured, even when the struck vehicle mass m_1 is larger or the striking vehicle mass m_2 is smaller in comparison to a head-on collision.

The width of the car affects the injury probability, as has sometimes been shown in side-impact tests and simulations.[8][9] As the width of the car increases, more space becomes available for reinforcing structures, door beams or door padding, and the distance between occupant and door increases. Fig. 21 shows the relationship between car width and the probability of injury to the struck side driver. The probability of serious or fatal injury decreases linearly with car width. Note that width directly affects the vehicle mass, as does length, so that we cannot pinpoint the width effect alone using the data in Fig. 21.

SINGLE-CAR COLLISION - In 1995, the number of fatal single-car accidents was 1,868, which amounts to 18.3% of all fatal accidents (total 10,227). Cars colliding with fixed objects accounted for 75.4% of single-car accidents. In many cases the fixed object with which the car collided was a telephone pole, signpost or guardrail. Our research examined accidents in which the front ends of bonnet-type cars collided against fixed objects. The data indicate that from 1992 to 1995, 59,101 drivers of bonnet-type cars were involved in single-car collisions, resulting in 2,552 deaths, 8,530 serious injuries, and 36,297 minor injuries, with 11,722 collisions resulting in no injuries to the driver.

Fig. 22 shows the probability of driver injury in a single-car collision with a fixed object. The probability of fatal injury increases with the vehicle mass, while that of serious or fatal injury reaches its minimum value when the vehicle mass is 1150 kg, though for both cases the effect of mass is not so large as it is in car-to-car collisions. However, the severity of the collisions in which drivers are involved are not factored into this result.

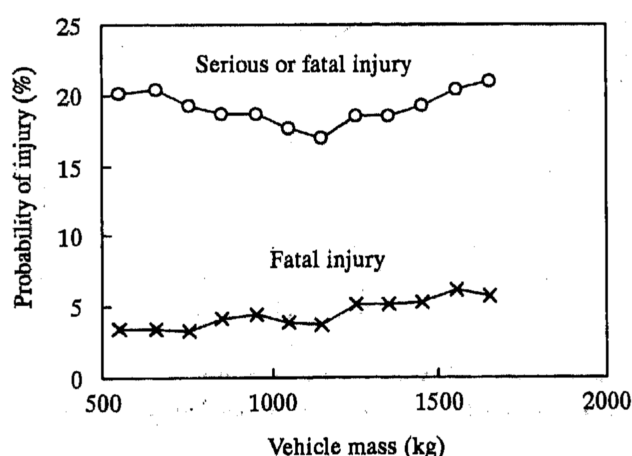

Fig. 22. Probability of driver injury in single-car collision

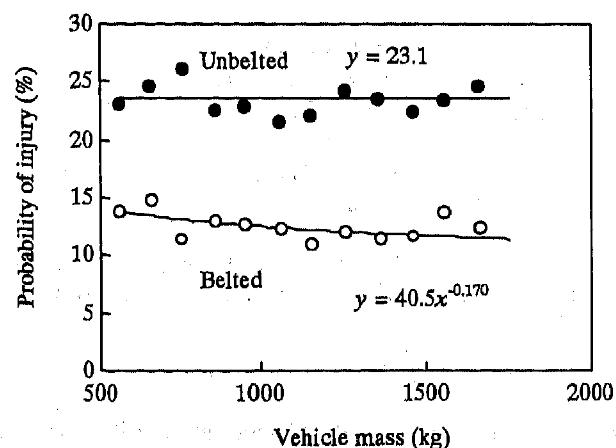

Fig. 23. Effect of seat belt on probability of serious or fatal injury to driver in single-car collision

The percentage of drivers wearing a seat belts in single-car collision is 44.2%, which is far lower than the 77.6% figure for head-on collisions. One reason for the low percentage is that younger drivers are disproportionately involved in single-car collisions. Note that there is a problem of reliability with the data on seat belt use, because it depends heavily on the testimony of the driver to the police. Nevertheless, the effect of wearing a seat belt is clear. For unbelted drivers, the probability of fatal injury is 6.6%, that of serious injury is 16.7% and that of minor injury is 61.3%, while for belted drivers, the probability of fatal injury is 1.4%, that of serious injury 11.3%, and that of minor injury 61.9%. Fig. 23 shows the effect of wearing a seat belt in a single-car collision. The probability of serious or fatal injury is higher for unbelted drivers, irrespective of vehicle mass. These results show the importance of wearing a seat belt in a single-car collision.

We examined the relationship between probability of occupants injury and vehicle mass, considering the occupant risk exposure in terms of accident velocity. Injury severity varies with accident velocity as shown in Fig. 24. As the accident velocity increases, the probability of fatal injury increases. A heavier vehicle is likely to be involved in a more severe collision, because the accident velocity tends to be higher for a heavier car than for a lighter car, as shown in Fig. 10. Fig. 25 shows that the accident velocity for a car weighing 550 kg is lower than that for a car weighing 1750 kg. The accident velocity distribution for a car weighing 1055 kg is similar to the average distribution. The probability of injury is calculated assuming the average accident velocity for all cars, regardless of mass.

The probability of injury to the occupant can be obtained from the velocity distribution and the probability of injury in a vehicle of mass m_i at a given velocity. Thus, the probability of occupant injury in a single-car collision, $R(m_i)$ is obtained as:

$$R(m_i) = \sum_j s(m_i, v_j) \cdot r(m_i, v_j), \qquad (13)$$

where i: vehicle category by mass,

j: velocity category by its range,

$s(m_i, v_j)$: probability of accident velocity classified by vehicle mass,

$r(m_i, v_j)$: probability of occupant injury for vehicle i with velocity v_j.

The probability of occupant injury in a single-car collision with the same distribution of accident velocity is given by

$$R_v(m_i) = \sum_j s(\bar{m}, v_j) \cdot r(m_i, v_j), \qquad (14)$$

where $s(\bar{m}, v_j)$: probability of accident velocity averaged for all vehicles.

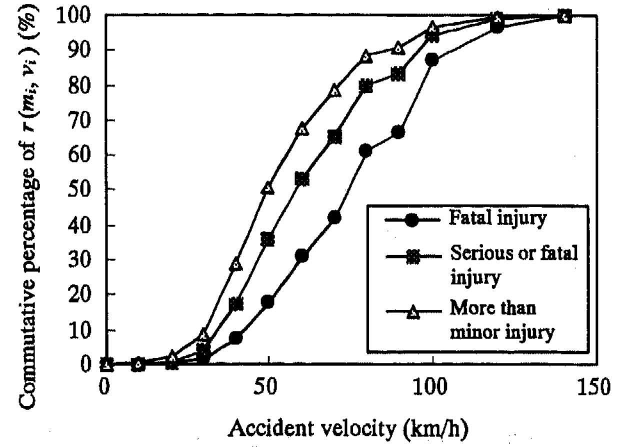

Fig. 24. Accident velocity distribution classified by injury severity in single car collision

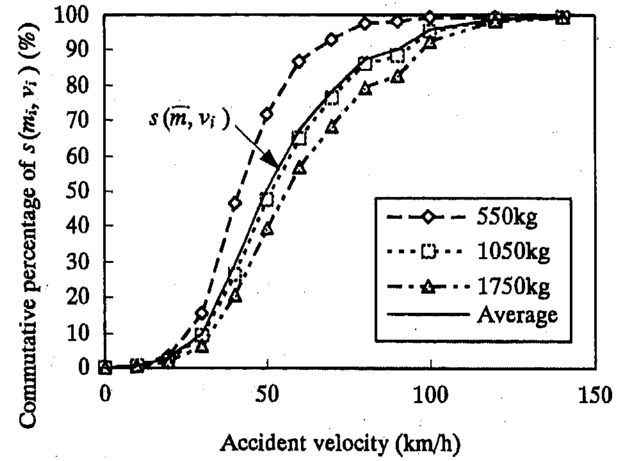

Fig. 25. Accident velocity distribution for vehicles weighing 550 kg, 1050 kg, 1750 kg in single-car collision

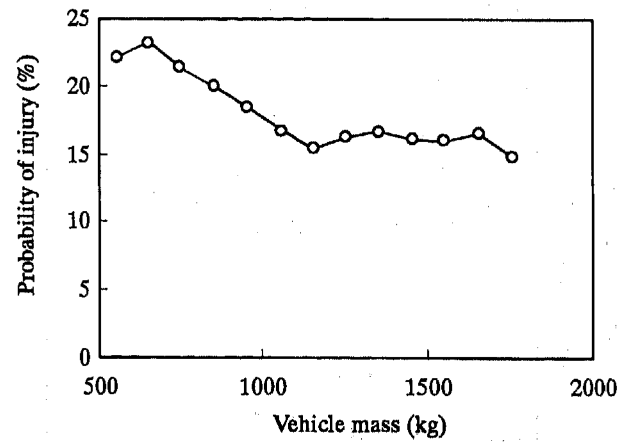

Fig. 26. Probability of serious or fatal injury corrected for accident velocity distribution in single-car collision

$R_v(m_i)$ is calculated for serious or fatal injury to the driver as shown in Fig. 26. As is evident from Fig. 26, the driver of a lighter car is at higher risk in a single-car collision when the accident velocity is the same as that of a heavier car. This can be explained by the fact that when the object with which the car collides is not as rigid as a fixed barrier, a heavier car is likely to destroy the object, making the occupant safer as a result.

BODY REGIONS OF INJURY

We examined the frequency of injury to different body regions in order to clarify the differences in injury patterns with different accident configurations and vehicle sizes. Fig. 27, Fig. 28 and Fig. 29 illustrate the frequency of injury to major regions of the driver's body, classified by severity, vehicle size, and occupant restraint in head-on, side-impact, and single-car collisions of passenger car.

Some characteristic differences can be found in the frequency with which injuries of a given level of severity occur in different body regions. The patterns of fatal injury in head-on, side-impact and single-car collisions are similar, irrespective of seat belt use. Among fatal injuries, head injuries account for 35-50%, chest injuries 18-26%, and the whole body, neck and abdomen about 10% each. However, for serious injuries, the patterns differ according to the accident configuration and occupant-restraint conditions. Serious leg injuries are proportionately more frequent in head-on and single-car collisions for both belted and unbelted drivers. In side-impact collisions, chest and pelvis injuries account for a higher proportion of serious injuries due to occupant contact with the side interior of the car. Neck injuries are the most frequent minor injuries in head-on and side-impact collisions. Wearing a seat belt prevents the occupant's head from striking the windshield or steering wheel in all accident configurations, thereby reducing the severity of injuries, but raising the proportion of minor neck injuries.

We can also find two remarkable differences in the pattern of body regions injured in different-sized cars. First, the frequency of head injury is higher for smaller cars in head-on and side-impact collisions, but is lower in single-car collisions. A smaller car is almost always a lighter car. In car-to-car collisions of the head-on and side-impact types, delta-V increases when the car is lighter or smaller. It is thought that the frequency of head injuries depends on delta-V. The second difference found is that the frequencies of chest and leg injuries are higher for smaller cars in head-on and single-car collisions with frontal impact. The frequency of leg injury is particularly high for mini-passenger cars. In single-car accidents, delta-V or deceleration is not necessarily higher for a smaller car because accident velocity tends to be lower for a smaller car. Thus, it is thought that the higher frequency of chest and leg injuries for a smaller car is due to its size rather than its lighter mass. In other words, it seems that the frequency of head injuries is due to delta-V and that of chest and leg injuries is due to the size of the car.

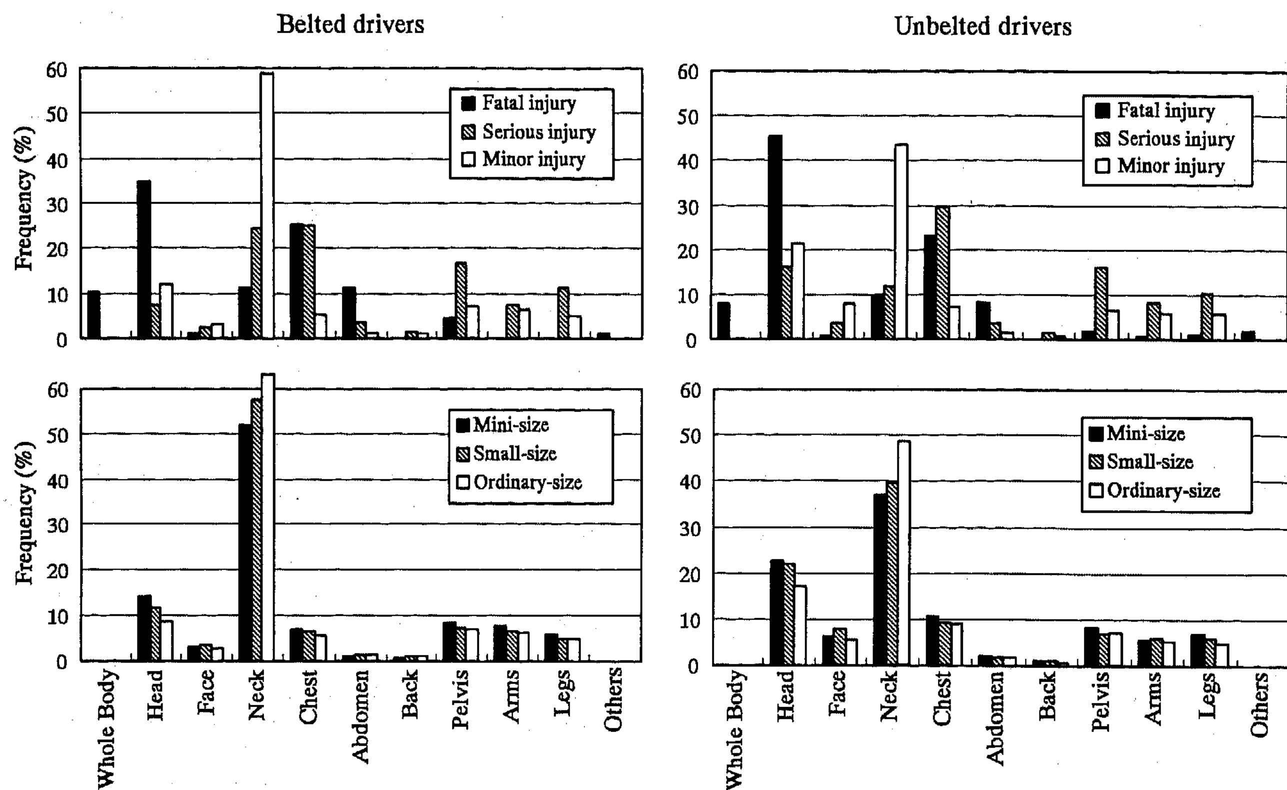

Fig. 28. Body regions of drivers injured in side-impact collisions

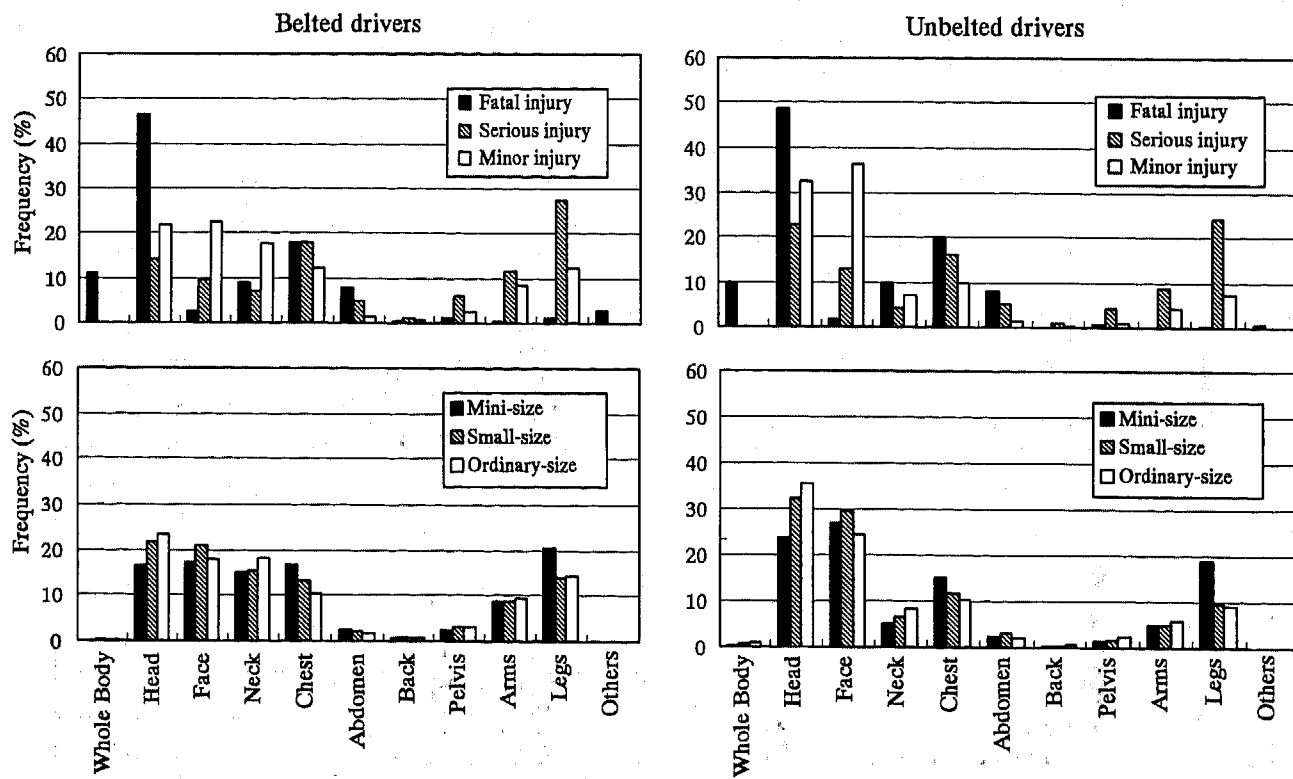

Fig. 29. Body regions of drivers injured in single-car collisions

NUMERICAL DISTRIBUTION OF VEHICLES

As the vehicle mass increases, the risk to occupants of the vehicle decreases, but the risk to occupants of the other vehicle increases. Thus, the number of injuries is influenced by the mass of both vehicles. The number of injuries in head-on collisions is expressed using Eq. (7) as follows:

$$N_I = (R_1 + R_2)N_A$$
$$= \frac{m_1^k + m_2^k}{(m_1 + m_2)^k} aN_A \qquad (15)$$

where N_I is the number of injuries and N_A is the number of accidents. N_I has the minimum value, $2^{1-k} a N_A$, when m_1 is equal to m_2 (k>1), which shows that N_I is small when the difference in the masses of the vehicles is small.

The total number of injuries in a collision will be influenced by the number of cars involved and the distribution of their respective masses. The total number of injuries, N, is calculated as

$$N = \sum_{i,j} p n_i n_j R_i(m_i, m_j), \qquad (16)$$

where i, j: vehicle category classified by mass, m_i, m_j,
n_i : number of vehicles in category i,
$R_i(m_i, m_j)$: probability of injury to occupant of vehicle i struck by vehicle j,
p : probability of accident.

Sensitivity analysis was conducted to clarify the effect of the number of vehicles of similar mass on the total number of seriously and fatally injured occupants. The sensitivity, γ_i, of the number of vehicles n_i to the total number of injuries N is calculated as:

$$\gamma_i = \lim_{\Delta n_i \to 0} \frac{\Delta N}{\Delta n_i} \qquad (17)$$

To simplify the analysis, we assumed that the probability of accident p is the same for all vehicles, though this is not true for the actual vehicle population. The probability of occupant injury in a bonnet-type car is used for $R_i(m_i, m_j)$ and the numerical distribution of passenger cars is used for n_i. The total number of cars is assumed to be constant ($\sum n_i = const.$). The probability of injury to the driver in a side-impact collision takes into account car's being struck from both sides. The results are indicated in Fig. 30 for head-on and side-impact collisions. When the sensitivity is positive, the number of serious and fatal injuries increases. In both head-on and side-impact collisions, the number of serious and fatal injuries decreases

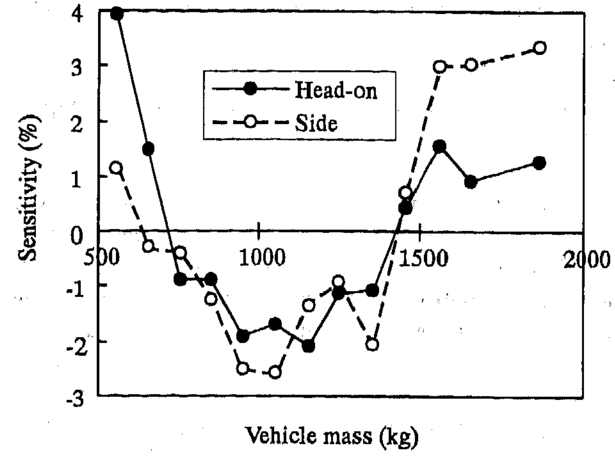

Fig. 30. Sensitivity analysis of the effect of the numerical distribution of vehicles of given mass on the number of seriously and fatally injured drivers

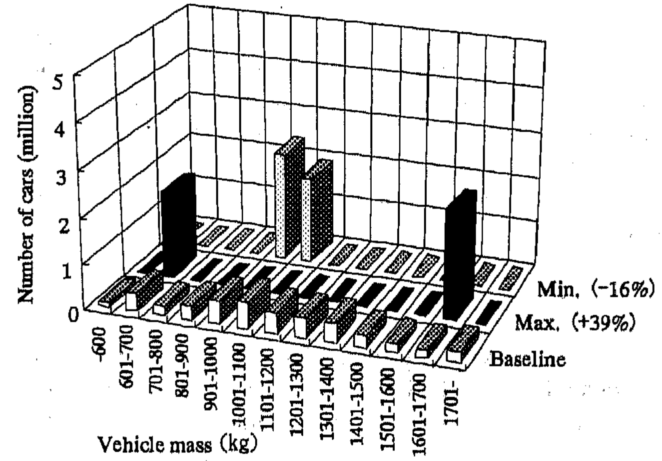

Fig. 31. The number of car distributions that gives the minimum or maximum number of serious and fatal injuries in head-on collisions

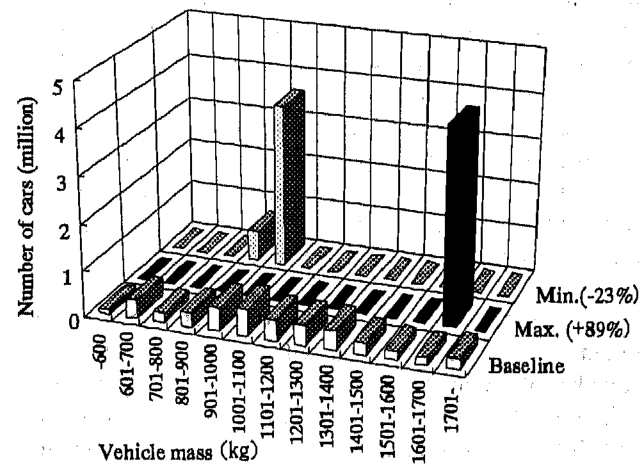

Fig. 32. The number of car distributions that gives the minimum or maximum number of serious and fatal injuries in side collisions

when the number of cars with mass from 700 kg to 1400 kg increases. Again it is found that the influence of the number of lighter cars is larger in head-on collisions, while that of the number of heavier cars is larger in side-impact collisions.

The total number of serious and fatal injuries per year is calculated by Eq.(16) as 2,645 in head-on collisions and 1,234 in side-impact collisions, using the actual numerical distribution of passenger cars as a baseline. The numerical distribution of cars which minimize or maximize the number of injuries in head-on and side collisions are given in Fig. 31 and Fig. 32 respectively. The number of serious injuries and fatalities takes the minimum value when the cars are concentrated in the mass region of 901-1100 kg and decreases injuries by 16% compared to the baseline distribution. On the other hand, the numerical distribution of cars in which the difference between car mass is large maximizes serious injuries and fatalities. In side collisions, the number of serious injuries and fatalities takes the minimum value when the cars are concentrated in the mass region of 801-1000 kg, however when all cars have an identical and large mass of 1601-1700kg, the number of serious injuries and fatalities takes the maximum value. The numerical distribution of cars which gives the minimum or maximum number of injuries is different in head-on and in side collisions because the effect of vehicle mass on the injury severity is different in each case.

DISCUSSION

The crash safety of a vehicle is estimated by a crash test with a fixed barrier in which the mass effect is small, so light and heavy cars are designed under the same safety concepts. The injury rate of the occupant is formulated by delta-V regardless of the vehicle mass. In head-on collisions delta-V depends on the car mass, the probability of injury in a collision can be expressed in terms of the vehicle mass as $a\{m_2/(m_1+m_2)\}^k$. As a result, the risk to the occupants in lighter cars is higher. The vehicle compatibility between light and heavy cars is discussed in many studies and some countermeasures are proposed —Heavier cars must be softer and have crush space for lighter cars, and lighter cars must be more stiff and have an optimum restraint system for the occupants. If the compatibility is accomplished for all vehicles, the injury rate will be expressed by delta-V in different ways for each car with different mass and the effect of car mass on injury rate will be smaller.

The effect of the numerical distribution of cars on the number of injuries is discussed. In head-on collisions, the number of serious and fatal injuries become larger when the difference between car mass is large. However, when the compatibility is accomplished and smaller cars become safer, the numerical distribution of cars does not affect the results so significantly as the analysis using the actual accident data of existing cars shows.

Mini cars occupies about one-eighth of the passenger car market in Japan. If all drivers of mini-passenger cars were to trade their current cars for small cars weighing 701-800 kg, it is estimated that the number of seriously and fatally injured drivers in head on collision accidents would fall by 108 from 2,645 per year, based on a calculation using the numerical distribution of passenger cars. Considering the economy of mini cars, it seems to be reasonable that mini cars should be made safer and compatible with large cars rather than replacing them with small cars.

CONCLUSION

This paper is concerned with the relationship between vehicle size, especially vehicle mass, and occupant injury, as determined from analysis of traffic accident data in Japan. The results are summarized as follows:

1. The fundamental formula of the probability of occupant injury in a head-on collision is expressed as $a\{m_2/(m_1+m_2)\}^k$ with k having a value of 2.67 for serious or fatal injury.

2. The struck vehicle mass influences occupant injury more significantly in head-on collisions than in side-impact collisions.

3. The occupants of smaller cars are likely to suffer chest and leg injuries when involved in frontal collisions.

4. As differences in mass in the vehicle population decreases, the number of serious and fatal injuries also decreases in head-on collisions.

ABSTRACT

This paper examines an originally designed airbag deployment system for use in static experimental testing. It consists of a pressure vessel and valve arrangement with pneumatic and electric controls. A piston functions like a valve when operated and is activated pneumatically to release the air in the tank. Once released, the air fills the attached airbag. The leading edge velocity can be controlled by the initial pressure in the tank, which can range up to 960 kPa. Three different test configurations were studied, which resulted in leading edge deployment speeds of approximately 20 m/s, 40 m/s, and 60 m/s. In experiments using this system, seven types of airbags were tested that differed in their material, coating, and presence of a tether. Data for each series of tests is provided. High speed video and film were used to record the deployments, and a pressure transducer measured the airbag's internal pressure. At 960 kPa initial tank pressure, the maximum leading edge velocity was 71 m/s. The maximum internal pressure of the airbag ranged from 88 kPa to 120 kPa. In addition to cost savings, the primary advantage of this system is its ability to quickly change the internal pressure while avoiding the hazards associated with the use of pyrotechnics. However, the leading edge velocity was typically below the average published values for common airbags. This discrepancy may be corrected in future designs by changing the orientation of the valve portion of this system.

INTRODUCTION

With increased interest in refining the airbag, the need arises for an inexpensive and safe means to test different airbag design and construction features. For example, if several airbag design characteristics are to be examined at several different pressures, the test matrix will require a large number of inflators to properly test each iteration. Given the significant cost of pyrotechnic inflators, alternate methods of testing should be considered. With the reusable pneumatic system described in this paper, the only two primary costs will be the bags themselves and the initial machining. Moreover, the increased risk of storing the pyrotechnic devices and the adverse effects of handling the combustion products after airbag deployment can be avoided [1].

The concept of a reusable compressed gas inflator for experimental testing is not new. Although a different design was used, previous laboratory studies note the advantages this type of system offers [2,3]. For example, the ability to readily change deployment parameters. In those studies, fast acting valves were used to control the compressed air as compared to the piston-valve arrangement presented here. Additionally, Melvin et al. (1993) compensated for the flow characteristics of high temperature pyrotechnic inflation gases by combining gases of various densities. This system uses compressed air, but could be adapted to use the combined inert gas approach, with the only drawback being increased cost.

REVIEW OF THE DEPLOYMENT SYSTEM

The airbag deployment system is shown in Figure 1 with a functional schematic detailed in Figure 2. An air compressor is used to provide the initial pressure for the 37 L pressure vessel. The horizontal structure comprises a large piston which acts as the valve. An aluminum alloy was the primary construction material.

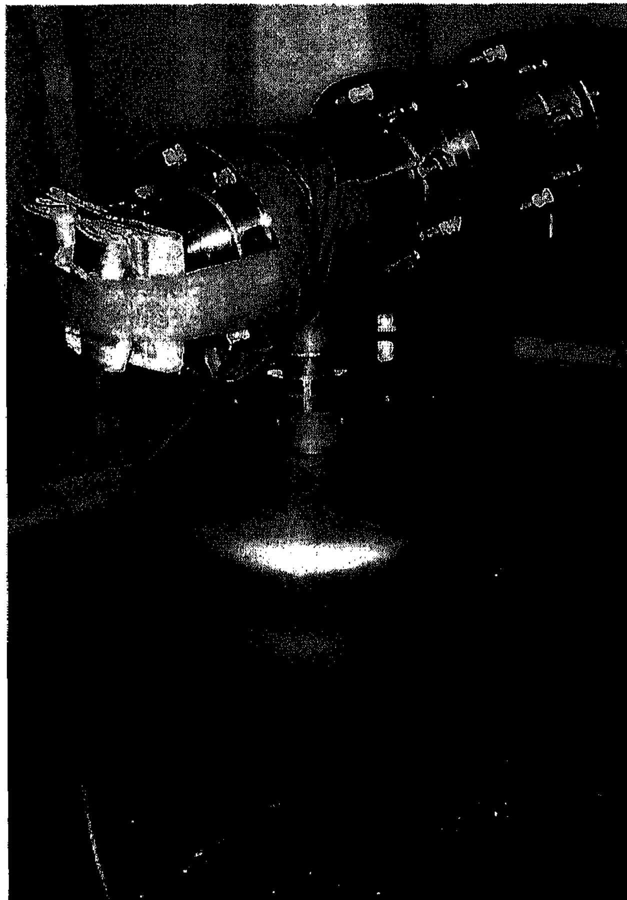

Figure 1: Airbag Deployment System

AIRBAG DEPLOYMENT - The airbags used with this system are modified so that they may be attached directly to the front of the system via the manifold as shown in Figure 3. On the airbag side of the manifold, a pressure transducer was installed to measure the bag's internal pressure throughout each deployment. A strap is used to hold the bag in place and model the performance of the airbag's cover as seen in an automobile. Before the tank is pressurized, the piston is placed in the forward position, thereby creating a seal between the tank and the airbag. Once the bag is attached and the tank is pressurized, the system is ready for deployment. In order to deploy the bag, a solenoid is activated which in turn opens the airway and supplies air to the middle portion of the cylinder as shown in Figure 2. This pressure forces the piston to the right allowing the air in the tank to fill the airbag. The piston assembly remains in the right position until reset for the next test.

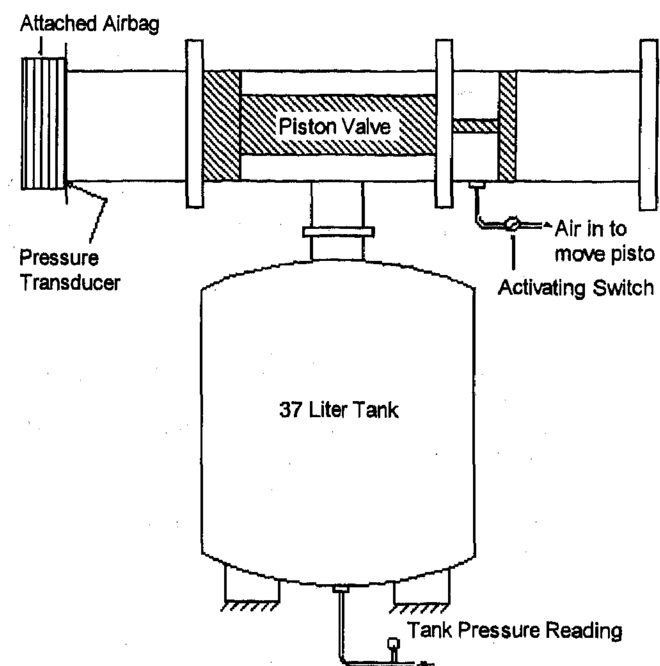

Figure 2: Functional Schematic of the Airbag Deployment System

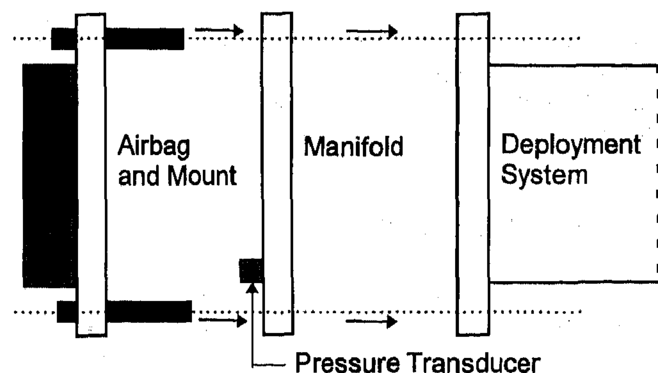

Figure 3: Assembly Diagram Depicting the Airbag Mount Attaching Through the Manifold to the Deployment System

DEPLOYMENT VARIANCE - The leading edge velocity can be varied by adjusting two factors: the internal tank pressure and the strap. First, a pressure gauge is attached to the line that feeds the deployment tank. From this gauge and data from previous tests, a reasonable estimate can be made of the future deployment speeds. The second variable is the presence of a cover. For the higher deployment speeds, a breakable strap is installed to allow a buildup of pressure behind the bag just before release. Three configurations have been established as detailed in Table 1.

Table 1: Deployment Configurations for Three Leading Edge Velocity Approximations

Test Config.	Initial Tank Internal Pressure	Cover/ Strap Present	Approximate Leading Edge Velocity
1	405 kPa	No	20 m/s
2	960 kPa	No	40 m/s
3	960 kPa	Yes	60 m/s

To demonstrate the ability of changing the leading edge velocity, all three configurations were tested using only one type of airbag. These tests are plotted at each of the three configurations in Figures 4, 5, and 6. Here it is shown that the leading edge velocity goals of 20 m/s, 40 m/s, and 60 m/s were met. Configuration 3 (60 m/s) was selected for the experimental tests since it was most similar to the production models.

SAFETY PRECAUTIONS - To avoid possible injury and lost time from an inadvertent deployment, the system has several important safety features. A pin, which is inserted between each test, is positioned perpendicular to the piston through two stays. With the pin installed, the piston cannot move and therefore, the bag cannot deploy. The secondary safety features are combined with the controls. The activation switch must be reset between each deployment and runs from a separate power supply to further decrease the risk of accidentally activating the system. Finally, an alarm is automatically sounded once power is supplied to the trigger system to warn of the imminent deployment.

EXPERIMENTAL RESULTS

Table 2 describes the seven types of airbags that were used in this test series. Material A was a high denier fabric while B, C, D all having subsequently lower deniers. All airbags were standard 60 L driver-side airbags, modified accordion fold with two windshield facing vents, that varied only in their coating, material, and presence of a tether as noted. Each had been modified to facilitate the mounting procedure by installing a new mounting flange; however, the modification was minimal and had no effect on the deployment characteristics.

Table 2: Airbag Construction Specifications

Airbag Type	Material Type	Coating Type	Tether/ Non-tether
1	A	A	N
2	B	B	N
3	B	B	T
4	B	none	N
5	B	none	T
6	C	none	N
7	D	none	N

LEADING EDGE VELOCITY COMPARISONS - The leading edge velocities for airbags deployed with this system were determined using high speed video and film. For each of the seven types of airbags, three deployments were conducted at configuration 3, which provided for the maximum deployment capability of the system. The leading edge velocity profiles of airbags with similar construction features, presence of tether and folding pattern, as those used in this test were gathered from published data [4,5]. For example, airbag type 1 has a tether and uses the modified accordion fold. Ideally all variables would be held constant, but the analysis is limited on the availability of published data. From the literature, it was determined that the 1990 Oldsmobile Toronado, 1990 Chevrolet Camaro, and the 1993 Chevrolet Caprice also have a tether and modified accordion fold. Therefore, in order to compare similar airbag types using the deployment system, three test profiles of airbag type 1 are plotted with the three production models as shown in Figure 7. This same technique was used in Figure 8 through Figure 13 for the other six airbags.

The average maximum leading edge velocity for 1990 airbags was 64.3 m/s and is given on these plots as well [5]. It should be noted that the comparisons in Figures 7-13 only consider the bag characteristics and not the inflator properties.

DISCUSSION

The leading edge velocity profiles in Figure 7 show that the deployment system mimics the three General Motor's models with similar bag characteristics reasonably well. Two of the peak velocities for the three experimental tests exceed the 1993 Caprice, which has the maximum velocity of the three comparison airbags. The leading edge velocity profiles match well for each airbag type. Figure 8 depicts the leading edge velocities of airbag 2 showing consistent behavior with the same models used in Figure 7. The identical three models are used again due to the fact that airbags 1 and 2 differ in material and coating, but both are non-tethered and have the same folding pattern as the comparison models.

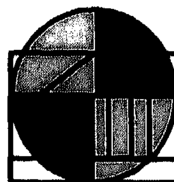
Airbags 3 and 5, in Figure 9 and 11, are similar to their respective counterparts, but have a slower rise time and do not reach the peak velocity of the 1993 Ford Taurus. Although both the 1993 Saturn and 1993 Ford have a tethered airbag with a modified accordion fold, the differences in the inflators and material are two reasons that account for the discrepancy between these comparisons.

The experimental tests exhibited a decrease in velocity from 75 mm to 110 mm deployment distance in Figures 7, 10, 12, and 13. This observation comprised airbag types 1, 4, 6, and 7 which show no significant similarities, thus implying that this behavior is a random aspect of the deployment system rather than an attribute of any one particular airbag characteristic.

The sample industry airbags chosen, with the exception of the 1990 Ford Taurus, do not exceed the average maximum leading edge velocity of 64.3 m/s for

airbags in 1990 vehicles. Therefore, even though the deployment system approaches similar velocity curves, its maximum velocity is still below the average maximum speed.

CONCLUSIONS



The pneumatic airbag deployment system proved to be a good tool for static airbag deployments with various leading edge speeds. The maximum velocity is easily adjusted by changing the initial tank pressure, but the velocity is limited in this design to approximately the 1993 industry average of 64.3 m/s. The velocity could be increased by designing the deployment system with a straight path from the tank to the airbag as opposed to the right angle in the current design.

The low cost of this system and its increased safety versus pyrotechnic airbags are two additional advantages. Two disadvantages of this system are the use of a strap to simulate the cover, and the inability to correlate the pressure curves with manufacturer's airbag tank tests. Future designs should incorporate a cover that reflects the exact characteristic of an actual airbag cover. This would insure a more realistic duplication of a deploying airbag.

ABSTRACT

Modeling and simulation are becoming increasingly popular to help develop restraint systems and enhance the value of the design. Various types of tests are being developed and used extensively in evaluating and optimizing the performance of restraint systems by both OEM's and system suppliers. The use of analytical tools along with laboratory testing can help improve the effectiveness and the speed of developing and implementing a restraint system to maximize the occupant protection.

The side airbags are used in conjunction with energy absorbing foams to manage the energy transfer to the occupant from the structural intrusions in a side impact. The requirement of deployment times are shorter in side impact than in a frontal impact due to the limited space between the occupant and door structure. In the design and development of seat integrated side airbag modules, it is important to predict deployment time and pressure which are affected by the characteristics of the seat-fabric material and tear seam. The PAM-SAFE numerical simulation tool allows us to simulate the tearing of seat fabric and subsequent deployment of the side airbag and its complex interaction with the module and the seat foam.

INTRODUCTION

Modeling and simulation are increasingly used to help develop restraint systems and enhance the value of the design. Parametric studies with a simulation model are regularly used by both OEM's and system suppliers and are effective in evaluating and optimizing the performance of restraint systems.

Several automobile manufacturers are implementing side airbags in addition to energy absorbing padding and structures to provide occupant head and thorax protection and reduced pelvic acceleration for the occupant during side-impact crashes. The development of the side airbag system is a considerably more difficult problem than the frontal airbag system due to the limited space and faster airbag deployment time requirements. Hence it is essential to learn as much about the physics as early as possible in the development of side airbags. The seat mounted side airbag which deploys through a seat foam and fabric and gets in-position between the occupant and the door and B-pillar of the vehicle, is one design to help protect the occupant's torso and head.

Proper deployment of the airbag is crucial in providing protection to the occupant. One of the factors controlling airbag deployment is the characteristics of the tear seam of seat fabric and the airbag cover structure. Hence, the measurement of pressure distribution on the fabric cover with tear seam or a door structure is important for the design and development of Side Impact Supplemental Inflatable Restraint systems. In the past, a methodology was developed at TRW-VSSI to experimentally measure deploying pressure distribution on the inner surface of a passenger-side airbag door [1].

The objective of this study was to develop a methodology to numerically simulate a full deployment of the folded side impact airbag including the breakage of the seat-fabric at the tear seam and the module deformation. Explicit dynamic finite element code PAM-SAFE [2] was used to simulate TRW dynamic test of a folded side airbag

interacting with the airbag module and seat-fabric. The main purpose was to analyze the effects of the bag pressure and bag unfolding interaction with a seat-fabric resulting into a tearing failure along the tear-seam. This type of simulation allows a detailed study of the separation process of the seat-fabric, module deformation, loading on the seat-frame, and the side airbag deployment kinematics. The model developed in this study could be used to estimate dynamic loading on the seat-fabric for different materials.

AIRBAG MODELING

The airbag mesh was generated from CAD drawings of actual design. The airbag dimensions were measured on the airbag in the flat configuration with the side tucked in once from each side. The mesh for the flat configuration of the bag was oriented to match with the position of the tethers. The mesh density was chosen such that there are at least 3 elements between two folds. An accordion folding pattern was incorporated. PAM FOLDER was used to fold the flattened airbag in a folded state. The distance between the folded layers is 0.0006m. The final airbag mesh consisted of approximately 1800 membrane elements.

The jet effect [2, 3] was considered to simulate the dynamic effect of the mass flow during the first 10 ms of the inflation. The leakage was defined by a pressure dependent outflow rate curve. The airbag fabric properties are given in the following table.

TABLE 1

AIRBAG FABRIC PROPERTIES	
Mass density	774.3 Kg/m^3
Poisson's ratio	0.20
Young modulus	1.e6 Pa for parent sheet 2.01E+8 Pa & 2.24E+8 Pa for fiber layers
Thickness	0.0003 m

As pointed out earlier, the mesh was based on an actual bag in a folded state. It is generally time consuming to design a mesh which can be folded easily to obtain actual folded bag configuration and which can be packaged in the limited space available. In order to save time in meshing and to obtain a properly folded state without penetration of the airbag fabric layers, an initial metric method [3] may be used. However, in the author's opinion the initial metric method does not capture correctly the airbag kinematics and pressure, which determine the time of breakage of the tear seam.

The airbag module consists of a rectangular shaped module which houses the inflator. Part of the folded bag is attached to the module. The following table depicts module material properties:

TABLE 2

Module Properties (steel)	
Thickness	0.001m
Mass density	7850 Kg/m^3
Poisson's ratio	0.30
Young modulus	207.E+09 Pa
Yield stress	500.E+06 Pa

TRW DYNAMIC SIDE AIRBAG DEPLOYMENT TEST

A special, dynamic side airbag test was devised to study the strength of various fabric materials. This test was simulated in PAM-SAFE to calibrate tear seam properties. The test setup as is shown in figure 1, consists of calipers across which the fabric sample is constrained such that it covers the top of the folded airbag. The reaction forces on the calipers due to the deployment forces exerted on the fabric are measured with a load cell.

The FE mesh for the seat-fabric contains approximately 500 shell elements. It was restrained on both sides along the edges as per the test set-up. The fabric material model uses only the elastic part of the force Vs deflection curve obtained from the actual seat-fabric material test. The following table shows the seat-fabric material properties:

TABLE 3

Airbag Seat-fabric Material Properties	
Mass density	400 Kg/m^3
Poisson's ratio	0.20
Young modulus	7.0E+06 Pa
Thickness	0.002 m

CALIBRATION OF THE TEAR SEAM

In the test, release occurs along a pre-defined tear-seam in the seat-fabric. In order to model this tearing effect, a discontinuity or a gap of 1 mm is

introduced at the location of the tear seam. The seat-fabric material strength is distributed along this tear-seam using nonlinear bar elements, one per each node of the element. The strength of each nonlinear bar element is calibrated according to the force deflection curve (Fig. 2) obtained from the test data. The fabric sample used for the tension strength test is 0.008 m thick, 0.1016 m wide and 0.1524 mm in length. The actual seat-fabric used in the calibration test, is 0.344 m along the tearing line with a same thickness. Thus the experimental curve has to be scaled by an appropriate scale factor. As the end nodes share only half the nodal forces, the scale factor for these nodes should be halved.

The airbag was attached to the housing through the nodal constraints along the bottom peripheral nodes of the module . Then, the whole assembly was fixed at bottom. In order to get a correct kinematics of the airbag interacting with the module and the fabric cover, proper definition and working of contact interfaces are important.

KINEMATICS OF DEPLOYMENT FOR THE SIDE AIRBAG

The kinematics of the unfolding sequence from the front side, during first 5 ms is shown in Figures 3. Figures 4 and 5 show the side and top views of the same sequence. The comparison of these results with the test data show very good correlation. The simulation is able to capture the bulging of the fabric cover during 0 to 3.5 ms. The breakage of the fabric cover occurs at approximately 3.5 ms. The airbag completely breaks out of the cover at about 6 ms. The airbag gets fully inflated at about 8 ms.

The side airbag deployment was simulated with and without the jet effect. The reaction forces from the simulations are compared with the test data in figure 6. When the jet effects are considered, tear-seam release occurs at 3.5 ms at the reaction force level of 1800 N., which compares very well with corresponding test values of 3.4 ms and 1860 N. However, without the jets a tear-seam release is delayed to 4 ms at the force level of 2486 N. This behavior is quite reasonable and can be explained as follows. The effect of the jet is to provide additional concentrated pressure forces on the parts of the airbag where it directly impinges. This causes early local release of the seat-fabric at a lower force level. When the jet effect is absent, the airbag pressure forces are more evenly distributed on the seat-fabric, allowing it to stretch more, and causing delayed release at a higher force level.

The module starts deforming due to the airbag pressure forces; this phenomenon is called fish mouthing and is captured very well as depicted in Fig. 7. The airbag max. module deformation occurs at 4 ms.

AIRBAG MODULE INTEGRATED WITH A SEAT STRUCTURE

The side bag validated with a dynamic test was packaged inside the seat with the seat foam surrounding the module (see Fig. 9) The seat fabric covering the seat foam was modeled using the same fabric material as described in Table 3, above. A similar methodology (as described earlier) was used to model the tear-seam in the seat.

Developing a suitable seat model was an extremely complex task; especially the modeling of seat-foam geometry. Only the parts of the foam immediately surrounding the airbag module are modeled as deformable. The rest of the parts of the seat are assumed to be rigid. The stress-strain curve for the seat-foam is presented in figure 8. As the punching forces due to the deploying airbag are locally concentrated, only a part of the seat was modeled and constrained at the boundaries as shown in the figure 9.

Figure 10, depicts the simulation of the kinematic sequence of side airbag deployment out of the seating structure.

It was observed from the simulation results that at about 3.5 to 4 ms the fabric tears off and the airbag comes out of the seat fabric. At about 8 ms the airbag is fully inflated. Various contacts; self-contact for the bag, contact between the bag and the module, the bag and the foam, the foam and the fabric work reasonably well. The contact between the bag and the module may be tuned further to enhance the contact behavior at the edges of the module. In this simulation, no attempt is made to correlate with the test data which in any case was not available for this complex case. In the future, the results of this simulation could be compared with the test data.

CONCLUDING REMARKS

TRW's dynamic test of the side impact airbag interacting with the seat-fabric and deformable module was successfully simulated with the finite element code PAM-SAFE. The kinematics of the

unfolding airbag, the plastic deformation of the module and the release along the tear-seam is captured very well in this simulation. This simulation was used to calibrate tear seam characteristics which were further implemented in the model of a folded airbag module integrated inside of the seat.

A deployment of the side airbag out of the seat is also successfully simulated using PAM-SAFE. In this simulation, a complex interaction amongst the bag, the module, the seat foam, seat fabric is captured fairly well.

A simple thermodynamic approach was adopted to simulate the dynamic effect of the gas pressure onto the airbag seat-fabric and the module. This approach illustrates the fact that the complex effects due to the gas flow dynamics in the folded airbag and its interaction with the foam and the seat-fabric during deployment, module deformation, and subsequent tearing failure of the seat-fabric material can be captured by a simple uniform pressure gas model coupled with a jet technique using PAM-SAFE.

As the jets exert additional pressure loading concentrated locally on the parts of fabric where the jets strike, the fabric can tear at an earlier time and at a lower pressure force magnitude than in the case without the jets effects. Hence it is important to consider the effect of the jets in the simulation where the fabric tearing phenomenon needs to be simulated.

The methodology developed in this study could be used to predict the deploying forces or the loading condition on the airbag fabric cover and the kinematics of bag deployment.

The seat integrated airbag model developed above can be used to study the performance of various tear-seam strengths and patterns.. The model can also be used in a full side impact, sled or barrier simulation to evaluate the seat integrated side airbag system and its effectiveness in reducing occupant injuries.

ACKNOWLEDGEMENT

Our thanks are due to Dr. Ilango Shanmugavelu of Johnson Controls Inc. for providing foam data.

Critical Comparisons of US and European Dynamic Side Impacts

ABSTRACT

Global engineering is increasingly becoming a practice within the automotive industry. Due to added engineering and manufacturing benefits, more and more new vehicles are being developed with common structure to meet the consumer needs in many local regions. While vehicle development and manufacturing process is becoming global, automotive safety regulations in various parts of the world have not been as uniform. A good example is the differing requirements for dynamic side impact protection of new vehicles. United States National Highway Traffic Safety Administration (NHTSA) and European Union (EU) have each produced their own distinct test procedures such as, different barrier faces, impact configurations, and anthropomorphic test devices (dummies). Although both test procedures have the same final objective - estimate occupant responses in side impacts, they differ greatly in execution and emphasis on occupant response requirements.

This paper discusses the differences in both side impact test procedures and vehicle & dummy performance in each case. Both dynamic side impact test data and analytical models are employed for this purpose. A full vehicle dummy-structure finite element is developed to investigate the two test conditions. Comparison of a typical vehicle performance such as, door and bodyside intrusion profiles, contact velocities with dummies, dummy kinematics in both test conditions are examined closely. It is determined that although each test induces different loading and responses, there may be some commonality in impacted vehicle performance. As the side impact regulations are still evolving both in USA and Europe, it appears that a unified approach for developing side impact countermeasures to meet the more demanding test condition may result in test mode simplification and robust side impact designs in new vehicles. One of the ideas examined in this paper is designing global new vehicles with a unified NHTSA/European procedure that simulates NHTSA side impact conditions with two EUROSID1 dummies, one in the front and one in the rear seat of the impacted vehicle.

INTRODUCTION

At present, two different side impact test procedures exist in North America and Europe. These are the US NHTSA FMVSS 214 and European Directive 96/27/EC dynamic side impact procedures. A NHTSA or European dynamic side impact test is composed of four basic elements. These are:

Test vehicle in stationary position with appropriate weight and instrumentation,

Deformable barrier to simulate striking vehicle stiffness at a specified velocity,

Anthropomorphic Test Devices (ATD) to help measure injury risk during impact, and

Test requirements based on various dummy responses.

Although both side impact test procedures have the similar objectives to provide understanding of vehicle and occupant responses, considerable differences exist in all four major entities described above. The procedures have unique dummies and barrier faces in each case.

Comparison of Test Procedures

The NHTSA dynamic side impact procedure was developed for passenger cars sold in the United States. It is being extended to truck vehicles ($\leq$ 6000 lbs GVWR) on September 1, 1998. The test uses U.S. DOT SID dummies located in the front and rear seats on the impacted side. The barrier is of honeycomb construction with different strength of honeycomb in barrier bumper (245 psi) and barrier body (45 psi). It represents an average U.S. vehicle size and stiffness. The barrier impacts with a crabbed angle of 27° to the target vehicle at 33.5 mph.

The European Directive dynamic side impact procedure has been developed for M1 and N1 vehicles sold in

Europe and it is still evolving, mostly in the area of barrier types, vehicle/barrier height and dummy seating positions. The European test procedure differs greatly from the NHTSA side impact procedure in that the barrier face, dummy, dummy measurements, impact speed and direction are all different. The test uses a single EUROSID1 dummy located in the front seat on the impacted side. The barrier specification in the European side impact procedure includes corridors for load-deformation behavior. It can be constructed of dense foam or honeycomb materials. Several European barrier types are available currently for side impact evaluation. These include KENMONT, UTAC, AFL, CELLBOND, FRITZMEIER, SHOWA, YOHAMA and PLASCORE constructions. The European barrier face is divided into six blocks with varying stiffness and represents an average European vehicle size and stiffness. The barrier impacts perpendicular to the target vehicle at 31 mph.

Comparison of Dummies

The NHTSA side impact procedure includes two US DOT SID dummies, and the European procedure requires one EUROSID1 dummy in the driver's seat on the impacted side. The dummies for the two types of tests are totally different in their construction. The Code of Federal Regulations (FMVSS 214) specifies the US DOT SID Thoracic Trauma Index (TTI) and the peak lateral Pelvis acceleration as the two criteria that have to be complied with for a vehicle to pass the dynamic performance requirements.

On the other hand, European Directive (96/27/EC) requires that the EUROSID1 dummy Head Performance (HPC), Thorax Rib Deflection, Thorax Soft Tissue (V*C), Abdominal Peak Force and Pubic Symphosis Peak Force criteria be used for approvals.

There are several requirements, as described below, regarding the seating positions for each of these two types of dummies.

SID Dummy Positioning

- Seats should be placed in mechanical mid position and full down (for the first two years the dummy's H-point must be within the door aperture). Seat backs are in nominal or 25 degrees, head rests full up, lumbar supports in lowest position and arm rests are lowered. Dummy is placed in the front seat and rear seats on the impacted side.

EUROSID1 Positioning

- Seats can be placed anywhere along the full seat track travel and full down. Seat backs are in nominal or 25 degrees, head rests full up, lumbar supports in lowest position and arm rests are lowered. Dummy is placed in the front seat on the impacted side.
- Arm is set at 40 degrees with respect to the dummy.

Comparison of Barriers

Listed below, in Table 1, is a brief summary of NHTSA and European barriers and test conditions.

Table 1: Comparison of Side Impact Barriers

Test	Barrier Wt	Barrier Speed	Impact Angle	Barrier Height
NHTSA	1360 kg	15.0 m/s	27°	280 mm
European	950 kg	13.8 m/s	0°	300 mm

Comparing the two deformable barrier data in Table 1, it is seen that the NHTSA barrier is heavier than the European barrier by 410 kg. Combined with a higher initial velocity the NHTSA barrier has approximately 40% more kinetic energy at the pre-impact state than the European barrier. Based on barrier dimensions and stiffness it is also seen that NHTSA barrier is bigger and stiffer than its European counterpart as the front end of an average US vehicle is bigger and stiffer than that of an average European passenger car or light truck. Figure 1 illustrates the difference in barrier stiffness by comparing dynamic force deflection characteristics of the two deformable faces. Based only on these statistics it may look as though the NHTSA test is more formidable than the European side impact test.

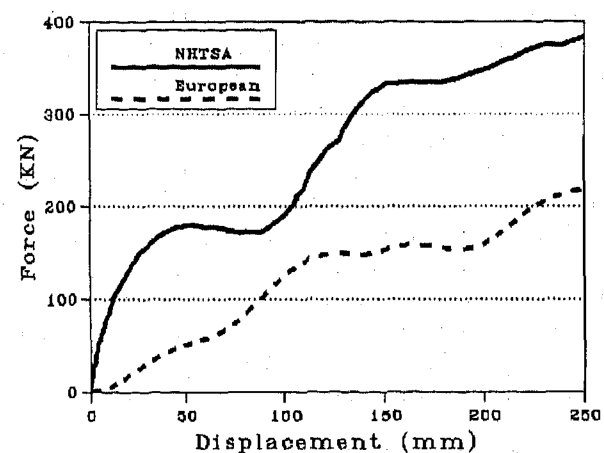

Figure1: Comparison of Barrier Face Force Deflection Characteristics

However, the barrier footprint on the body side structure must also be considered. Figure 2 illustrates how the two barrier faces are positioned against a mid size vehicle in NHTSA and European test conditions. The European barrier face being much smaller may contact only the B-pillar whereas the NHTSA barrier face may make solid contact with both hinge pillar and B-pillar. The effect of missing the hinge pillar in European test condition will be discussed further based on analysis results.

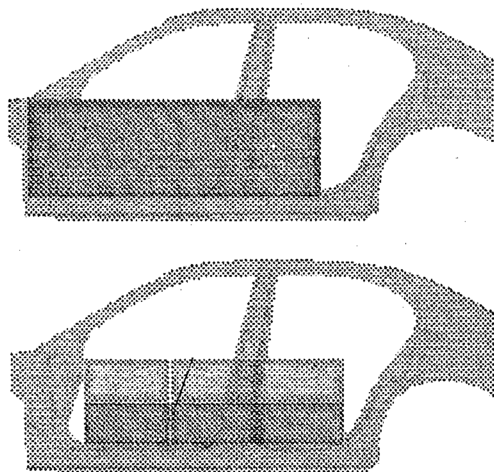

Figure2: Comparison of Barrier Overlap with Bodyside (NHTSA top / European bottom)

ANALYTICAL APPROACH

In this study, comparisons of the US and European Directive side impact performances are made using both side impact test data and full vehicle finite element models. Of the two vehicles modeled, one is a four door mid size vehicle and the other is a four door sub compact. The finite element system models of two vehicles contained the same vehicle structure and interior plus corresponding barrier and side impact dummies in each test set-up. The nonlinear simulations are performed using the commercially available code RADIOSS. Comparisons are made for barrier and vehicle energy absorption, impacted door and body side intrusion and velocities. Attempts are made to identify the vehicle components that play key a role in each test condition.

Since the European procedure has only a front seat dummy, in this study the front dummy responses are compared. As different types of responses are sought in US DOT SID and EUROSID1 dummies, for comparative purpose the individual dummy responses are examined in terms of margin relative to corresponding regulatory requirements. In addition to model responses, several sets of US and European test data from three similar vehicle tests are compared for this purpose.

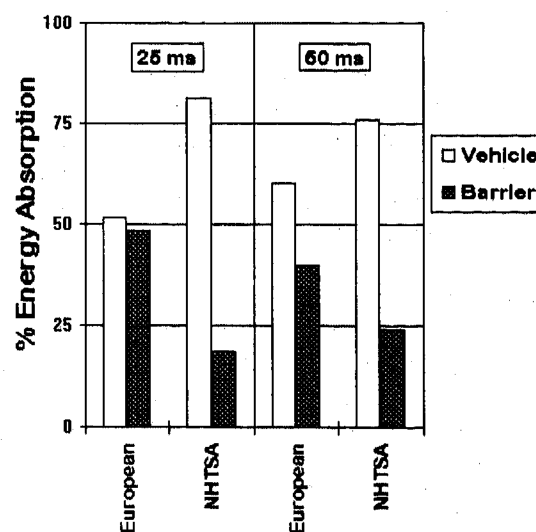
SIDE IMPACT SYSTEM MODEL

Finite element models simulating dynamic side impact test are in use in the industry for the past several years. The FEA dummy-structure system model contains the vehicle structure, trim/bolster, side impact dummy and a barrier. Details of a typical side impact dummy-structure system model have been published by several investigators [1 3,4,7,10]. The primary component of the system model is of course, the vehicle structure model, built in detail with finite elements to include all sheet metal components, door closures, interior trim/padding, as well as suspension and powertrain components. The barrier model and the SID and EUROSID1 dummies are also created using finite elements based on component crash characteristics derived from various sled test configurations [2,5,6]. The dummy models are capable of predicting the physical responses accurately and sensitive enough to localized impacts as observed in side impact vehicle tests. The side impact system models provide insight into both structural performance such as, intrusions, accelerations, velocity histories and the occupant responses at pelvic, torso and head level.

ENERGY ANALYSIS

A side impact test involves contact between a deformable barrier face and the vehicle structure. Initially, the impact energy is mostly contained in the deformable barrier. As the impact proceeds the vehicle structure behaves as the primary energy absorbing component. A breakdown of the strain energy distribution between the vehicle and barrier at 25 and 50 milliseconds is shown in Figure 3 for impact against a mid size vehicle. The European barrier face absorbed about 48 percent of total strain energy and NHTSA barrier absorbed about 19 percent at 25 ms. At 50 ms these amounts are 39 percent and 24 percents, respectively. Both at 25 and 50 milliseconds the share of internal energy absorption by European barrier was higher than the NHTSA deformable barrier.

Figure 4 indicates how the vehicle internal energy is distributed among the body structural components of the vehicle at 25 and 60 milliseconds. It is seen that the major structural subassemblies contributing to the vehicle energy absorption are i) body side, ii) front door and iii) rear doors. The body side, front door and rear door percentages decrease at 60 milliseconds. This is primarily due to progressive inward crush of backup structures, i.e. front floor pan, seat cross members and roof panel. The rear door in the NHTSA test condition has a larger percentage of energy absorption (18.2%) than in EEC condition (11.1%). This is a direct result of the crabbed angle of the NHTSA barrier. As indicated above it appears that in both NHTSA and European procedures the body side played a large role in absorbing impact energy, followed by front and rear door systems.



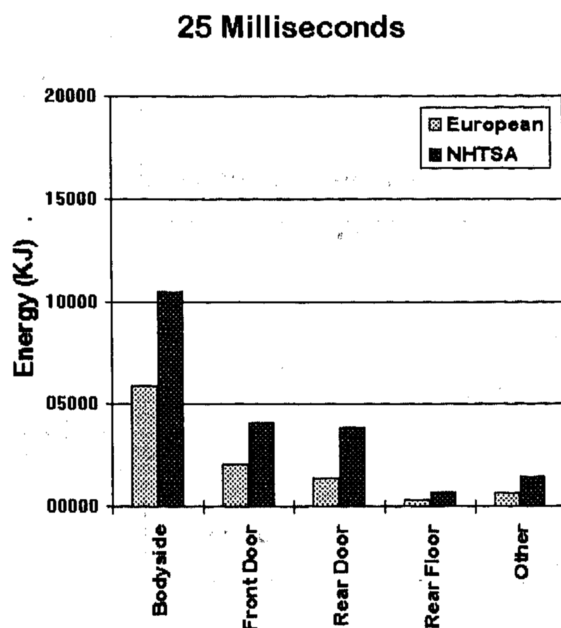


Figure3: Comparison of Vehicle and Barrier Energy Absorption in European and NHTSA Side Impact

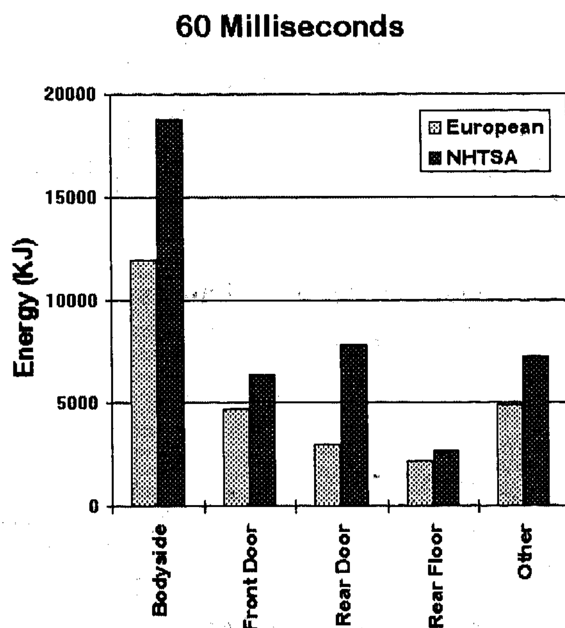
25 Milliseconds

60 Milliseconds



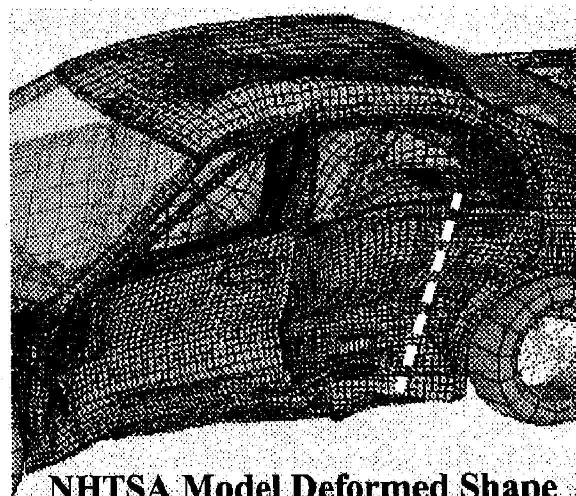


Figure4: Comparison of Internal Energy Absorbed by Vehicle Structure Sub-assemblies

INTRUSION COMPARISON

Shown in Figures 5 are the deformed bodyside geometries of the NHTSA and European side impact models. Figure 6 shows vehicles which have undergone similar testing. It is seen that the NHTSA model deformation pattern captures the barrier bumper imprint along the bottom of both doors and the deformation around the lower hinge pillar area. The model also captures the rear door vertical bending about mid belt line. The European model deformation pattern also matches well with what was observed in the test vehicle. Both test and model for the European Directive shows more deformation at the B-pillar and roof side rail joint when compared to that in the US procedure. The hinge pillar area is relatively untouched.

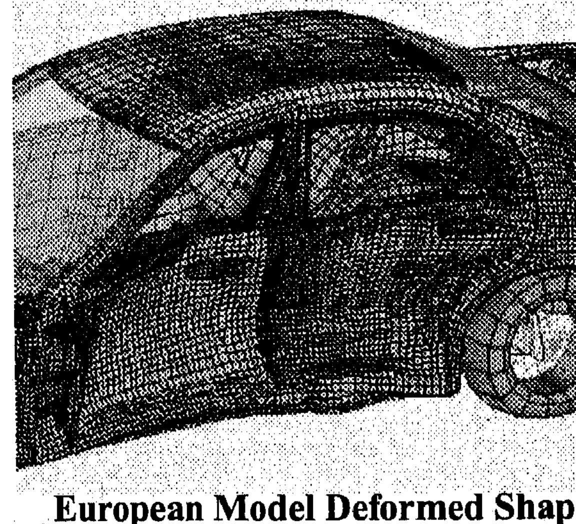

Figure5: Comparison of Deformed Geometry at 60 milliseconds

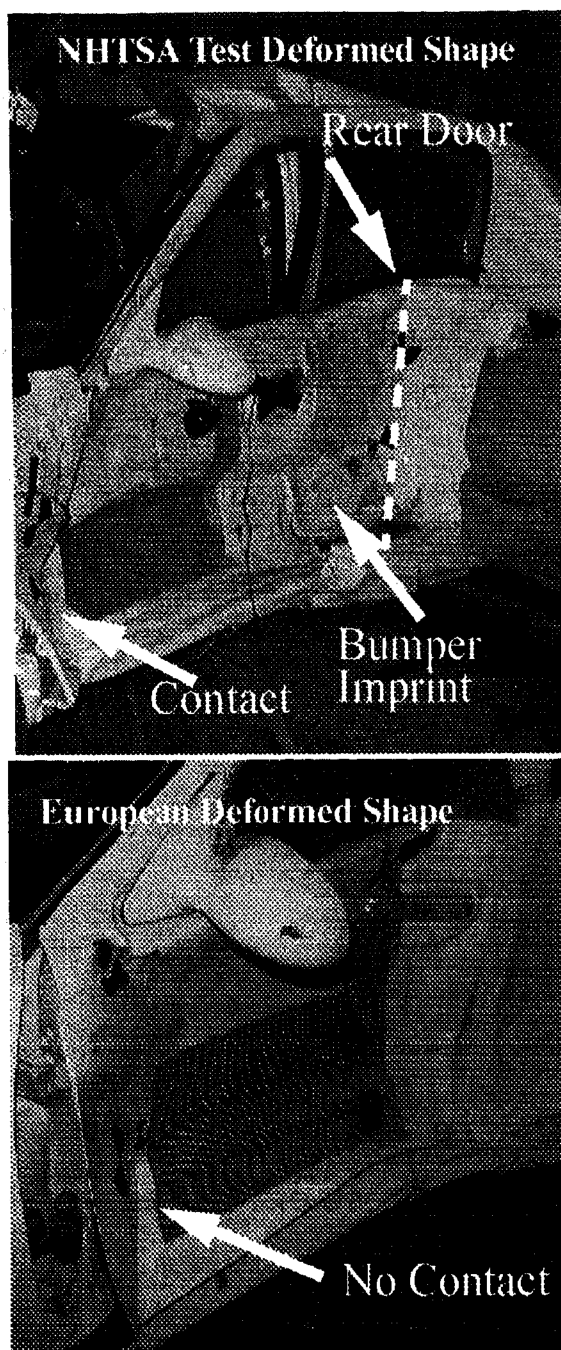

Figure6: Body Side and Door Deformation of a Vehicle in NHTSA and European Side Impacts

The deformation profiles of the front and rear door at the belt line at 60 ms are shown in Figure 7. The Figure includes door profile with a typical bodyside design to meet or exceed FMVSS 214 requirements only and the door profile with stiffened bodyside structure to meet or exceed both FMVSS 214 and European Directive requirements. For the design "as is", the door beltline intrusion in European condition is larger than NHTSA. However, with structural enhancements intrusions in European condition are close to or fall below NHTSA intrusions. The European belt line profile is somewhat circular primarily due to the normal impact and soft barrier edges whereas, NHTSA deformation pattern is flat and stretched rearward due to the crabbed velocity vector.

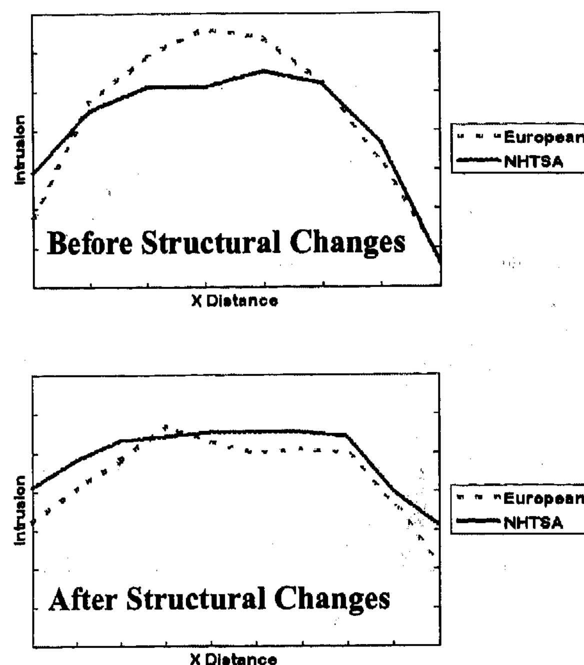

Figure7: Deformation Profile at Front and Rear Door at Beltline at 60 milliseconds

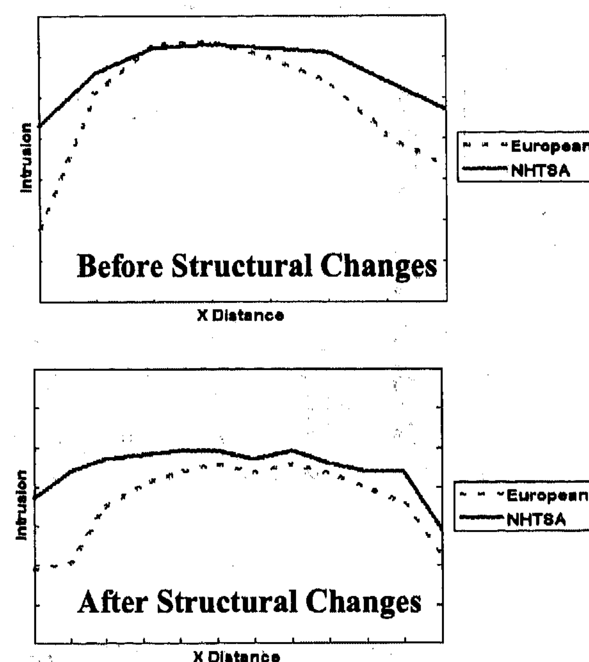

Figure8: Deformation Profile at Front and Rear Door H-point at 60 milliseconds

Figure 8 shows similar comparisons of the door profile at the H-point. The more protruding NHTSA bumper profile and stiffer barrier face accounts for its higher H-point intrusion. This is further illustrated in Figure 9 which shows vertical profile through the dummy's H-point at 15 ms. The

flatter European barrie face completely crushes the door outer panel and the NHTSA barrier face deforms only at the bottom portion of the door leaving more door volume at the top of the door at rib level.

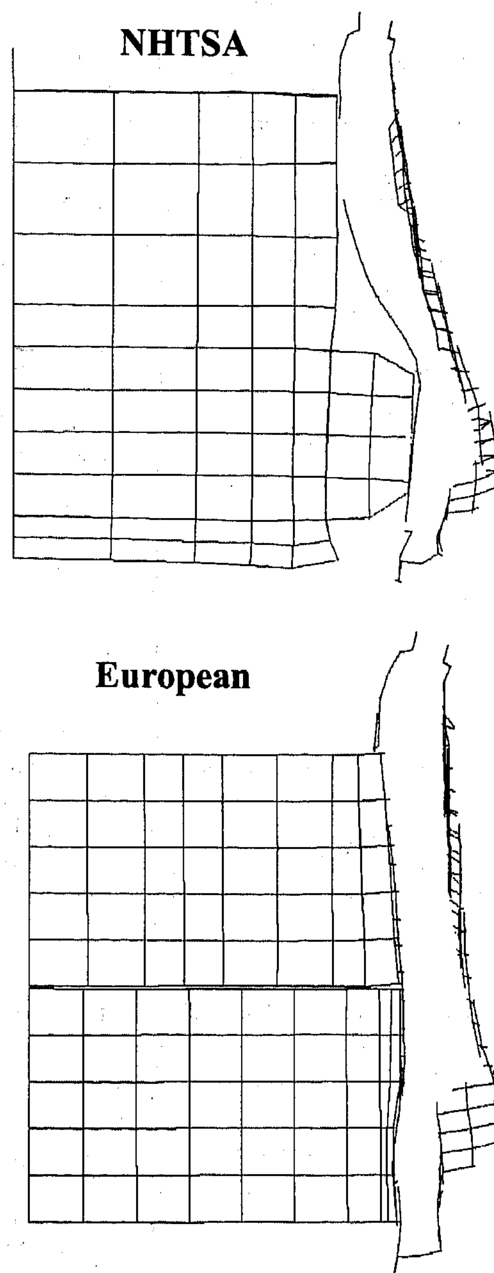

Figure9: Deformed Door Sections of NHTSA and European Barriers at 15 milliseconds

FRONT DUMMY RESPONSES

As mentioned earlier, the requirement for dummy response measurements in US DOT SID and EUROSID1 dummies are considerably different. Generally, the SID dummy responses are measured in terms of acceleration at ribs, lumbers spine and pelvic locations. In addition to pelvic G, the other FMVSS 214 requirement, Thoracic Trauma Index (TTI), is a combination of rib and lower spine acceleration.

On the other hand, the EUROSID1 measurements include many more variables, such as HPC, rib displacements, rib compression in terms of V*C, and lateral load at abdomen and pubic symphosis locations. The comparison of severity becomes harder in this case since measurements in two dummies are so different.

However, it is generally seen that meeting the US DOT SID dummy TTI requirement is more demanding than meeting the pelvic G requirement. Similarly meeting the EUROSID1 dummy rib deflection requirement is considerably harder than others.

In Tables 2 and 3, the model predicted front dummy responses of the mid size vehicle are shown against the corresponding requirements in NHTSA and European Directive side impact conditions.

Table 2: Mid Size Vehicle NHTSA S.I. Model Results

SID Responses	NHTSA Req	Model	Margins
TTI	85	64	25%
Pelvic Acc (G)	130	83	36%

Table 3: Mid Size Vehicle European Directive S.I. Model Results

EUROSID1 Responses	European Req.	Model	Margins
HPC	1000	254	75%
Upper Rib Deflection	42 mm	38	9.5%
Mid Rib Deflection	42 mm	37	12%
Lower Rib Deflection	42 mm	36	14%
V*C	1.20	0.82	31%
Abdomen Load (KN)	2.50	1.0	60%
Pubic Symphosis Load (KN)	6	4.0	33%

As stated earlier the TTI in NHTSA side impact and rib displacement in European side impact are the critical variables that in most cases controls compliance. Based on model predictions, it is seen that for European condition there is only 9 to 14 percents margin for the rib displacement requirement, where as in NHTSA condition there is a 25% margin in TTI for this vehicle.

Results from prototype tests of similar vehicles are now shown in Tables 4 and 5, in this case focussing on TTI and rib displacements, respectively.

Table 4: NHTSA S.I. Test Data

Tests	SID Resp	NHTSA Req.	Test Data	Margin
Test 1:	TTI	85	55	35%
Test 2:	TTI	85	61	28%
Test 3:	TTI	85	53	38%

Table 5: European Directive S.I. Test Data

EURO-SID1 Resp.	European Req.	Tests PT1 PT2 PT3	Margins (%) PT1 PT2 PT3
Upper Rib Deflection (mm)	42	38 47 28	7 -12 33
Mid Rib Deflec-tion (mm)	42	33 40 46	22 5 -10
Lower Rib Deflection (mm)	42	30 32 37	28 23 12
Average Rib Deflection (mm)	-	34 39 37	19 7 12

Again, it is confirmed based on test data of similar vehicles that rib deflections in European test conditions generally have much smaller margins against the corresponding requirement. The average rib deflection has a 7-19% margin and in 2 cases there is even a negative margin. On the other hand, TTI in three NHTSA tests has a larger margin of 28 to 38%.

DUMMY RESPONSES IN SUB COMPACT VEHICLE WITH STRUCTURAL ENHANCEMENTS

Next, the performance of a sub-compact vehicle designed to meet or exceed European test requirements are discussed. Considerable amount of structural enhancements in terms of bodyside reinforcement and other counter measures are added to the base design to be able to meet or exceed the European side impact requirements. The model responses in Table 6 shows that all rib deflections are meeting or exceeding the European requirements in addition to other parameter such as, HPC, V*C etc..

Table 6: Sub-Compact Vehicle European S.I. Model Response

EUROSID1 Response	European Req.	Model Resp.	Margin
HPC	1000	191	80%
Upper Rib Deflection (mm)	42	32.5	22%
Mid Rib Deflection (mm)	42	27.5	34%
Lower Rib Deflec-tion (mm)	42	28.3	32%
V*C	1.20	0.46	61%
Abdomen Load (KN)	2.50	1.61	35%
Pubic Symphosis Load (KN)	6.0	3.2	46%

The same vehicle was then analyzed to simulate the NHTSA side impact condition. Both pelvic acceleration and Thoracic Trauma Index (TTI) predictions are shown in Table 7 against corresponding NHTSA requirements. Based on model responses, it is seen that the sub-compact vehicle designed for European Directive side impact is already meeting the FMVSS 214 requirements with very large margins.

Table 7: Sub-Compact Vehicle NHTSA S.I. Model Responses

SID Responses	NHTSA Req.	Model Resp.	Margin
Pelvic Accelera-tion (G)	130	51	61%
Thoracic trauma Index (TTI)	85	64	24%

It is thus seen that both the mid size and sub compact vehicles provide similar conclusions in terms of front seat occupant responses in NHTSA and European test conditions. Both the model and test data indicate that for a specific vehicle designed with common structure and other common contents, it may be easier to meet or exceed the requirements in US test condition than the European Directive test condition. In other words, a new vehicle with common structure and restraint system may meet or exceed the US requirements once it is designed to meet or exceed the more demanding European Directive requirements.

UNIFIED US/European APPROACH:
NHTSA SIDE IMPACT WITH EUROSID1 DUMMIES

There is one other major difference between US and European side impact conditions. In the NHTSA test, there is an additional SID dummy located at the rear seat on impacted side of the vehicle. The European test condition thus, can not provide evaluation of side impact protection for a rear seated occupant. To meet this challenge and to explore commonizing other aspects of NHTSA and European test conditions, a third test set up is being looked at in this study. This test condition uses a NHTSA test up with NHTSA barrier face impacting at 27 degree crabbed angle at 33.5 mph. However, instead of US DOT SID dummies, it uses two EUROSID1 dummies in front and rear seats on the impacted side, in same seating position exactly as in NHTSA condition.

A simulation of this hybrid test up is also performed in this study. The structural responses such as door and B-pillar velocities are then compared with US and European test conditions as in Figure 10.

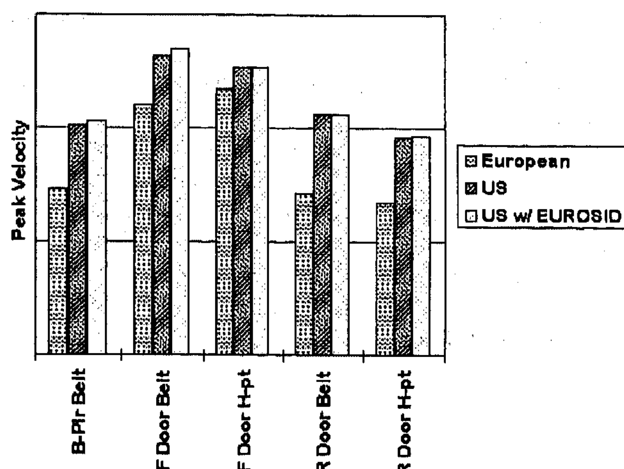

Figure10: Maximum Door and B-Pillar Velocities

As expected the velocity histories are very close to NHTSA condition.

Next, the front occupant responses are compared with the European test condition in Table 8;

Table 8: Comparison Of Front Dummy Responses

EUROSID1 Responses	European Req.	European SI Resp	US w/ EUROSID
HPC	1000	254	61
Upper Rib Deflection (mm)	42	38	32
Mid Rib Deflection (mm)	42	37	41
Lower Rib Deflection (mm)	42	36	42
V*C	1.20	0.82	0.82
Abdomen Load (KN)	2.5	1.0	2.1
Pubic Symphosis Load (KN)	6	4.0	4.7

It is seen due to higher intrusion of NHTSA barrier at lower door level, lower torso responses such as, abdomen and pubic symphosis loads are higher in unified US/European set up than the European Directive condition. For the same reason, the mid rib and lower rib deflections are much higher than the upper rib deflection.

Further investigation of this unified approach is needed based on model and prototype tests of different size and weight class vehicles before any conclusion can be drawn if this is a viable alternative.

CONCLUSIONS

The following conclusions are derived based on comparisons of structural and dummy responses of a mid size and a sub-compact vehicle simulating both NHTSA and European Directive dynamic side impacts:

Both the model and test data indicate that for a specific vehicle designed with common structure, it may be easier to meet or exceed the requirements in NHTSA test condition than in European Directive test condition. In other words, a new vehicle with common structure may meet or exceed the NHTSA requirements once it is designed to meet or exceed the more demanding European Directive requirements.

The European barrier face absorb more internal energy than the NHTSA deformable barrier.

The flatter European barrier face collapses the outer door panel completely, whereas the NHTSA barrier

primarily crushes the lower portion of the door.

The three major energy absorbing structural components in both NHTSA and European side impact tests are the impacted body side, front door and rear door, in order of magnitude.

The unified US/European test condition produces very similar structural responses, such as, intrusion and bodyside velocities of the impacted vehicle as seen in NHTSA side impact conditions. However, front dummy responses are considerably different.

The unified US/European test procedure might be a potential solution to simplify side impact test modes for global vehicles. However, this finding based on analytical data of one mid size vehicle needs to be further verified using model and test data for car and truck vehicles of different size and weight class.

ACKNOWLEDGMENT

The CAE contributions of Rabin Bhojan and Matthew Makowski of VSCAE, Ford Motor Company are greatly acknowledged.

A Method of Mapping Pre & Post NASS-93 Injury Descriptions to Enable Multi-Year Data Comparisons

E. A. Garthe and N. K. Mango
Garthe Associates

Copyright 1997 Society of Automotive Engineers, Inc.

Abstract

The National Highway Traffic Safety Administration's (NHTSA) National Accident Sampling System Crashworthiness Data System (NASS/CDS) collects detailed information on a sample of all police-reported motor vehicle crashes in the United States that involved passenger vehicles towed from the scene due to damage.[1]

This system's occupant injury definitions and severity levels, which are based on the Association for the Advancement of Automotive Medicine's (AAAM) Abbreviated Injury Scale (AIS), are periodically updated. The last major revision, in 1993, changed the injury identifier of all injuries, added injuries, deleted injuries and changed the body region and severity of a substantial number of injuries.[1] These changes confound the direct combining or trending of pre-1993 and 1993 and later NASS data.

This paper reports on the results of using a conversion method to equate pre-NASS-93 and NASS-93 and later injury descriptors and severities. The conversion maps each listed injury description and aspect in the NASS-93 coding manual to the injury descriptions and aspects listed in the NASS-88 coding manual.

This "full" conversion allows analyses of severity of injuries, frequency of injuries, and comparisons of injuries on an injury by injury basis as well as by category, body region, aspect or lesion by adjusting the NASS-93 and later data to be consistent with pre-NASS-93 data.

The paper discusses the conversion results and illustrates how the conversion can assist organizations that are analyzing data or creating standards based on multi-year NASS data.

Introduction

The (NASS/CDS) collects detailed information, such as exterior and interior vehicle damage, restraint use, occupant injuries and the possible sources of these injuries for about 5,000 crashes annually. Information about injuries is collected using methods based on the AAAM's AIS. Weighting factors permit the prediction of national estimates from this sample.[1].

The most recent 8 years of NASS occupant injury data were collected using two different injury system revisions. The "85 Revision" (based on the 1985 revision of the AIS or AIS-85) was used for data collected during the years 1988 through 1992.[2] For purposes of this paper, this system's coding manual will be referred to as the NASS-88 manual and the injuries collected during **1988-1992** will be referred to as NASS-88 data. The "90 Revision" of occupant injury data (based on the 1990 revision of the AIS or AIS-90) was used for data collected during the years 1993 to date.[1] For purposes of this paper, this system's manual will be referred to as the NASS-93 manual and the injuries collected during **1993-to date** will be referred to as NASS-93 data.

Due to the sample size, NASS CDS data in the years 1993 and later may not contain sufficient numbers of serious injuries for certain analyses. The use of the conversion adjusts the data between the systems to permit comparisons or trending over all years from 1988-to date. The additional data included using the conversion increases the data sample by about 4 times from about 55,000 (1993-94) to about 210,000 (1988-1994) injuries.

Tables are presented to show the conversion's effect on the NASS-93 manual's codes and on injuries by severity level for the years 1993-1994 when converted to NASS-88 severities. Examples are provided to illustrate how the conversion can help prevent misleading results during data analysis.

DESCRIPTION OF THE NASS-88 SYSTEM

The NASS-88 system is based upon, **but is quite different from** the AIS-85 and was used for NASS data collected 1988-1992[2,3]. There are two parts to the NASS-88 Occupant Injury Classification (OIC). The leading part of the code, the "pre-dot" is a four character alphabetic injury descriptor, which includes injury body region, aspect, lesion and system/organ identification characters. The body region and aspect characters can include "wild cards" (such as + . /) and other characters[1] that indicate the code can be expanded to a selection of body regions or aspects.[2] The fifth character in the code is a single numeric digit that specifies the severity level based on the AIS-85.[2] NASS-88 uses severities 1-6 like AIS-85, but uses 7 instead of 9 for an injury of unknown severity. The severity numbers correspond to the levels of injury shown in Table 1, with AIS-1 representing a minor injury and AIS-6 representing a maximum injury.

Table 1. Severity Numbers and Descriptions

AIS Severity Number	Description
1	Minor
2	Moderate
3	Serious
4	Severe
5	Critical
6	Maximum[2]
7	Injury of Unknown Severity
9	Unknown Injury
0	Not listed as an injury[3]

Differences between NASS-88 and AIS-85

While NASS-88 is based on AIS-85, the organization of the coding manual, the injury descriptions, code structure and severities are substantially different. The NASS-88 manual contains substantially more chapters (15 vs. 7) and injuries than AIS-85. NASS-88 also specifies 20 body regions, over three times the number used by AIS-85. The AIS system, regardless of the revision, collapses its injury list into 6 body regions as defined by the Injury Severity Score (ISS).[4,5]. The ISS is defined as the sum of the squares of the highest AIS score in each of the three most severely injured ISS body regions (Head or Neck, Face, Chest, Abdomen or Pelvic Contents, Extremities or Pelvic Girdle and External).[5,10] The NASS-88 manual is not organized to easily use ISS. The authors believe that the conversion discussed in this paper is the first time that ISS Body Regions have been assigned to NASS-88 and NASS-93 codes on a system wide basis to permit the computation of ISS for any combination of injuries.

NASS-88 also includes an "aspect" characteristic that is recorded as part of every NASS-88 data code, and has no equivalent in the AIS-85 coding structure. Aspect is used in NASS-88 to describe the location of an injury (left, right, anterior, posterior, whole area, etc).[1,2] NASS-88 defines which aspects are permitted for each code on a code by code basis, on occasion using the same aspect "wildcard" placeholder in different locations in the coding manual with different meanings. This makes the expansion of the manual for aspect difficult. The use of aspect changes the meaning of some codes with similar injury descriptions in AIS-90 and AIS-85.

NASS-88 and AIS-85 do not always recognize the same injury or assign the same severity to injuries described in the same way. For example, NASS-88 places the code for pituitary injury with brain stem injuries (hypothalamus, medulla, midbrain, pituitary, pons and thalamus) with a severity level of AIS-5 or AIS-6, depending on the precise injury. In contrast, AIS-85 did not list pituitary injury in its definition of brain stem injuries (hypothalamus, medulla, midbrain, pons) nor did it list a separate code for pituitary injury elsewhere in manual.[2,4] This particular difference in the systems was changed later in both NASS-93 and AIS-90, a pituitary injury code is listed separately from brain stem injuries and is assigned a severity of AIS-3.[1,5] Creating a conversion by code matching without referring primarily to the injury descriptions can misclassify this type of match. This is why the author's conversion is based on matching the full injury descriptions.

Unlike the AIS systems, the NASS-88 system does not use a unique injury code to identify a single unique injury description. In NASS-88 two or more injury descriptions often share a common injury code. Further, an injury description may be repeated several times in different locations of the coding manual, a practice also not used in AIS-85 or AIS-90. Skin injuries are an example, many of which are replicated between the Skin Chapter and the individual body regions. As a result, while there are 5,698 fully expanded NASS-88 injury descriptions, there are only 3,724 unique codes to describe them. Also unlike AIS-85, a single injury "pre-dot" code can have more than one AIS severity associated with it. In these cases, as the severity changes, the definition of the injury changes.[2] Example 1 illustrates an example of this effect.

---

[1]Note: The use of the "." in the predot code required NASS-88 to use the dash as the separator between the pre and post code parts.

[2]Note: NASS-88 also listed this level as "virtually unsurvivable"

[3]Note: While not defined in NASS, the injury severity of zero is used in this paper to indicate a NASS-93 injury that has no equivalent listed injury in the NASS-88 system (hence the level '0' indicating no severity attached to the injury code).

Example 1.
CODE STRUCTURE FOR NASS-88 CODE: H_UB

Body region:	H = head (NASS region)
Aspect:	_ = right, left, anterior, posterior, superior, inferior, whole region or unknown (one only)
Lesion:	U = unknown
System/Organ:	B = brain
Severities:	**5 = critical**, 4 = **severe**

If the severity assigned is **AIS-5** (critical) H_UB is used to represent - diffuse brain axonal injury (white matter shearing injury) as well as cerebellum and cerebrum hematoma /hemorrhage -- epidural or subdural >100cc. However, if the severity is **AIS-4**, H_UB represents the injuries cerebellum and cerebrum hematoma/hemorrhage -- epidural or subdural less than or equal to 100cc or unspecified as well as hematoma/hemorrhage -- intracerebral or intracerebellar (including petechial and subcortical). The code "pre-dot" (H_UB) is the same in both cases. As a result of this type of code structure, the combination of pre-dot and severity is necessary to describe an injury in NASS-88 in the most accurate way. Users of AIS-85 and AIS-90 can be confused by NASS-88, since those systems uniquely identify injuries with the pre-dot part of the code alone and do not replicate codes or re-use injury identifiers.

DESCRIPTION OF THE NASS-93 SYSTEM

Like NASS-88, NASS-93 was based upon the AIS, in this case AIS-90. However, unlike the NASS-88 system, NASS-93 shares much of the organization and structure of the base AIS-90 manual. There are three parts to the NASS-93 injury code. The "pre-dot" part of the code is a six character injury descriptor, which includes injury body region, type of structure, specific structure, and level identification characters. The second part of the injury code is a single numeric digit that specifies the severity level based on the AIS-90.[1] NASS-93 uses severities 1-6 like AIS-90, but uses 7 instead of 9 for an injury of unknown severity. The severity levels are shown in Table 1. The third part of the code is the injury aspect (left, right, etc) and is represented by a single numeric digit. The coding manual uses "wildcards" for body region and aspect characters to indicate the injury description can be expanded to cover a range of body regions or aspects.[1]

Differences Between the NASS-93 and AIS-90

The first part of the injury code in both systems is a 6 digit injury descriptor. This descriptor is all numeric in AIS-90, but the NASS-93 coding manual contains some "wildcards" for body region. NASS-93 changes the injury code for some injury descriptions compared to AIS-90, skin injuries in particular. NASS-93 also changes some injury descriptions for the same injury code used in AIS-90. In the cases where NASS-93 uses body region "wildcards" in the injury code, these must be expanded before coding the injury. AIS-90 does not use any "wildcards". A review of the differences between NASS-93 and AIS-90 conducted by the authors has shown that about 250 (19%) of the original 1315 AIS-90 codes differ in some manner between the two systems (**before** the codes are expanded for injury aspects). The second part of the injury code, AIS severity, is similar between NASS-93 and AIS-90. Codes that share the same injury description almost always have the same severity. While AIS-90 has only two code parts, NASS-93 adds a third part to every code to represent injury aspect. AIS-90 has no direct equivalent, although a few AIS-90 codes specify aspect in their *descriptions* (e.g. bilateral lung injuries). The range of aspects defined in NASS-93 for use with a specific code change on a code by code basis. The aspect code selected for an injury is indicated by an additional digit at the end of the code.[1] The aspects are the same as those defined in NASS-88, but are represented in NASS-93 by numbers rather than letters as in NASS-88.

Once properly expanded for body region, the injury descriptor in NASS-93 uniquely identifies the injury, as it does in AIS-90. AIS-90 contains 1315 injury descriptions and codes and there is no expansion required. NASS-93 contains, after expansion for body region and aspect, 3176 codes. The number of injury descriptions and unique codes in NASS-93 are identical at 3176, so there are no re-used codes. Because the injury descriptor and severity are independent quantities, it is possible to revise and update severities in NASS-93 without altering the injury definitions, a process not possible in the NASS-88 system.

ILLUSTRATION OF DIFFERENCES BETWEEN NASS-93 AND NASS-88

Table 2 shows an example of the differences in NASS-88 and NASS-93 injury codes for the same injury.

Table 2

Injury Description	NASS-88	NASS-93
Right Femur Fracture, NFS <12 years old	TRFS-3	851802.2-1

In this example the TRFS-3 code in NASS-88 indicates a thigh body region, right aspect, fracture of the skeletal system, with the injury description "Right femur fracture-Condyle, Head, Neck, Trochanters, Shaft, Or Intertrochanteric--With Or Without Sciatic Nerve Involvement". The -3, included as part of the code identity, specifies an AIS-3 level (serious) severity. The NASS-93 injury code 851802 specifies a lower extremity, skeletal femur fracture NFS, age < 12 years old. The ".2" specifies the severity as AIS-2, (moderate) while the following -1 specifies right aspect.[1,2]

NASS-88 AND NASS-93 SYSTEM DIFFERENCES THAT CAN CONFOUND ANALYSES OF INJURY DATA

The following differences between the NASS-93 and NASS-88 systems can confound analyses unless adjustments are made:

- severity changes - numerous decreases and increases in injury severity occur due to revisions in the coding system
  - without conversion, changes in severity related to coding system revisions may confound severity changes related to safety interventions
- injury description changes - text descriptions change in some way for many injuries
- changes in code identifier format: NASS-88 uses an alpha code and NASS-93 uses a numerical identifier
  - the lack of a common identifier between the systems prevents direct comparison of the data
- addition of codes - for example, a list of 51 intracranial blood vessel injuries, ranging from AIS-3 to AIS-5 in severity, was added to NASS-93
- deletion of codes - for example, some injuries involving major respiratory difficulty (e.g., hyoid fracture and vocal cord injury, both AIS-5) were deleted from NASS-88
- aspect changes - valid aspects change for some injuries, for example bilateral may be listed as a valid aspect for a particular injury in NASS-93 but not for the same injury in NASS-88
- body region changes - NASS-93 uses 9 and NASS-88 uses 20 body regions
- age adjustments - NASS-93 added injury codes that are age adjusted for severity (e.g., certain types of brain, rib cage, femur and burn injuries)

CONVERSION PROCESS

The first step in the conversion process was to fully expand the NASS-93 and NASS-88 manuals. This expansion was needed to describe as precisely as possible every injury in each system, using the written text, valid body region and valid aspect expansion. This step was crucial for improving the precision of the matching process. The following example illustrates how this improves match precision.

Table 3

Fully Expanded Descriptions:

NASS-93		NASS-88	
Injury	right injury	Injury	right injury
	left injury		left injury
	bilateral injury		(right + left)

Using the fully expanded code for each injury, it is possible to make a precise match of the bilateral injury in NASS-93 to an equivalent (right + left) injury in the **same occupant** in NASS-88. This type of match would not be possible with unexpanded or partially expanded code descriptions. Without this expansion, there would be no match for bilateral injury and the (right + left) injuries in NASS-88 would be counted as two injuries instead of one bilateral injury, confounding the injury totals.

The full expansion of the NASS-93 manual to account for valid body regions (e.g., head, neck, upper extremity, etc) and multiple matches results in a total number of 1396 codes, unexpanded for aspect. Further expansion for aspects (e.g., right, left, bilateral, etc.) results in 3,176 unique injury codes, in contrast to the total number in the current manual (1,297). A total previously reported by the author represents an "unexpanded" total of 1,292 codes, [3] prior to the addition of 5 new codes in 1996 by NHTSA [6].

A complete listing of NASS-88 injuries also was created by expanding the injuries in the printed manual to account for valid body regions, aspects and severity upgrades (e.g., add severity of +1 if open fracture). The expansion of the NASS-88 manual required a complex multi step process. This was done to obtain all the proper unique injury descriptions. The first step was to expand the original 755 injury codes in the manual to 1271 injury codes by expanding the "wildcards" for body regions and adding the listed severity upgrades. Considering each unique description, without aspect expansion, there are 2193 entries. Further expansion of the "wild card" aspect specified for each code, results in 5,698 unique injury descriptions, but only 3,724 unique NASS-88 alpha codes plus severity to describe these descriptions.

The distribution of injury codes for NASS-88, AIS-85, NASS-93 and AIS-90 by severity level is shown in Table 4. This table shows that the percentage of injury codes listed in the manuals that were AIS-3 or higher (excluding AIS-7) decreased from 62.8% in AIS-85 to 50.6% in AIS-90.[3] However, the opposite is true between the unexpanded NASS-88 and NASS-93 systems, where the same AIS-3 and higher injuries increased from 37.7% in NASS-88 to 47.9% in NASS-93. These opposite trends illustrate the differences that exist between the AIS and NASS systems. Because lower severity injuries tend to have more aspects than the higher severity injuries, when the NASS systems are expanded for aspect, the AIS-3 and above percentages (excluding AIS-7) shift down for the NASS-88 and NASS-93 expanded systems to 32.7% and 38.9% respectively. While the systems' distribution of injury codes by severity does not directly correspond with the distribution of injuries coded using the systems, this table does illustrate the differences between the AIS and NASS systems, and also points out the effect on severity of system aspect expansion. Compared to the conversion results shown later, Table 4 also illustrates how it is not possible to deduce the effect of a conversion by looking at a system's severity distributions alone.

A systematic and comprehensive line by line review of all 3,176 NASS-93 expanded injury classifications was conducted and the appropriate NASS-88 injury

*Note: AIS-90 and AIS-85 use 9 for "Injury, Unknown Severity'

descriptor(s) and severity code(s) for each NASS-93 injury were assigned by an experienced AIS user with input from expert NASS and AIS coders. Using the fully expanded (numeric or alphanumeric) codes and complete text description for each injury, matches were made to the most precise code(s) available in NASS-88. The matches were made to the most appropriate code(s) and severity level(s), factoring in the injury aspect, age of injured occupant, combinations of injuries and multiple injuries. The conversion of the expanded NASS-93 into the expanded NASS-88 manual results in a "3 dimensional" conversion that accounts for body region, aspect and severity. In contrast, a conversion that uses unexpanded codes or focusses on one of the three variables is "1 dimensional" in nature. The full conversion contains over 30,000 description to description matches.

The conversion was structured to convert injury severity and body region data in either direction; however, this paper reports on the results of converting NASS-93 injuries to NASS-88 descriptions and severity levels. This direction was chosen by the authors because preliminary analysis indicates that better match precision is possible to obtain by converting from the system with generally more detailed injury description information (NASS-93) to the one of generally less detailed information (NASS-88). However, the authors plan further analysis of the bidirectional capabilities of the conversion.

Since NASS is based on AIS, the conversion was designed to be consistent with assumptions used to develop other AIS-related conversions, in particular those between AIS-90 to AIS-85 (completed by the authors) for use with hospital injury severity data and NASS-93 to AIS-85 for use in an earlier unexpanded conversion to NASS injury severity data.[7] A limitation of this earlier conversion developed by the author was that it assigned AIS-9 (injury, but of unknown severity) to NASS-93 codes that did not exist in the earlier system.[7] This particularly affected the injuries in the head body region because NASS-93 added a section of intracranial blood vessel injury codes (n=51) that did not exist in NASS-88. These injuries range in severity from AIS-3 to AIS-5, but were coded in the data as AIS-7 or injury of unknown severity by coders using the NASS-88 manual.[7]

In this conversion, these codes can be treated as AIS-7 for frequency analyses but as either AIS-7 or special "reference" codes for severity analyses. Whenever possible, "reference" severity codes were assigned in cases like these, using the injury code and severity for a related (but not matchable) injury in NASS-88. An example would be an intracranial injury involving a hemorrhage used as a reference code for an unmatchable intracranial blood vessel laceration. Although these "reference" codes are "flagged" and should not be used in analyses in the same manner as a "matched" code, they preserve more information about the injury severity than assigning AIS-7. In cases where no reference code was identified the general AIS-7 code for the body region or an AIS-0 (no injury) code was assigned.

The conversion described in this paper provides a method for adjusting for these confounding factors, so that the NASS data from 1988-1992 and 1993 and later can be used together for a variety of injury severity, body region and frequency analyses. In addition, it links NASS-93 and NASS-88 in a unique way so that, for the first time, data queries involving injury descriptions, codes, aspects or severity can be made in a consistent manner from one system to the other, **in either direction.** However, this paper presents data on the "historical" conversion only, which assigns NASS-88 codes to the current NASS-93 injuries. The conversion also provides an enhanced ability to "filter" the NASS data sets for "invalid" codes used in either data base, since it

TABLE 5

maintains a listing of all codes, aspects and severities for each NASS system.

CONVERSION RESULTS

Table 5 summarizes the distribution of severity in the unexpanded NASS-88 and NASS-93 systems, and compares them with the NASS-93 system after conversion. The conversion process maps all possible matches to each NASS-93 code and therefore may contain several code matches of differing severity. In these cases the tables present a summary number representing the severity of all the codes matched. Since the conversion preserves all the code matches, it is possible to look at the precise codes, **and even the individual descriptions** matched to a given injury and obtain the severity of all injuries. The 30,000+ matches involved in the conversion, however, require the simplified representation of the conversion results shown.

Table 5 shows that the percentage of codes that are AIS-3 and higher (excluding AIS-7) is 37.7% for NASS-88, 47.9% for NASS-93 but increase to 56.4% for the converted NASS-93 codes. A higher percentage of converted codes are AIS-3 and above than either of the base systems. The conversion creates a **net** gain of 118 codes of AIS-3 or higher severity. This result is not perhaps surprising in perspective, as the revisions in the AIS have tended in general to lower severity for some injuries over time.[1,3] This is to be expected as a result of advances in medical technology.

Table 6 shows the percentage distributions of codes by severity for the expanded NASS-88, NASS-93 and converted NASS-93 systems. The percentage of codes that are AIS-3 or higher in severity is 32.7% in the expanded NASS-88 system and 38.9% in the expanded NASS-93 system. When the NASS-93 system is converted, the percentage of codes AIS-3 or higher increases to 48.5%. The conversion creates a **net** gain of 306 codes of AIS-3 or higher severity. The effect of the conversion is an increase in both the proportion and number of AIS-3 and higher codes.

Changes in Severity by NASS Body Region

The conversion also provides a method to reconcile different body regions that may be assigned an injury in NASS-88 and NASS-93. As noted previously, there are 9 and 20 body regions in NASS-93 and NASS-88, respectively. Some injuries are distributed into more specific body regions (e.g., upper extremity injuries are split into upper arm, elbow, forearm and wrist/ hand/ fingers) while others change body region (e.g., diaphragm injuries move from the Thorax to the Abdomen body region). The changes in NASS body region assignments affect analyses using Maximum AIS (MAIS) by NASS body regions. (MAIS is the highest single AIS code in a patient with multiple injuries and has been used by investigators to describe overall severity.)[5]

The conversion also addresses problems which may arise when using ISS with NASS data. ISS is sensitive to changes both in severity number and changes in the allocation of specific injuries to ISS Body Regions. Without correction by the conversion, the relocation of injuries to different ISS Body Regions caused by the revisions of the systems will affect the ISS for that occupant record.

MAIS has been more widely used with NASS data than ISS. However, prior to this conversion there was no specification in the NASS systems of which injuries were assigned to the six ISS body regions. **Without ISS body region assignment it is not accurate to compare NASS injury ISS data to hospital ISS injury data because body regions are defined differently.**

Both AIS and ISS are being used to evaluate emergency medical care and state-wide trauma systems, [8,9] so the need for ISS and Body Region comparisons between NASS and AIS data may increase. The

conversion provides a tool for identifying and adjusting for differences in body region and severity for individual injuries or groups of injuries between the NASS systems.

IMPACT OF THE CONVERSION METHOD ON TRENDED OR COMBINED INJURY DATA

Sample Case 1 illustrates how the differences in NASS-88 and NASS-93 discussed in previous sections can affect the accuracy of combined or trended data and how the conversion adjusts for these affects. A sample motor vehicle accident injury is shown as it would be described in data coded with NASS-88 and NASS-93.[1,2] The NASS-88 column indicates how the injury would be classified by severity in data collected from 1988 to 1993, while the NASS-93 data shows how the data would be classified by severity in the 1993 and later data. The converted data column shows that adjustments to NASS-93 can make it comparable to data coded in NASS-88. In Sample Case 1, the conversion generates a MAIS and ISS that are the same as the NASS-88 coded data.

Sample Case 1 also shows the use of additional qualifying information such as age of patient or blood loss from injury that is used in NASS-93 but not in NASS-88.

Sample Case 1

An 11 year old child sustains a fractured femur, a dislocated knee and a LeFort III fracture of the maxilla (with ≤ 20% blood loss) in a motor vehicle accident.

Injury Description	NASS-88	Unadjusted NASS-93	Converted NASS-93 To NASS-88
ISS Body Region - Extremities or Pelvic Girdle:			
Right femur fracture, NFS, (age <12)	TRFS-3	851802.2-1	TRFS-3
Right knee dislocation, NFS.	KRDJ-3	850806.2-1	KRDJ-3
MAIS for Body Region:	3	2	3
ISS Body Region - Face:			
LeFort III fx of maxilla (with blood loss ≤ 20% by volume), aspect is central	FCFS-4	250808.3-4	FCFS-4
MAIS for Body Region:	4	3	4
MAIS Overall	4	3	4
ISS	$3^2 + 4^2 = 25$	$2^2 + 3^2 = 13$	$3^2 + 4^2 = 25$

Qualifying information can change the level of severity of an injury that otherwise would have the same severity between the systems.

Although the difference in maximum AIS between the two systems is only 1 severity point for each ISS Body Region and overall, the difference in overall severity, as calculated using ISS is 12 points. Depending on the criterion used, this difference can mean the severity of the NASS-88 coded case would be classified as major trauma, while the severity of the NASS-93 coded case might not be. (ISS greater than or equal to 13 or 16 criteria have been used in studies to identify major trauma patients.[9])

ISS has been shown to correlate with mortality.[10,11]. The survival rate for a patient under age 55 with blunt trauma and ISS=13 is approximately 25% better than that for a patient with ISS=25.[12] A researcher observing that the older NASS-88 coded data shows a more severe injury and the more recent NASS-93 coded data shows a less severe injury might attribute the reduction to the effects of safety interventions, if these were present in the vehicle with the lower severity score. **The difference in ISS and the survival rates observed in this example are "phantom" and are entirely attributable to the changes between the NASS-88 and NASS-93 systems.** The conversion can help adjust for these "phantom" results.

Since the ISS uses the highest severity from the three most severely injured ISS Body Regions, cases where injury codes change ISS Body Regions between the systems can also impact the ISS just as the severity changes did in Sample Case 1.

Sample Case 1 illustrates the impact of the revisions between NASS-88 and NASS-93 on MAIS and ISS. The ISS value can be substantially increased or decreased when severity numbers change by only 1 point. In special situations resulting from the conversion, other major changes in ISS values can occur. For example, a NASS-93 injury code of 7 that converts to AIS-3 could have a large impact on the ISS. The change from a 7 would allow the computation of an ISS for the occupant (as long as none of the other injuries present was a 7).

Injury codes that convert from a severity of 1-6 to a 0 ("no injury") also impact ISS and MAIS. These represent injuries present in NASS-93 that are not listed as injuries in NASS-88. For example, NASS-93 lists 8 injury codes as "other trauma", whereas NASS-88 doesn't list any in this category.[1,2] All of these codes (which are related to either inhalation injury or hypothermia) were converted to AIS-0.

*Total, 1993-1994 = 55600 Injuries

*Note: 39 injuries not defined in NASS93 manual filtered out, 25 in 1993, 14 in 1994

Because these injury codes were assigned severities of 1-5 in NASS-93, **their conversion to AIS-0 in NASS-88 can effect the ISS by as much as 25 (5^2) points.**

To determine the effects of severity adjustment from NASS-93 to NASS-88 on the NASS data base, all the NASS-93 injury codes contained in the data for years 1993 and 1994 were converted. This converted NASS data was then compared to unadjusted data. Table 7 shows the conversion's affect on the NASS data. The distribution of injuries by severity by year is shown for each year of NASS data 1988-1994, compared to the converted data for 1993 and 1994.[13,14,15,16, 17,18,19] Table 7 shows that the percentage distributions of injuries by severity have been very steady over the years. Using unadjusted data for the most recent three years, the percentage of injuries that is AIS-3 or higher in severity (excluding AIS-7) ranged from 9.8% in 1992 to 10.9% in 1994.

However, when the conversion is used to adjust the data collected using the NASS-93 system, (1993-1994), a shift in injuries by severity levels occurs. The converted 1993 data show that 13.7% of all injuries are AIS-3 or higher in severity (excluding AIS-7), with a net gain of 913 injuries in this category. The converted 1994 data show that 14.4% of all injuries are AIS-3 or higher in severity (excluding AIS-7), with a net gain of 910 injuries in this category. Table 8 summarizes the percentage change of injuries between converted and unconverted NASS-93 data for the combined years 1993-1994.

For both the 1993 and 1994 converted data, the combined percentages of 1 and 2 level injuries declines slightly compared to the unconverted data, about 3% for each year. For 1993, the conversion increases the

TABLE 8 SUMMARIZED NASS INJURY DISTRIBUTIONS

*Note: 39 injuries not defined in NASS93 manual filtered out

number of AIS-3 injuries by almost 30% (from 2030 to 2633). For the 1994 data, the conversion increases the number of AIS-3 injuries by 34% (from 1844 to 2473).

Another interesting aspect of the data is the change in AIS-5 injuries when NASS-93 was adopted in 1993. (Shown in Table 7) There was an increase of nearly 65% in the number of AIS-5 injuries recorded between 1992 and 1993. An examination of the data reveals that this may be the result of changes in the coding of certain AIS-5 (critical) injuries. These injuries existed in NASS-88, but as severity AIS-3. The change in the coding system had the affect of moving these injuries from AIS-3 to AIS-5. These same codes appear to also cause the relatively moderate 11% increase in AIS-5 injuries in the converted NASS-93 data for 1993 and 1994. Injuries at severities 3, 4 and 6 increase several times this amount. Because the codes in question are equivalent to AIS-3 in NASS-88, the conversion correctly assigns these injuries to the 3 severity, thus greatly reducing the number of AIS-5 injuries in the converted data. Thus the same affect that causes the shift in AIS-5 level injuries between 1992 and 1993 also produces the lower increase in AIS-5 injuries in the converted data.

CONCLUSION

NHTSA, through the NASS/CDS has collected highly valuable data on a sample of automobile crashes over the past decade. However, the occupant injury data for the past 8 years is collected in two different formats, one for the five years ending in 1992 and the second for the years 1993 to date. This paper discusses a method to convert the 1993 and later data to be compatible with the earlier 5 years of data. The paper covers the following points regarding this conversion.

1. Because the NASS system is a sampling system, only a relatively small number of cases are available for each year (about 5,000). The cases are expensive to collect because of the depth of information included, and are therefore very valuable. It is unlikely that large numbers of additional cases can be easily or quickly collected per year, due to budgetary and other constraints.

2. The relatively small number of cases means that certain types of injuries (including severe ones such as head and spinal trauma) may have very low occurrences in each year. The occurrences may be so low as to confound statistical analysis. Of all the defined severe or higher injuries (AIS 4, 5, 6) n=421 of 478 (88%) have 10 or less occurrences in the 1993-94 data. A large percentage of defined injury codes of all severities n=1722 of 3176, 54% have 0 (zero) occurrences in the 93-94 data.

3. Additional cases that are available in the occupant injury data collected prior to 1993 are unavailable for use because this data is not compatible with the data collected for the years 1993 to date. This incompatibility is due to major differences in both the injury descriptor codes and the basis used to assign the injury severity.

4. The conversion discussed converts the injury descriptions and normalizes the severities to allow data from the years 1988-1992 and 1993 and later to be combined or trended. This expands (by about 4 times) the number of injuries available for analysis. The injury pool for the 1993 and 1994 years of data (about 55,000 injures) can be augmented, using the conversion with the five earlier years of data (about 160,000 injuries) to create a sample of 215,000 injuries.

5. The conversion "normalizes" the severities of the injuries in the two systems to a common baseline. When applied to the 1993-1994 NASS injury data, the conversion produces an overall increase of about 30% in the percentage of AIS-3 and higher injuries (excluding AIS-7) when the data are converted to be consistent with NASS-88. Although this conversion makes many changes (increases and decreases in severity) the net effect of the conversion on 1993-1994 injury data is an adjustment for the reduction in severity scores that has occurred in the current system as a result of advances in medicine and revisions to the severity scoring system. Without this normalization it is possible to confuse reductions in severity that are a result only of the scoring system used with the real effects produced by safety interventions.

6. A case example is given to show the effect of the conversion. The case illustrates on a "micro" scale how combining the original and converted data can increase the number of serious (AIS-3 or higher) injuries available for study. The case also illustrates the effect of the conversion's "normalization" of severity, and how the conversion adjusts what otherwise would be a substantial difference in the overall patient severity score (for the example shown an ISS of 13 vs 25, and a maximum AIS of 4 rather than 3). The conversion difference in the example was enough to change the classification of the injuries between major and non-major trauma, solely on the basis of the severity scoring system artifacts.

The authors believe that the conversion is an important tool for adjusting a substantial number of differences in severity, body region and aspect between the NASS-93 and NASS-88 systems. In addition, it can be used as a method to identify injuries that were described differently between the two systems and as an enhancement to the data filtering process.

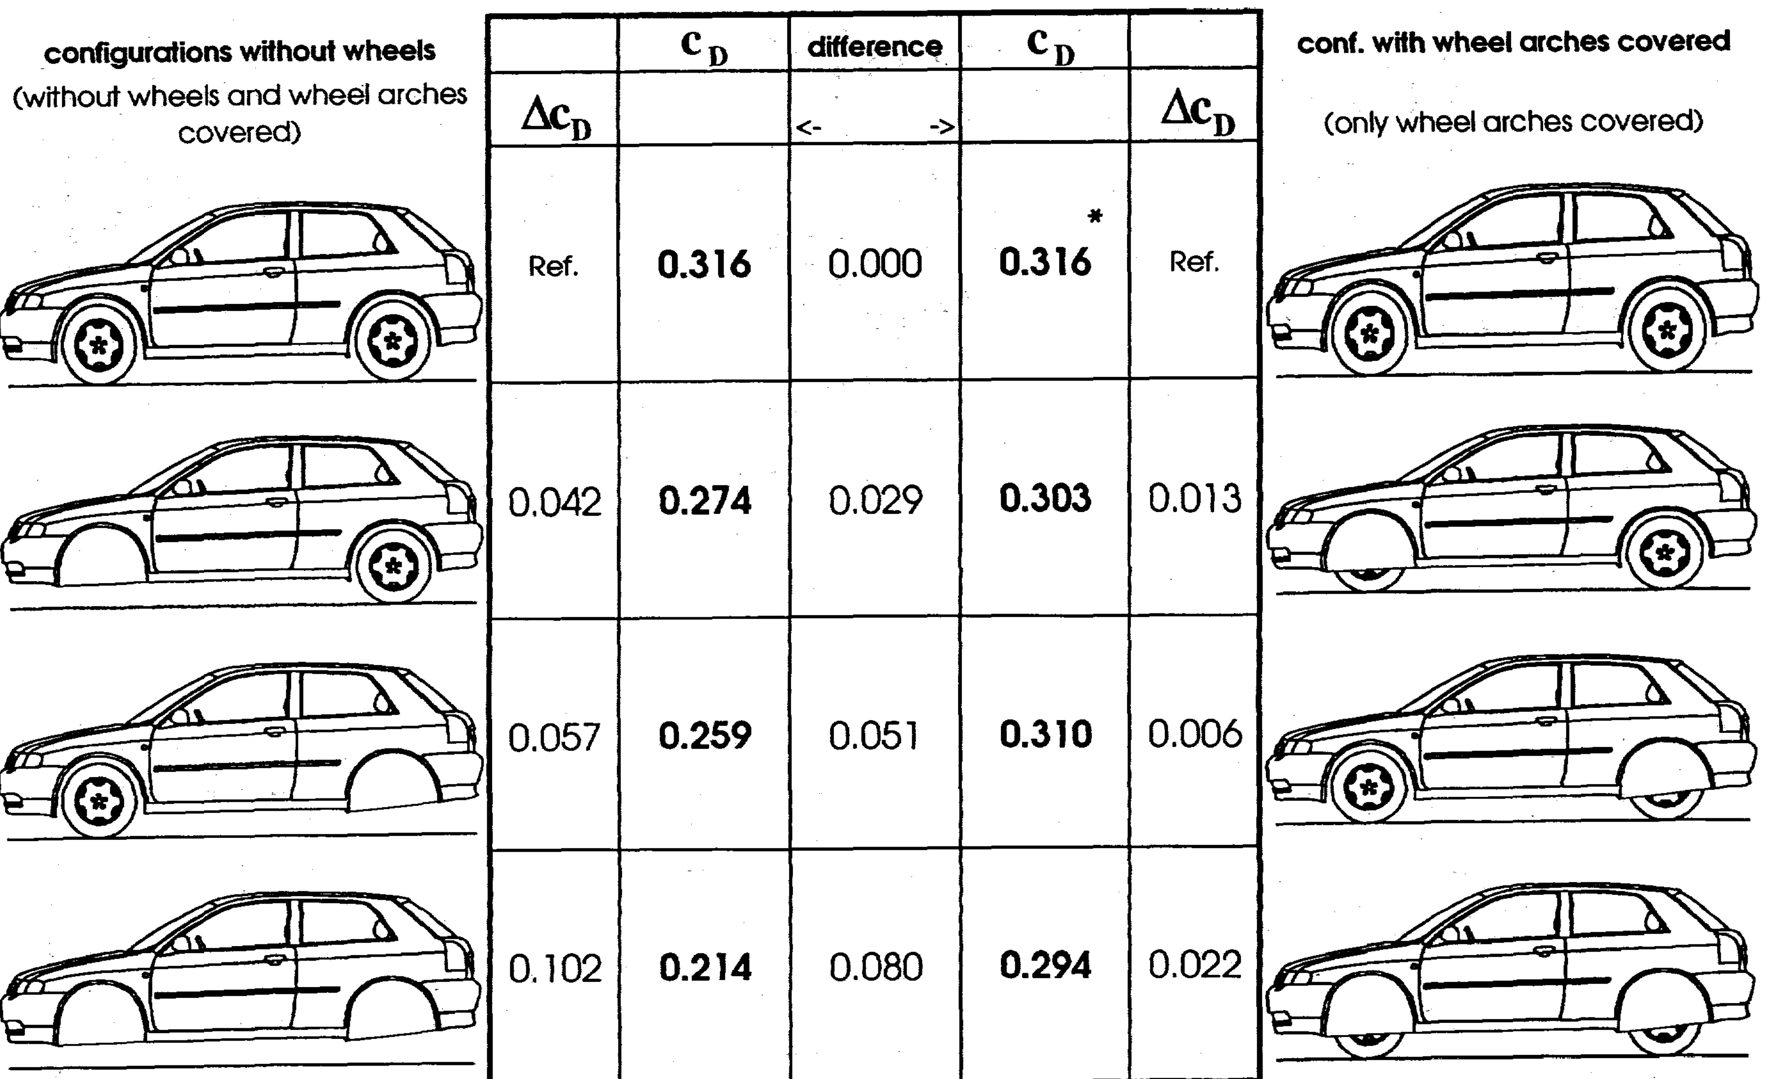
Rotating Wheels - Their Impact on Wind Tunnel Test Techniques and on Vehicle Drag Results

G. Wickern, K. Zwicker, and M. Pfadenhauer
Audi AG

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

The question of the proper simulation of wheel rotation has not so far been a major concern. Within the scope of an examination of the influence of wheels and tyres on aerodynamic drag it will be shown that their contribution to the overall drag value - whether they are rotating or not - is of about the same magnitude as the proportion of the rough underbody. Therefore the question of the importance of the simulation of wheel rotation is posed.



This paper discusses how a measurement with a better simulation can look like and what the major changes in the flow field are. In particular a new physical quantity, which has to be determined, the so-called "fan moment" is introduced. . The problems that arise in the determination of the fan moment of the wheels and hence in the required isolation of the rolling resistance, are described in detail. This is done for a test set up with full width moving belt and measurement via internal balance and sting support. An alternative set up with separate wheel drives and external balance is discussed briefly.

In a presentation of vehicle test results it is shown that the simulation of wheel rotation has a significant effect on the aerodynamic resistance. The dependence of the effect on the wheel/ tyre configuration is demonstrated in several examples. Finally, using the experimental results from a special test rig with a single wheel, the manner in which the tyre contact area and the yaw angle effects the forces at the rotating wheel is shown.

INTRODUCTION

For a long time, the influence of wheels and tyres on vehicle aerodynamics was an aspect of aerodynamic development only in terms of tyre width and flush wheel covers. The area of concentration was on optimization of the basic vehicle body. Nevertheless, since a level has been reached in the optimization of the visible outer shell that – considering stylistic matters – is difficult to improve upon, aerodynamic engineers have given their attention to the underside of the vehicle to a greater degree. In the course of exploiting the optimization potential of the underside of the vehicle, the conventional method of measuring aerodynamic values – with a stationary vehicle located in a fixed position in a wind tunnel – has been questioned. For a better simulation of the actual conditions on the road, several different groups have tried out the installation of a moving belt underneath the vehicle, which modifies the underbody flow to correspond better to the real situation. The first moving belt measurements with a production car (see Mercker and Knape [1]) showed that not just a stationary ground surface but also stationary wheels result in inadequate simulation. The simulation of rotating wheels, however, puts new demands on wind-tunnel measurement technology, which go well beyond difficulties in the simulation of the moving floor as an influence on the boundary layer.

Here the question arises as to what degree it makes sense to take these additional measures and to consider the percentagein drag of the wheels and tyres as equivalent to the percentages of the vehicle's shape and underbody. Furthermore, we should discuss what the fundamental options are for determining this percentage, and what degree of accuracy of simulation must be demanded, for example, how important the simulation of the tyre contact area could be.

THE PROPORTION OF THE WHEELS IN THE OVERALL DRAG OF A PRODUCTION VEHICLE

The significance of the wheels' contribution can be demonstrated with the results of a few basic experiments that were conducted by Audi on this issue. The results from Mercker et al. [2] served as the starting point. They measured a production vehicle without wheels and with covered wheel wells and thus deduced the percentage of the wheels and wheel wells on the aerodynamic drag. They determined a percentage of approximately 33 % of the overall aerodynamic drag for the vehicle, but in a configuration with a smooth underbody. This experiment was repeated by Audi with a production car with realistic underbody (Audi A3); additionally investigations were made with different variations to determine the influence of the front and rear wheels and of the wheels and wheel arches, at least in terms of order of magnitude.

Figure 1 shows the summary of the experimental results. In a series of experiments, the vehicle was measured over a moving belt in the following states while suspended from a rear-located support:

- initially with all four wheels in position (wheels rotating)
- once with only the rear wheels installed and the front wheel arches blanked off
- once with only the front wheels installed and the rear wheel arches blanked off
- finally with no wheels and all wheel arches blanked off.

As the results show, the wheels exert a considerable influence on overall drag, with this being initially distributed almost uniformly between the front and rear wheels.

However, the proportion attributable to the wheels still contains an element due to the wheel arches, which it would not be logical to allocate to the wheels themselves. In order to determine this proportion the sheet metal covers placed over the wheel arches in the first series of experiments were cut away so that they could be installed with the wheels in position, but would seal the gap between wheel and wheel arch. In a second series of experiments (now in an conventional wind tunnel), the vehicle always stood on all four of its wheels, but measurements were taken with the covers installed over the wheel arches in a similar manner to the first series of experiments. It was found that the proportion accounted for by the open wheel arches is distinctly smaller than the proportion from that part of the wheel which is not covered by the body (this result was also obtained in similar form by Mercker et al [1]). If the effects at the front and rear are compared, a common experience is confirmed, namely that sealing off the wheel arches at the front is much more effective than at the rear. At this point it should be noted, that the c_D - values obtained in the second test series (with fixed ground) to determine the influence of the wheel wells were adjusted to the same level as the results of the first series for configuration 1. This was done for ease of comparison. Strictly spoken, only the Δc_D of the second series are valid, and they are exact only for the case with stationary wheels.

A Δc_D of 0.08 or a 25 % of the total vehicle drag remains for the protruding part of the wheel. This Δc_D of 0.08, interestingly enough, corresponds precisely to the proportion which Hörner [3] established as long ago as 1951 for vehicles from the nineteen-thirties. However, in those days the complete vehicle's aerodynamic drag coefficient was $c_D = 0.75$. According to Mercker et al. [2], the Δc_D for the wheels was also in this order of magnitude for a car with flush underbody.

It is also noticeable in these results that after substraction the wheel-arch proportion, the rear wheels exhibit a higher level of drag. This may be due to the rear-end outline of the vehicle investigated (squareback), and should therefore not be regarded as generally valid without further investigation.

The proportion of the vehicle's aerodynamic drag which originates at the wheels is not necessarily identical with the aerodynamic force acting directly on the wheels. We assume for the purpose of estimating an order of magnitude that the interference drag (caused by the wheels at the body) is low. Then if the wheels' proportional drag is related to the sum of the wheels' frontal areas (only the area not covered up) a c_D value of approximately 1 is obtained. In other words, the wheels' aerodynamic quality is about as unfavourable as a vertical plate exposed to the airflow.

The results of the experiment shown in *Fig. 1* can be summed up as follows:

- The proportion of the wheels in the total drag of a production vehicle can easily amount to 25 %. The cause of this high figure is the unfavourable shape of the wheel when exposed to the airflow.

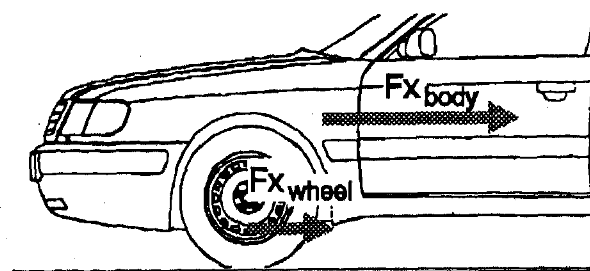
Furthermore the following additional conclusions can be drawn:

- Optimization of the wheels must be given the same importance as improving the underbody of the vehicle, since considerable potential is available here not only in terms of the absolute value for the proportional drag but also the poor aerodynamic quality as a starting level.
- Accordingly, simulating the rotation of the wheels must be given the same priority as simulating the movement of the ground surface beneath the vehicle.

However, the correct measurements with the wheels rotating cause certain difficulties, which will be discussed in the following sections.

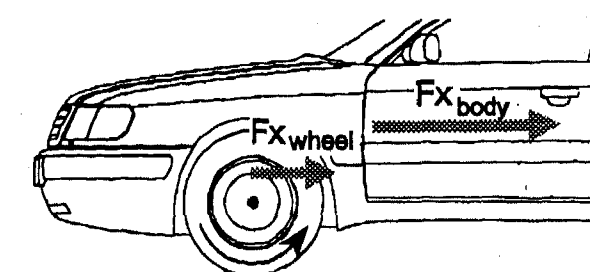
BASIC CONSIDERATIONS FOR WIND-TUNNEL TESTS WITH ROTATING WHEELS

In order to measure a vehicle with rotating wheels correctly in the wind tunnel, we must first analyse which forces and moments act additionally on the vehicle in case of rotating wheels in contrast to a conventional test set up. *Fig. 2* illustrates these forces.



Considering first a stationary wheel, the airflow forces can be divided into an element acting on the body and one acting on the wheel. The force acting on the wheel is normally applied off-centre, below the axle in the case of a wheel partly shielded by the wheel arch.

If the wheel is set in rotation by a suitable simulation technique, the flow field around the wheel changes, first of all because of the moving wheel surface (which creates different boundary conditions for the boundary layer). Secondly, in case that air is passing through the wheel this air is given a rotation by the wheel spokes (acting similar to the blades of a fan). As a result, the magnitude and point of attack of the aerodynamic forces on the wheel change. The change in airflow around the wheels, however, also gives rise to an indirect effect on the body, that is to say the interference drag. Conventional measuring techniques are unable to separate these two partial forces, but if the wheels are independently suspended this ought to be feasible.



A third value has to be taken into account in the case of rotating wheels: the moment round the wheel axis. As has already been shown on the stationary wheel, the airflow force does not act at the centre point of the axle. However, this is the only point at which forces can be introduced to the vehicle's structure. If the force is displaced to the centre point of the wheel, an additional moment is caused; if the wheel is stationary, this acts in the direction of forward travel. If, in other words, the wheel were to be attached to the axle and supported on the ground without friction, the wind load would start it rotating in the forward travel direction. This supporting effect of the airflow force is reversed, however, at full wheel speed on account of the fan-blade effect of the wheels. The moment reverses its sign and the vehicle's engine has to supply more power in order to maintain wheel rotation at a constant speed. The necessary drive moment for this is referred to below as the "fan moment". The resultant force on the wheel, in view of the sign change in the airflow -force moment when the wheel is rotating, is displaced to an effective line above the axle (*Fig. 2*). (This change in the sign of the moment will normally occur in all cases which are of technical interest, though cases can certainly be envisaged in which it does not occur, possibly because the fan-blade effect is small.)

The fan moment can be regarded as being a combination of three elements:

the aerodynamic force on the wheel acting off-centre

forces at the stationary wheel

forces at the rotating wheel

Fig. 2: Forces acting on the rotating wheel in comparison with those at the stationary wheel

- the fan-blade effect, which gives a rotational component to the flow through the wheel
- the skin friction of the rotating wheel in relation to the oncoming flow field.

All three are related to the square of the speed: The aerodynamic force rises with the square of the flow velocity v (primarily pressure forces); the fan-blade effect causes a moment rising with the square of angular velocity, i.e. speed of the vehicle and at last, the skin friction is scaled with v^n where $n \approx 2$ (a detailed discussion of the skin friction term will be given later).

The wheel's fan moment can therefore be converted into a contribution to the aerodynamic drag coefficient (a Δc_D). Since the contribution to the vehicle's driving resistance as a result of the fan moment is caused by air friction, can only be determined in the wind tunnel and can only be optimised by aerodynamic measures, it would appear logical to add this amount to the c_D value in practice. On the other hand the c_D value is by definition a nondimensional force, and there might be applications where the pure force is of interest only. Therefore a two term representation of these two aerodynamic driving resistance portions seems to make

sense. For a complete description of the driving resistance as needed for example in performance calculations both drag force and fan moment have to be taken into account. Nevertheless, for ease of comparison with the amount of total drag the share of wheel ventilation will be expressed in terms of Δc_D (instead of a moment coefficient) in this paper.

However, the technical problems of determining the fan moment are considerable. This is discussed below with reference to measuring techniques already being state of the art.

MEASURING SET-UP WITH AN INTERNAL BALANCE AND THE WHEELS DRIVEN BY A MOVING BELT WHICH SIMULATES THE ROAD SURFACE

As already mentioned in the introduction, the classic procedure when simulating movement of the road surface beneath the vehicle is to perform the measurements on a moving belt. The vehicle is supported on a bar ("sting support") from the rear or the top (see *Fig. 3*) and the forces measured with an internal balance. The test set-up used in this investigation has already been described in detail by Mercker et al. [1, 2], so in here reference will only be made to special features of measurement with rotating wheels. In this test procedure the wheels are allowed to rest on the moving belt with a low load (< 50 N) and thus forced to rotate. To minimise friction losses it is customary to remove the drive shafts and the brake pads or linings, and to rework the wheel bearings.

Although it is the belt which supplies the power needed to overcome the fan moment, this force is evident again at the internal balance on which the model and therefore the wheel are supported. The balance therefore measures aerodynamic drag as an integral value containing all the elements discussed above. Unfortunately the measured values also include the wheels' rolling resistance, which must therefore be determined and subtracted. As a common solution, a tare measurement ("zero measurement") with the wheels rotating is suggested, but this gives rise to fresh sources of error and will therefore be discussed in detail in a separate section.

ELIMINATION OF ROLLING RESISTANCE BY TARE MEASUREMENTS (INTERNAL BALANCE)

When measuring with rotating wheels, the problem referred to here occurs when the question of correct tare measurement arises. In order to examine this, we should first recall the drag forces which occur when the actual measurement on exposure to the airflow takes place (see *Fig. 4*).

1 Possibly mass forces

2 Rolling resistance of the wheels, since these are driven by the belt and therefore measured by the balance as a reaction force. This consists of
- tyre rolling resistance
- wheel bearing friction

3 Aerodynamic force on the body

4 Aerodynamic force on the wheels

5 Force needed to overcome the fan moment of the wheels when exposed to the airflow (also a reaction force, as **2**)

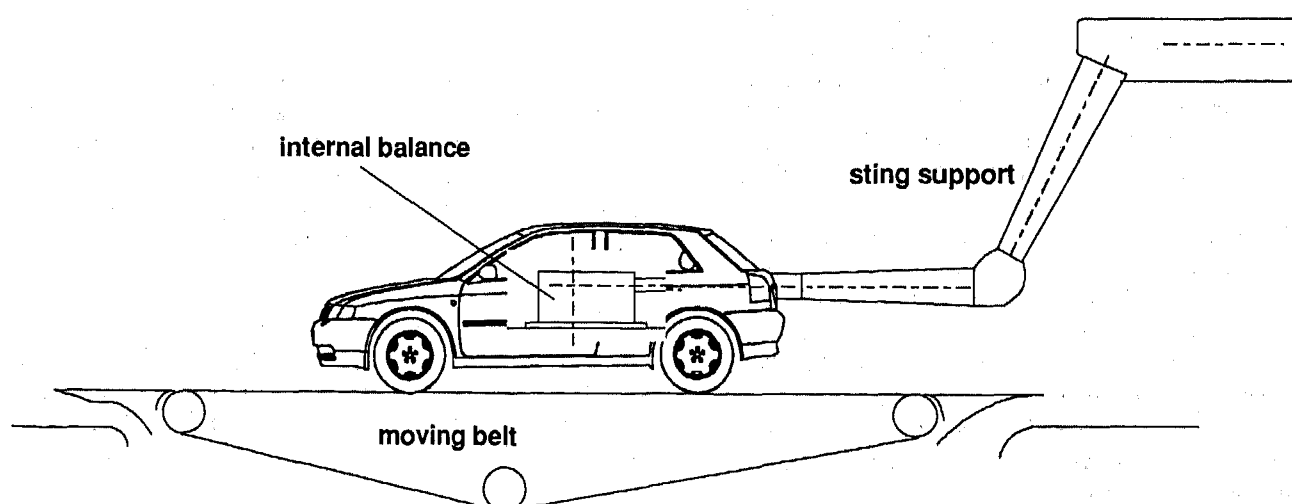


Fig. 3: Set-up for measurements with internal balance (wheels driven by moving belt)

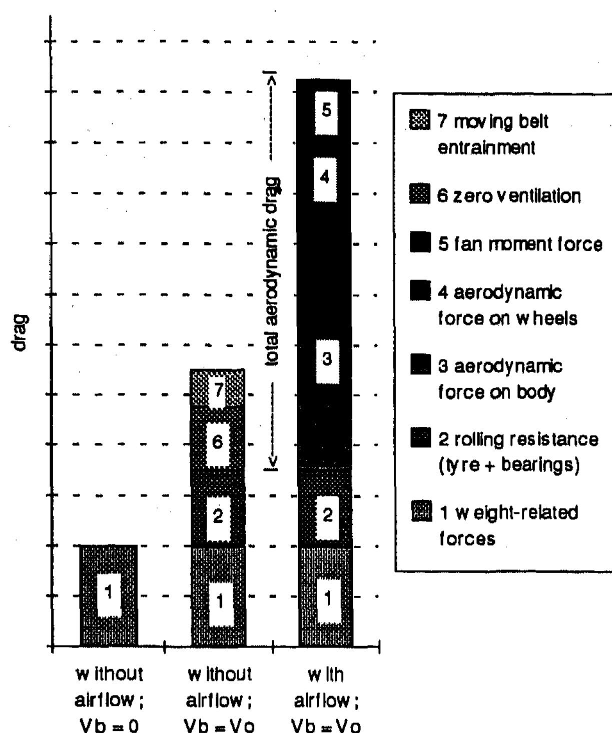

Fig. 4: Forces in the x direction when measured with the internal balance

In addition to forces **3** and **4** the total aerodynamic force must also contain the component from fan moment **5** (see section 2), so that the sum of 3, 4 and 5 must be separated from 1 and 2. This is done in the conventional way with a tare measurement. By analogy to the measurement with stationary wheels, it can be performed without airflow and with the moving belt stationary (V_b = 0). It is common practice, however, to eliminate rolling resistance by performing the tare measurement without airflow but with the moving belt in operation ($V_b = V_0$).

The forces measured in each case here can also be seen from *Fig. 4*. Although the tare measurement with moving belt in operation, as often used today, takes the rolling resistance correctly into account, additional terms arise which have nothing to do with determining the aerodynamic forces:

6 Zero ventilation (fan moment of the wheels without the airflow)

7 Forces on the vehicle body caused by the entrainment effect of the moving belt (boundary layer)

A tare measurement with the belt stationary, however, merely takes into account the forces generated by the vehicle's weight **1** and therefore also supplies an incorrect value.

The magnitude of these errors was determined by the following experiment, which also provides a means of separating the fan moment and rolling resistance components:

For the vehicle to be measured (Audi A3) a tare measurement at V_b = 0 was carried out, so that any weight-related forces **1** were eliminated. Next, the forces without airflow were determined as a function of moving belt speed from V_b = 0 to V_0 (here 140 km/h), in other words a variation of the tare method within the limits of the methods described above. Accordingly, this measurement contains only components from rolling resistance **2**, zero ventilation **6** and moving belt boundary layer effect **7**. Two cases were investigated:

- first a standard summer-tread production-car tyre on a wheel with a series-production wheel cover (see *Fig. 14.1* in the Annex)
- second a tyre with no tread but otherwise with a similar external shape (a "slick") and a smooth, full-diameter wheel cover (see *Fig. 14.2* in the Annex) to represent the ideal situation in terms of zero ventilation).

Fig. 5 shows the measured drag force in both cases.

Below 10 km/h probably non-linear incipient rolling processes occur (in the moving belt system, in the tyre and bearings) which need not be examined here. Above this speed the forces run in a very similar manner in the x-direction. Assuming that zero ventilation **6** changes with the square of wheel speed and therefore with V_b^2, and that the force **7** generated by belt speed also changes with V_b^2, component 6 + 7 can be separated off. This assumption is correct within the observed levels of accuracy to the extent that zero ventilation is primarily made up of a friction component at the surface of the wheel and tyre and a through-flow component.

The moment as an integral wall shear stress value increases with an exponent of 1.8 in the limiting case represented by a rotating disc in still air (see Schlichting [7] and Annex), whereas the moment from the through-flow component rises according to the square of the peripheral speed, in a manner analogous to rotating fluid dynamic machines.

The remaining force after substraction of the quadratic part in both cases is the same in magnitude within the limits of measurement accuracy, and remains more or less constant when plotted against belt speed from V_b = 20 km/h upwards (this limit undoubtedly depends on the vehicle being measured). As an initial approximation, this proportion of the total value can be identified as the tyres' rolling resistance plus wheel-bearing losses, that is to say as wheel rolling resistance **2**.

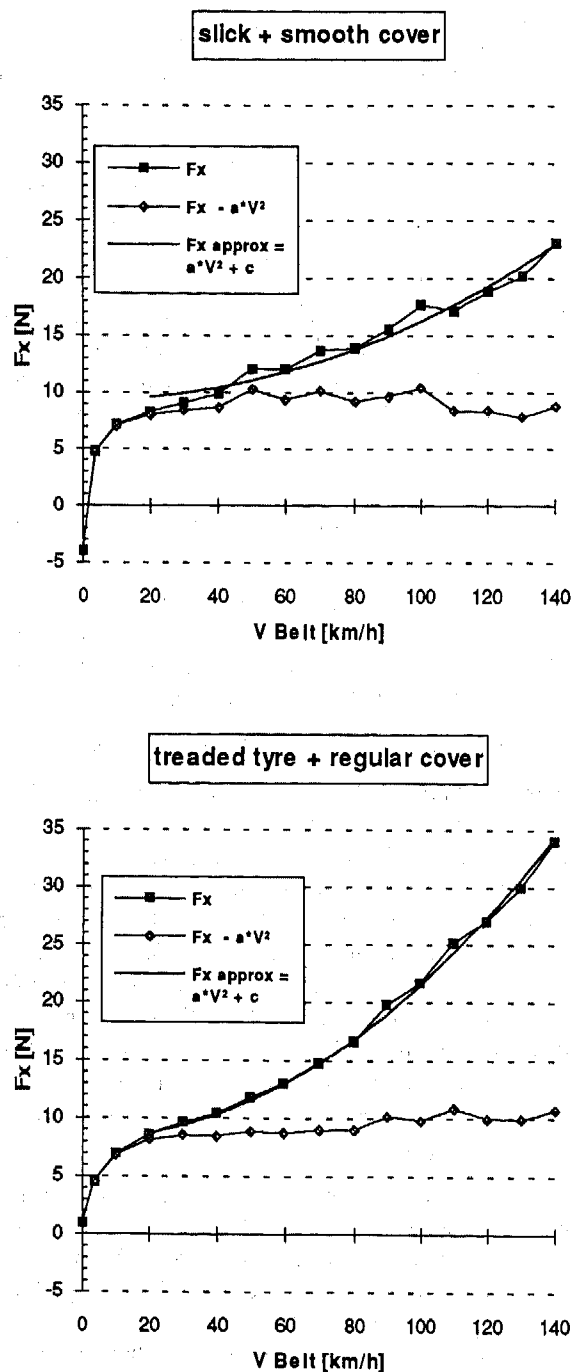

Fig. 5 : Force in x direction without airflow as a function of belt speed. Upper: plots for wheel with treaded tyre and regular wheel cover; lower: "slick" with smooth wheel cover. See text for further explanations

This means that the force in the x-direction is made up approximately from squared and constant elements. This can be shown by a formula such as $F_x = a\ V_b + c$ with an approximation of the measured values, for example by help of a least-square-of-error method; if applied to the two cases under investigation, the following results are obtained:

- The constant component is about the same in both cases

  F_{Roll} = app. 9 N

  This element is not taken into consideration when the tare measurement takes place with the belt stationary, that is to say the measured aerodynamic drag is too high by this amount, equivalent to Δc_D = 0.005 at V_o= 140 km/h (A=2.06 m²)

- The squared element (zero ventilation plus moving belt) depends on the wheel/tyre combination and must be determined afresh for each change of wheel. For the cases investigated, two typical results for V_b = 140 km/h are obtained:

  $F_{\text{zero ventilation}} + F_{\text{belt boundary layer}}$ =

  = 14 N ("slick" with smooth wheel cover)

  and

  = 24 N (treaded, with regular cover)

  When a tare measurement is carried out with the belt moving, this is accordingly the amount by which the aerodynamic drag will be too low; here it is equivalent to Δc_D = 0.007 or 0.012.

  The proportion caused by the moving belt's boundary layer effect is, in our experience, relatively small (app. 2 ... 3 N, measured with all four wheels lifted off the belt).

The values stated above show that the forces which occur cannot be neglected when undertaking aerodynamic drag measurements. It is therefore desirable to examine the forces relevant to the tare measurement more closely. The measurement of forces as a function of V_b, as described here, is a practicable method of separating rolling resistance from the fan-moment component.

The above reflections can be summarised as follows:

- c_D in the case of moving belt measurements with an internal balance is quoted as larger than previously by the amount represented by the zero ventilation and the belt boundary layer effect, when the tare measurement took place with $V_b = V_o$ The magnitude of this error is approx. Δc_D = + 0.010 (here between 0.007 and 0.012)
- If a different wheel/tyre is fitted, the change in zero ventilation must be taken into account as appropriate, since the wheels will otherwise be allocated a value

in the calculation which is incorrect by this amount (here $\Delta c_D = 0.005$)

Tare measurement at low belt speed, which can be carried out with the above procedure, is a simple and practicable solution to the problems of improving drag measurement as described here.

In order to check the magnitude of the zero ventilation, measurements were conducted using a different measuring technique and without the vehicle being present, on the tyre test rig operated by the Continental Tyre company. The above values for the two wheel combinations were confirmed to a most satisfactory extent.

Zero ventilation is by definition the fan moment without incoming airflow. As *Fig. 4* shows, separating the fan moment with airflow from the other aerodynamic forces is not possible in a set-up as shown in *Fig. 3*, since here only the integral value of the relevant forces can be determined. For correct separation the force which the rotating wheel exerts on the belt when exposed to the airflow would have to be determined on its own. Therefore no data is available on the amount of the fan moment with airflow for the configuration investigated here. Moreover, to our knowledge neither in the literature any data is available except for the work of Deubert [8], who published results of Mercedes-Benz. In the reported case the fan moment was measured in a conventional wind tunnel and the wheel was driven by an external electrical motor via torque-measuring shaft. The tyre dimension (195/65 R15) was exactly the same, whereas the wheel designs and the vehicle (MB W 124) were of course different. Nevertheless these results give us useful hints. If we compare the results for the zero ventilation of the treaded tyre with regular cover shown in *Fig. 5* with the summer tyres on steel wheels in the Mercedes-Benz results in *Fig. 7*, we find quite similar Δc_D -values. Thus the zero ventilation value maybe is a workable approximation if an initial estimate of the magnitude of the fan moment is required. Another interesting result is, that for the steel wheel with cover the fan moment for front and rear is nearly identical. For the more open (light) alloy wheel the results differ in a similar way as the results for the wheel arches (blanked off or not). Due to suction peak on the outside of the front wheels a larger effect is obtained there compared to the rear wheels. Not surprising is that the winter tyre with a more coarse tread has a larger fan moment than the summer tyre.

The magnitude of the fan moment is of special interest when comparing results of a test with full width moving belt and internal balance with results from test set-ups, where the fan moment is not included in the measured drag force. A such a set-up will be discussed in the next section.

wheel location	wheel configuration	Δc_D for single wheel

MEASUREMENTS WITH AN EXTERNAL BALANCE AND SPECIAL WHEEL DRIVE UNITS

In order to avoid the complexity of suspending the vehicle from a support arm, an alternative method of simulating rotating wheels was developed, with the wheel drive elements forming part of the weighed system. The forces can then be measured in the conventional manner, using an external floor-mounted balance. To complete the simulation, a moving belt can be installed between the wheels. An example for this type of facility is the Pininfarina wind tunnel, as described by Cogotti [4].

In the beginning of rhe development of this testing method the vehicle was placed on additional supports connected to the balance, and drove its own wheels by way of its all-wheel drive system (see for example Wickern [5]; Mercker, Soja and Wiedemann [6]). The balance plates were equipped with plain rollers or brush systems to prevent air from flowing under the rotating wheels. As a refinement the drive can be transferred to the balance plates, resulting in the set-up shown in *Fig. 7*. The drive is no longer part of the test vehicle, but is still within the weighed area of the balance, so that no power bypass can falsify the measurements. Compared with internal-balance measuring,

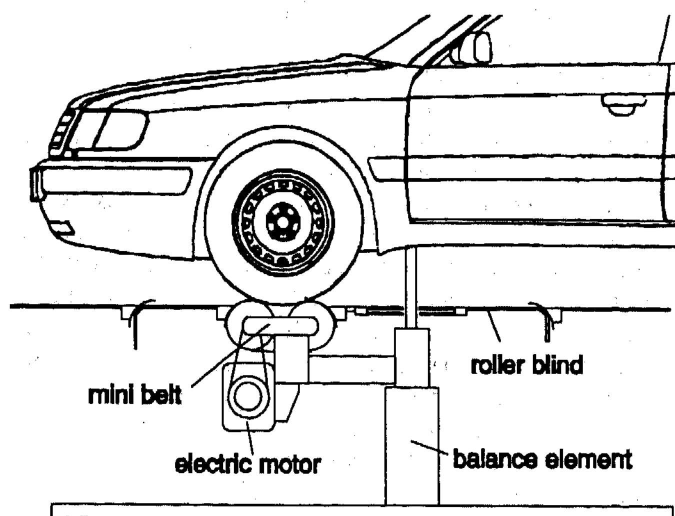

Fig. 7: Set-up for measurement with external balance (wheel drive integrated into balance plates)

this method has the fundamental advantage that rolling resistance cannot influence the results, since the wheel drive forces are absorbed internally by the balance frame. The integral aerodynamic drag value does not include the proportion for wheel fan moment, since this is also part of the wheel drive forces. The wheel drive forces must therefore be measured separately and then divided into a fan element and a rolling resistance element in the same way as for the moving belt measurement. This can be seen as a drawback, since an additional measuring device is necessary. On the other hand measurements with full wheel load should be possible without loosing accuracy for the aerodynamic forces (except for the fan moment).

TARE MEASUREMENTS WITH EXTERNAL BALANCE

In the case of measurements with an external balance, the problems of registering the fan moment are quite different in nature, on account of the difference in the testing set-up. The drag forces recorded during measurement (see *Fig. 8*) are in this case

- **1** possible weight-related forces
- **3** aerodynamic force acting on the body
- **4** aerodynamic force acting on the wheels

Rolling resistance **2** does not cause any problems here, since these are internal forces which are not measured. To this extent the tare measurement is also unproblematical, since it contains no foreign components.

However, once again fan moment **5** cannot be determined, so that the integral value for the measured drag is fundamentally falsified (too low by the fan moment value). In order to determine the fan moment, the wheel drive force at the wheel contact points must also be measured. Since the wheel drive units are installed on the weighed section of the balance, the drive force must be measured as an internal force in the balance structure by means of separate sensors. There are various ways to achieve this:

- with an additional load cell to measure the force in the x-direction on the balance plate (with low-friction mounting) with wheel drive
- the power needed to drive the wheel is determined from the motor reaction torque, so that the force at the wheel contact point can be calculated
- by means of strain gauges mounted directly at the axles of the wheel drive rollers, all forces at the wheel can be determined (drive force plus supporting force -> determination of wheel lift forces)

None of these three posibilities is available at present in an existing facility. Therefore we can not give any measured data for the vehicle under investigation here. In a future wind tunnel with the wheel drive force determined in the described way is once again the sum of the fan moment and the rolling resistance, and must be divided up into these two components by a suitable method, as in the case with the internal balance.

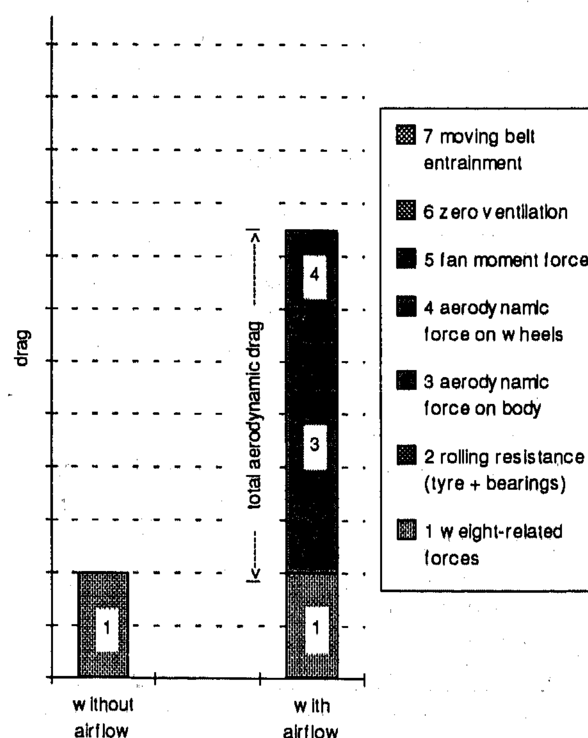

Fig. 8: Forces with the external-balance measuring set-up

The process of separating the rolling resistance encounters technical measurement problems at the full wheel load, which is desirable as a means of showing the correct patch. The question is to what extent simulation of the realistic wheel load is necessary for the measurement of the fan moment alone. If not, the fan moment could be determined in a "second shot" without wheel load.

MEASUREMENTS ON DIFFERENT WHEEL/TYRE COMBINATIONS ON THE VEHICLE

With the internal-balance experimental set-up already described, measurements were carried out on an Audi A3 with different wheel/tyre combinations. Measurements were taken both with rotating wheels and moving belt, and with stationary wheels on fixed ground for purposes of comparison. For the rotating-wheel measurements, two different forms of tare measurement were compared. One was the tare measurement at low belt speed as discussed before, the other the frequently used form of tare measurement with belt moving at $V_b = V_0$ (here 140 km/h). This supplies information on the influence of wheel rotation and of the type of tare measurement used.

The following parameters were investigated:

- Wheel design
- Tyre tread
- Cooling air

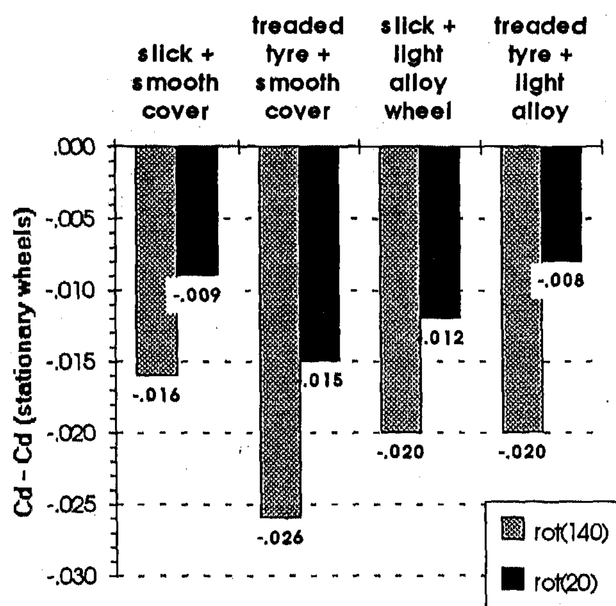

Fig.9a: Assessment of different wheel/tyre combinations evaluated by different measurement setup:
- stationary wheels and fixed ground (reference)
- rotating wheels, tare measurement at 20 km/h
- rotating wheels, tare measurement at 140 km/h

In each case the tyres were of size 195/65 R15 on rims of size 6 J x 15. The wheels investigated are shown in *Figs. 14.1* and *14.3* in the Annex.

The results (see *Fig. 9a*) indicate first of all that wheel rotation and the form of tare measurement affect the level of the measured aerodynamic drag coefficient: the absolute value c_D is always larger in case of stationary wheels compared to rotating wheels (it is the effect of the wheels and not of the moving belt, since moving belts increase drag). This effect has already been noted by various observers (see [1], [2], [6]). When measuring with a tare measurement at 20 km/h, however, the difference is distinctly smaller. Hence, with a tare measurement at 140 km/h, a considerably lower c_D is stated.

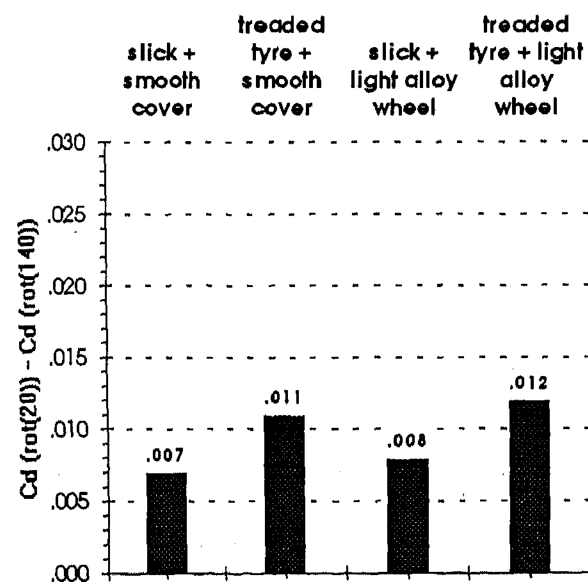

Fig. 9b: Difference in assessment of wheeld/tyre combinations usibg different tare measurements
- tare mesurement with 20 km/h
- tare measurement with 140 km/h

referred to a measurement with stationary ground and wheels

The nature of the tare measurement also reveals a significant difference in the Δc_D of different wheel/tyre combinations:

$$\Delta c_{D\ rot(20)\,/\,rot\,(140)} = \text{between } 0.007 \text{ and } 0.012$$

This difference, according to what has already been discussed, is quite exactly the off-set caused by the zero ventilation value of the wheels plus the boundary-layer effect of the moving belt. Accordingly, the difference is at its lowest when the wheel exhibits low zero ventilation ("slick" plus smooth wheel cover), with the opposite

applying when a treaded tyre and a light-alloy wheel are used.

Broken down according to the stated experimental parameters, the results are (see *Fig 9c*):

- **Wheel design:** measurements with rotating wheels illustrate the difference between the individual wheels more clearly than if the wheels are stationary. However, the wheel cannot be assessed in isolation but only in conjunction with the tyre:

Δc_D (alloy wheel/smooth cover) =

= + 0.014 (treaded tyre)

or = + 0.007 ("slick")

- **Tyre tread:** Measurements with rotating wheels yield the surprising result that the treadless tyre on a wheel with a smooth wheel cover performs worse than the equivalent tyre with tread:

Δc_D (treaded / "slick") (smooth cover) = - 0.005

This is not the case with the light alloy wheel:

Δc_D (treaded / "slick") (alloy wheel) = + 0.002

Here too, therefore, the tyre cannot be assessed without the wheel.

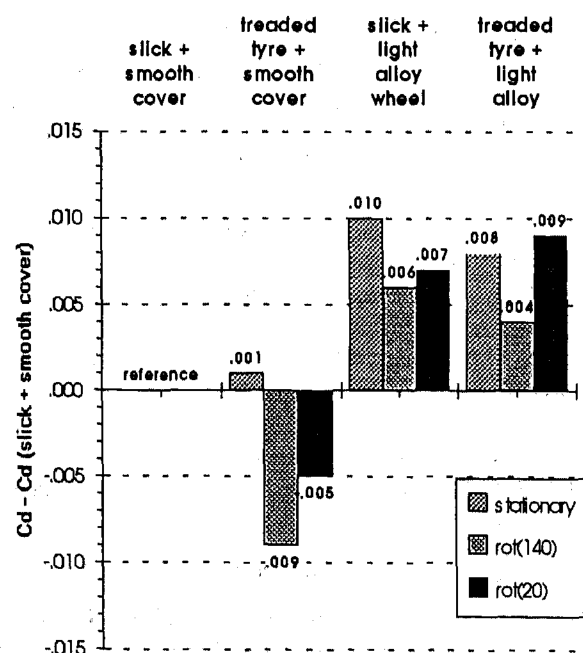

Fig. 9c: Assessment of different wheel/tyre combinations depending on the measurement technique and tare measurement; reference is the slick tyre on wheel with smooth cover

- **Cooling air:** It had been found by Mercker et al.[1,6], that cooling air is closely related to the aerodynamic drag at the wheels. In our case (see *Fig. 9d*) the cooling air flow does not have any significant effect on the assessment of the two wheel/tyre combinations:

Δc_D (light alloy wheel/smooth cover) =

= + 0.014 (cooling open)

= + 0.013 (cooling closed)

Nor does this result if the tare measurement is varied. This initially seems to contradict the measurements obtained by Mercker et al. [1,6], but we should have in mind that this result is certainly vehicle-specific and secondly only one integral value for the drag change at wheels and body was measured. Individual drag values could certainly be subject to some kind of influence. This problem is discussed in more detail by Pfadenhauer [9].

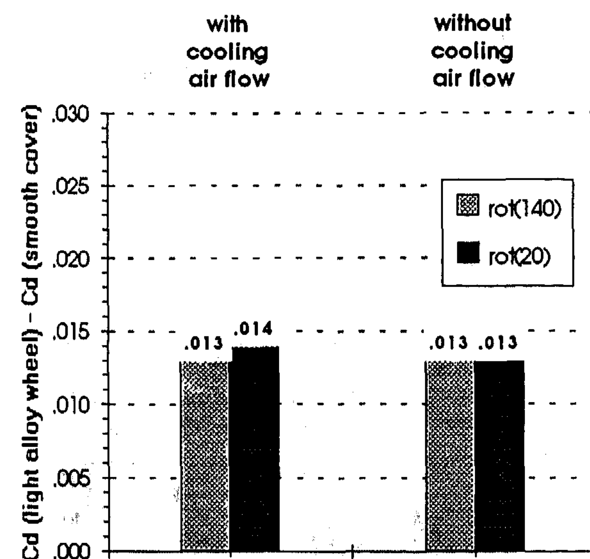

Fig. 9d: Assessment of different wheels with and without airflow. Measurement with rotating wheels and ground and different tare measurements

Taking these measurements as an example, we can see the extent to which the nature of the measurement influences the assessment of various wheels. Measurement with the wheels rotating represents none the less a definite improvement in the simulation of road conditions. With a change in tare measurement, a further correction of the same magnitude is obtained.

Another, possibly important aspect is the occurrence of deformation corresponding to tyre load at the contact point or "patch". When the transition from stationary to rotating wheel takes place, the simulation worsens in this respect. This will be examined in the following chapter.

INFLUENCE OF THE TYRE CONTACT PATCH ON DRAG VALUES (PRINCIPLE TEST ON A SINGLE WHEEL)

The simulation of a realistic tyre contact patch in wind tunnel tests with rotating wheels has been quite unsatisfactory so far. To simulate it in conjunction with rotating wheels caused problems of a technical nature. High friction losses and the associated thermal loads reduced the operating life of the moving belts when operating at full wheel load to such an extent that in many cases an inadequate simulation of the tyre contact patch was given preference instead, in order to maintain the progress of the test. In a fundamental test conducted in the FKFS wind tunnel in Stuttgart, it proved possible to undertake single-wheel tests with the wheel rotating under full load. The influence of the tyre contact patch on wheel drag was examined in relation to the incoming airflow and to wheel rotation.

To a better understanding of the flow conditions at the front and rear wheels of a complete vehicle first the flow field in a horizontal plane underneath the car is discussed (see Fig. 10). This will help us to apply the result of a single wheel test to the much more complicated situation at a real car.

The situation at the front wheels is dominated by the displacement flow from the nose of the vehicle and the wheel, which causes the airflow to strike the front wheel at an angle. The lower part is exposed freely to the flow without interference with wakes of other parts upstream. The local yaw angle was investigated on several vehicles, and is always approx. 15 degrees. No significant influence oft vehicle dimensions on the local yaw angle at the front wheels was detected.

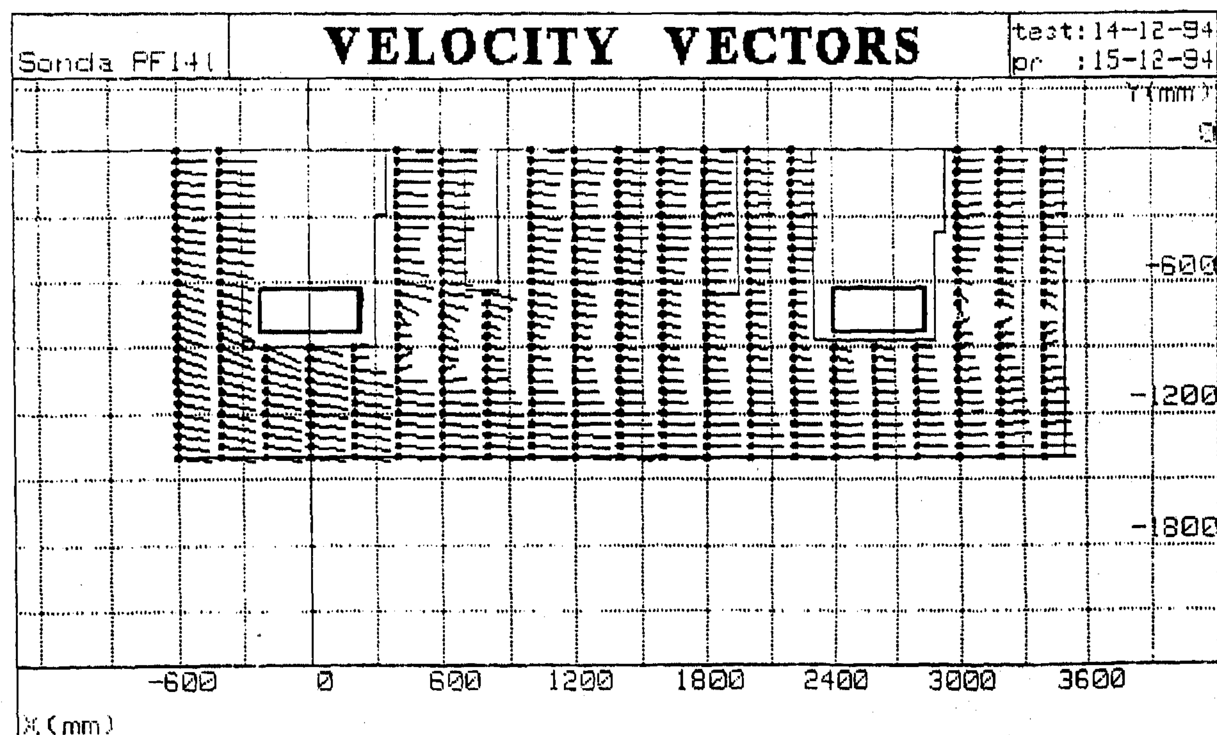
At the rear wheels the flow arrives at a smaller angle than at the front. Flow losses from the front-wheel outflow and losses at the underfloor of the vehicle distinctly reduce the velocity at this point.

The complex flow patterns at the rear wheels seemed to be less suitable for investigations into the basics of wheel drag. However, giving priority to the front wheels should not be taken as implying that the rear wheels make less of a contribution to aerodynamic drag than the front wheels.

To drive the wheel, a miniature moving belt developed by FKFS was used (see J. Potthoff, R.-G. Fiedler [10]). This belt permits the simulation of wheel rotation at full wheel load. It is possible in this case to investigate the effects of tyre contact patch formation and the associated dynamic deformation of the rotating tyre on wheel drag.

The experiments were made with a standard light-alloy wheel with perforated wheel disc, size 6 J x 15, with a 195/65 R 15 tyre. The c_D values stated refer by way of an example to a vehicle with 2.0 m² frontal area.

The test setup for determining forces and moments consists of a vertical post and a cantilever arm. Since post and arm are part of the weighed system, the airflow forces acting on the mounting were determined by calibration measurement before the experiment was undertaken. For this measurement the wheel, as an interference body, was



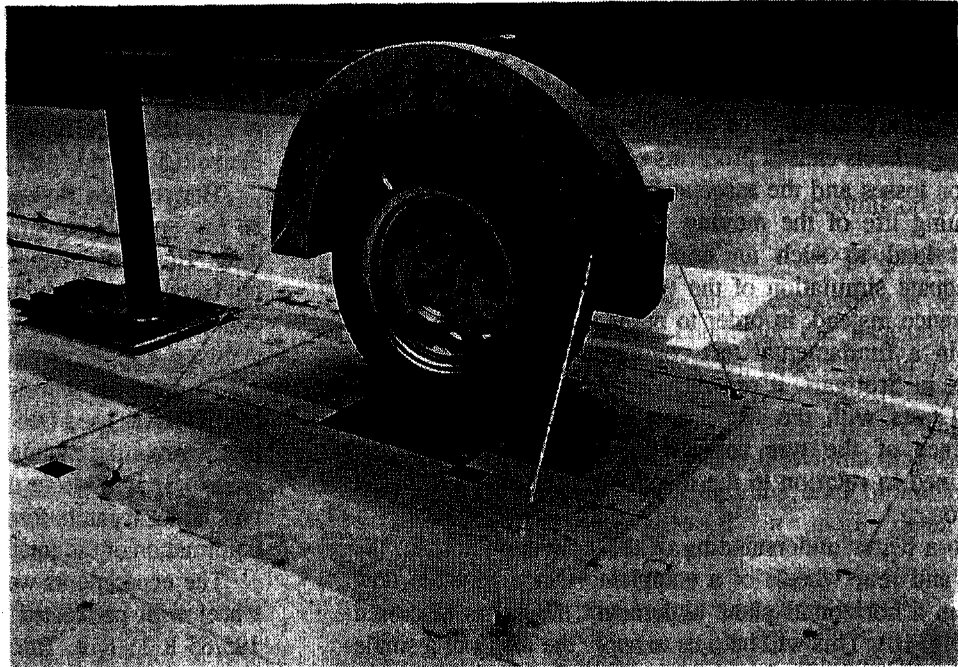


Fig. 10: Flow zone speed vectors on the underside of the vehicle, in a plane parallel with the road surface at height Z = 100 mm.

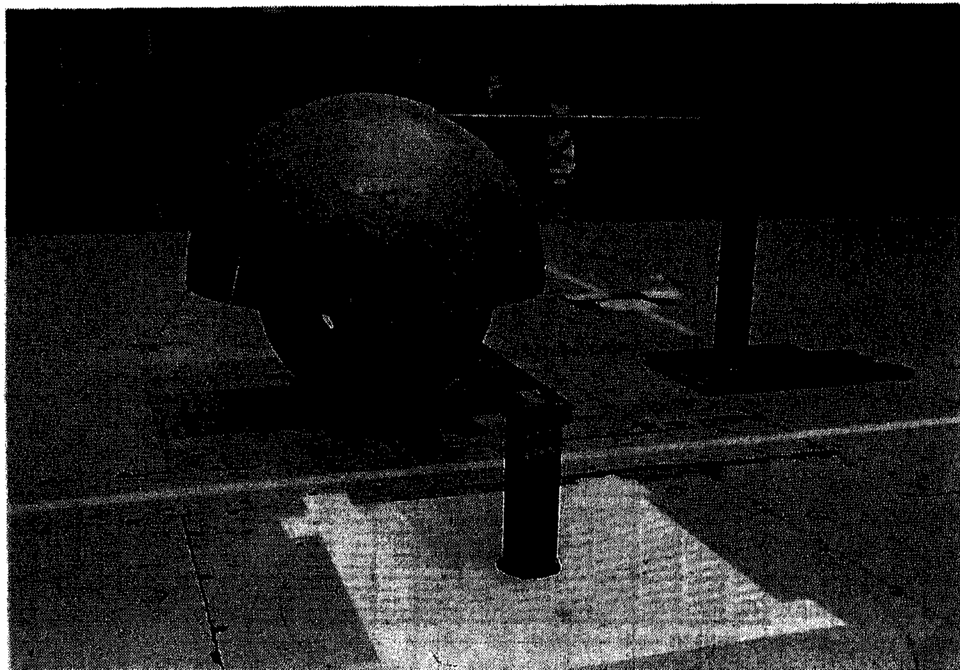
decoupled from the weighed section in force terms. Interference of the rotating wheel on the mounting was not determined separately, so that this force element is present in the evaluations for the rotating wheel.



A wheel well simulator was developed to represent the flow conditions in the wheel well. It was a double-walled structure with its inner contour modelled on the wheel well of a standard production vehicle. The outer contour has the configuration of a quarter-sphere segment, in order to ensure almost constant incoming flow conditions when the inclined flow incidence angle is varied, regardless of the outer contour. The wheel well simulator is decoupled from the weighed section in terms of force transmission, and acts exclusively as an interference body.

The wheel load applied to create the correct tyre contact patch (preload and unspring mass) was 2,620 N. When the load is applied to the wheel, the moving belt is lowered by a certain amount between the two reversing rollers (see *Fig. 7*). The belt mainly yields only in the zone represented by the tyre's contact patch. However, with the belt lowered between the rollers and a load of this magnitude, the contact patch simulation is sufficient for an initial estimation.

Variation of the yaw angle is achieved by rotating the turntable carrying the complete experimental set-up. A positive flow incidence angle is one on to the inside of the wheel and describes the realistic flow conditions for the car.

Experimental set-up (view on open side of wheel well)

Experimental set-up (view on closed side of wheel well)

Fig. 11: Experimental set-up: principle tests on a single wheel at the FKFS.

At this time it was not possible to assess fan moment by the setup used, so that the values quoted for this test do not include the proportion of fan moment contributed by the moving belt . It is also assumed that the exact form taken by the tyre contact patch has no influence of fan moment or on the interference effect between wheel and body.

In order to present the results correctly to derive the influence of the tyre contact patch, it is first necessary to ge

briefly into some detail regarding the pattern of drag at the stationary and rotating wheel in relation to the yaw angle (as presented in *Fig 12*).

Without yaw (β=0°) the drag coefficient is reduced by approx. 60 % when the wheel is rotated. As the yaw angle is increased up to β=25°, drag increases at both the stationary and the rotating wheel. However, the increase is distinctly steeper at the rotating wheel, so with the yaw angle exceeding 10° the rotating wheel exhibits higher drag than the stationary wheel. The cause of this increase in drag at the rotating wheel is more intensive flow seperation at the side of the tyre. These results are discussed in detail by M. Pfadenhauer [9].

Since it has until now not been possible to show the tyre contact patch adequately, assessment of wheel drag has suffered from various uncertainties. Use of the miniature moving belt, however, has permitted investigations with realistic tyre deformation (both contact-patch and dynamic deformation) when the wheel is rotating.

At low yaw angles, the tyre contact patch results in an increase in drag. If wheel rotation is simulated, this influence is reduced by an almost constant offset of Δc_D < 0.001. As the yaw angle increases, the tyre contact patch's drag-increasing effect is lost. Neutral drag occurs, depending on wheel rotation, at approx. 12 degrees (rotating) or 15 degrees (stationary). At angles greater than 25 degrees, which however are not relevant to vehicles, the presence of the tyre contact patch always has the effect of causing a slight reduction in drag.

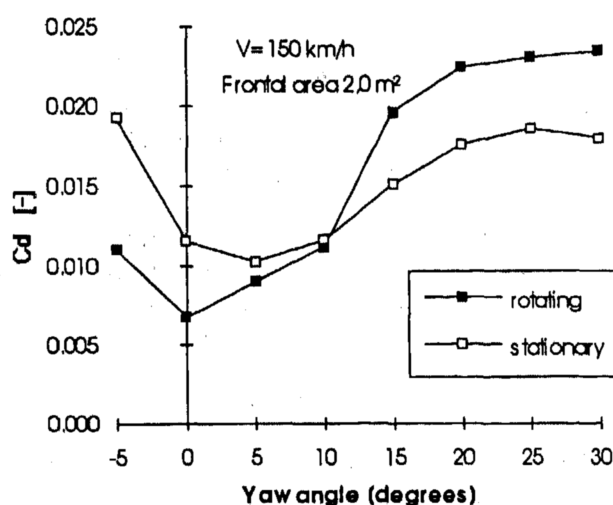


Fig. 12: Relationship between drag at the stationary and rotating wheel and the yaw angle. (The drag coefficients referred to a frontal area of 2.0 m² → complete vehicle).

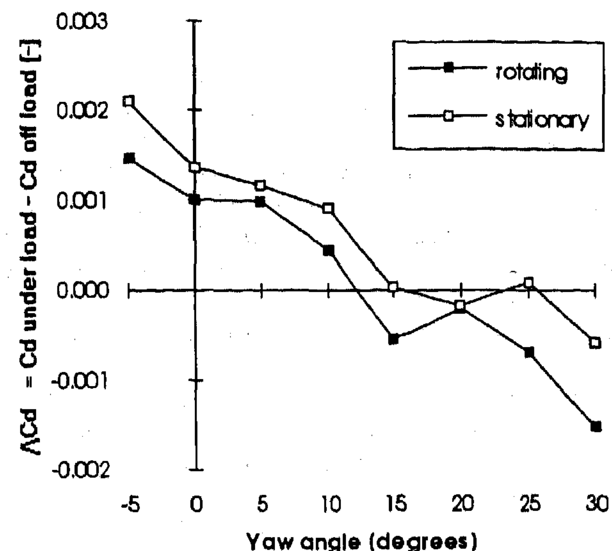

Fig. 13: Influence of the tyre contact patch for the stationary and the rotating wheel in relation to the yaw angle.

In order to estimate the influence on the vehicle's drag coefficient caused by the tyre contact patch, we need to know the flow angles at the front and rear wheels. From *Fig. 13* we can deduce the influence of one wheel on total drag.

At the front wheels, with an yaw angle of 15 degrees, the change in drag due to the contact patches of both front wheels is Δc_D < +0.001 stationary and Δc_D = -0.001 rotating.

The tyre patches at the two rear wheels change the vehicle's overall drag at an yaw angle of 3 degrees by Δc_D = +0.003 for stationary wheels and Δc_D = +0.002 for rotating wheels.

The influence of the tyre contact patch on the drag coefficient of the complete vehicle can therefore be estimated as

Δc_D = +0.003 for stationary wheels and

Δc_D = +0.001 for rotating wheels.

From these results we can conclude that realisation of the tyre contact patch has only slight effects on the vehicle's total drag coefficient, and that this influence is weakened still further by the rotating wheels. In view of this, simulation of the tyre contact patch, which involves considerable technical effort with rotating wheels in particular, can be regarded of minor importance. Therefore it can be neglected when determining a vehicle's aerodynamic drag.

SUMMARY

An experiment devoted to establishing fundamental values was able to demonstrate that the wheels and tyres can account for 25 % of a vehicle's total aerodynamic drag, with the wheel wells causing much less than the wheels. If this proportion is to be correctly measured with the technical facilities at our disposal, it is in our opinion necessary to simulate rotation of the wheels. In principle, measurements can be taken either with an internal balance and the wheels driven by a moving belt, or with an external balance and special wheel drive units.

In the first of these arrangements, the force generated by the wheels' fan moment is included in the total drag value. Since this force is aerodynamic in character and also increases approximately in accordance with the square of the speed, we feel that it is correct in physical terms to convert it into a Δc_D and add it to the vehicle's aerodynamic driving resistance. If measurements are taken with an external balance and rotating wheels, the aerodynamic drag value will accordingly be too small and will need to be completed by the amount represented by the fan moment. Until now, we have been unable to determine the fan moment in isolation. However, it is suspected to exert an influence on the drag of the same magnitude as the zero ventilation which we have measured.

Depending on whether internal- or external-balance measurement is undertaken, either the zero ventilation or the fan moment must be separated from the wheels' rolling drag. We have described a practical means of doing this when measuring with an internal balance, with the rolling resistance eliminated by means of a tare measurement at low belt speed. For the external-balance measuring method this method could also be applied as appropriate, but the necessary technical facilities must first be made available.

With the aid of examples we were able to show that the measuring method has a decisive influence on the assessment of typical types of wheels. In addition, these measurements confirmed the importance of recording the aerodynamic drag of the wheels and tyres correctly.

A principle test with a single wheel on a moving belt demonstrated that in the case of rotating-wheel measurements the so far unavoidable simplification by reducing the wheel load has only a slight effect on the measured results. Accordingly, aerodynamic drag measurement with rotating wheels under reduced load is a much better compromise than testing with stationary wheels.

ANNEX

1.Evaluation of drag moment of a rotating disk in still air

The proportion of the skin friction for a rotating wheel in still air can be approximated by a formula given by Schlichting [7] for rotating disks in turbulent flow (i.e. the case of a turbulent boundary layer):

$$2M = 0.073 \cdot \rho\omega^2 R^5 \left(\nu/_{\omega} R^2\right)^{\frac{1}{5}}$$

where M is the moment for one side of the disk, R is the radius of the disk, ω the circular frequency and ν and ρ are fluid properties.

This can be reformulated nondimensional:

$$c_M = 0.146 \cdot Re^{-\frac{1}{5}}$$

with a Reynoldsnumber based on disk dimensions. Recast in terms of Δc_D this gives for a single wheel:

$$\Delta c_D = 0.146 \cdot Re^{-\frac{1}{5}} \cdot \frac{R^2}{A_M}$$

Calculating the Δc_D for four wheels for the case investigated here yields to:

$$\Delta c_D = 0.002$$

Thus the the major part of the fan moment is not produced by pure skin friction.

Assessing the Effects of Shear and Turbulence During the Dynamic Testing of the Crosswind Sensitivity of Road Vehicles

Roger Macklin and Kevin Garry
Cranfield Univ.

Jeff Howell
Rover Group

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

With increasing speeds and the anticipated reduction in weight of modern cars, the issue of crosswind sensitivity is becoming increasingly important. In a previous paper by the same authors, the normal method of testing such aerodynamic characteristics at model scale, using static models at yaw to the freestream, was compared with dynamic testing, in which the model is propelled across a 'gust' simulated by a wind tunnel. A direct comparison using a similar gust profile for both static and dynamic tests was made with the conclusion that the simple static test technique was underestimating the true transient loads.

Further tests have been carried out, on a generic squareback (or estate) model, during which the effect of varying both the vertical velocity profile and the turbulence intensity within the gust was considered. Although these gust characteristics were not necessarily representative of an atmospheric boundary layer they give a good indication of the differences that might be expected between tests done using a static model at yaw and the more accurate dynamic simulation.

The data show a considerable variation in aerodynamic load on the model as the vertical velocity profile was altered but less variation with turbulence intensity. An attempt is made to determine, a simple relationship between a reference velocity, representative of the shape of the gust profile and the resultant forces and moments.

INTRODUCTION

This paper will begin by summarising previous work on the aerodynamic characteristics of vehicles in crosswinds conducted using the crosswind track facility at Cranfield University. It will then go on to detail work done to assess the impact of the nature of the crosswind gust by introducing both turbulence and changes in the vertical velocity profile.

The methodology behind scale model crosswind testing was detailed in an earlier paper by Macklin et al[1]. Here the advantages and disadvantages of static-static, static-dynamic, and dynamic-static testing techniques were considered, the later being adopted in the present investigation as being the most practical way of investigating changes to the gust characteristics.

In the previous paper[1] the crosswind track technique was evaluated by comparing data from three generic passenger vehicle configurations with data from the same models tested under conventional static-static conditions over a fixed ground plane and range of yaw angles. During

these tests the vertical velocity profile was deliberately kept uniform to ensure that the effective profile seen by the moving model did not contain any 'skew'.

The results presented by Macklin et al[1] show that at yaw angles below 15 degrees, the conventional static-static tests give a conservative measure of the model forces and moments when compared to the dynamic-static data from the crosswind track. At yaw angles greater than 15 degrees (measurements were made up to 45 degrees) the magnitude of the dynamic coefficients was generally greater than the corresponding static data. This was particularly evident in peak values of yawing moment.

It was recognised during this programme that dynamic tests with a uniform gust profile (ie without skew) would be the 'worst case' scenario and that the introduction of skew would most likely give lower aerodynamic coefficients. The degree to which the gust velocity profile is modified is therefore important and the current paper analyses the impact of five different profiles on the transient aerodynamic characteristics of a generic squareback vehicle configuration. In addition the issue of which velocity, or dynamic pressure, should be used to non-dimensionalise coefficients, when considering a non-planer incident flowfield, is addressed.

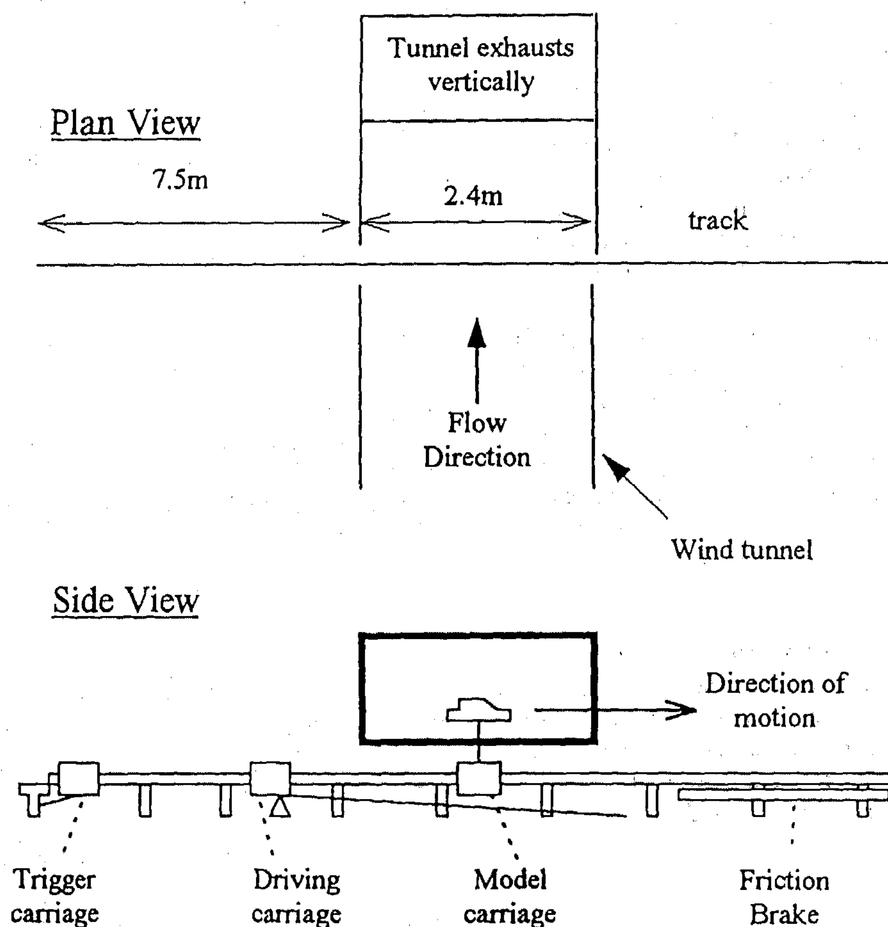

Figure 1
Schematic layout of the crosswind track and 2.4m x 1.2m boundary layer wind tunnel.

EXPERIMENTAL FACILITY

The crosswind track runs perpendicular to the 2.4m x 1.2m boundary layer wind tunnel and is shown schematically in Figure 1. An outline of the essential features of the facility is given here for convenience, while a more detailed description of the facility is given by Macklin et al[1]. The model under test (typically a 1/5th scale passenger car) is propelled across the wind tunnel working section, together with it's internal 5 component strain gauge balance, on a carriage, having been accelerated by a bungee driven catapult. The model speed is regulated to within 0.5 m/s by the release position of the driven carriage and is typically 12-18 m/s. The model carriage also carries a data acquisition system and power supply which, after being activated by track mounted LED's, records balance data and model position which are down loaded to a PC at the end of each run for analysis.

Aerodynamic coefficients, with the exception of drag are evaluated from a balance calibration matrix. The signals are filtered to remove track induced noise and a 'wind-off value' signal is subtracted such that the resulting data relates only to the influence of the crosswind gust.

The necessarily lightweight model is intended to represent an estate configuration (or squareback) and is shown in Figure 2 together with the force/moment sign convention and reference point. Table 1, reproduced from ref.[1] shows the standard deviations of the coefficients at zero and 17 degrees yaw for the squareback model over 9 runs.

Gust Characteristics

The difficulty of changing the vertical velocity profile of the gust or wind tunnel flow, without changing the turbulence characteristics was recognised. A series of tests were therefore carried out using gusts of varying turbulence intensity and scale but with a uniform velocity profile. The turbulence characteristics of these gusts, generated by introducing rectangular grids at the upstream end of the wind tunnel working section, are shown in Figure 3. A total of four turbulence levels were evaluated corresponding to freestream turbulence intensities nominally in the range 1% to 3.5%. Turbulence intensity was seen to increase considerably at heights below that of the model mid-height. Turbulence length scale, evaluated on the basis of the auto correlation function, is given in Figure 3.

THE INFLUENCE OF TURBULENCE

In his review of the effects of turbulence on bluff bodies, Bearman[2] identified three basic mechanisms: (i) accelerated transition to turbulent flow within shear layers (ii) enhanced mixing and entrainment and (iii) distortion of freestream turbulence itself by the mean flowfield. The overall effect of changes in turbulence were seen to be the result of more than one of these three basic mechanisms and each is effected differently by the two principal characteristics of the turbulence - intensity and scale.

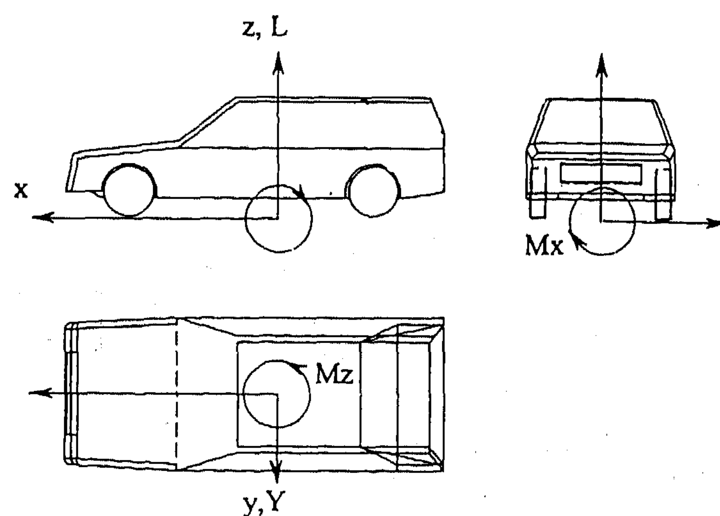

Figure 2
Schematic diagram of the 'squareback' model together with the axis and force and moment sign convention.

In an attempt to define a single turbulence parameter, Bearman[3] used a 'power index' (*m*) which has subsequently been used by a number of researchers

$$\left(\frac{u'}{U}\right)\left(\frac{L}{D}\right)^{m}$$

The significance of the ratio of the turbulence length scale (L) to some characteristic dimension of the flowfield (D) is reflected in the fact that the power index (*m*) varies according to the problem being considered.

The data showing the influence of turbulence on ground vehicles, and particularly on trains and HGV's, suggests that there are two main areas of interest. The first, usually referred to as 'micro' effects relate to the mechanisms discussed in the previous paragraph, and influence the position of separation and reattachment lines, together with the size and structure of vortices in the wake. The second 'macro' effect relates to the concept of 'aerodynamic admittance' where variations in the forces and moments are directly related to the variation in the instantaneous velocity.

Whilst micro turbulence effects have been shown by Baker[4] to be significant for trains, particularly to the C_y vs ψ and C_L vs ψ characteristics, it is recognised that the relative length scale of turbulence is of the same order of magnitude of the vehicle's wake. This will not be the case for a typical passenger car and indeed Bearman[2] shows that there is very little effect of changes in turbulence, either scale or intensity, on the base drag of a series of car body shapes.

Influence of turbulence in crosswind gust

Dynamic force and moment coefficients were recorded for the squareback vehicle configuration under four different turbulence profiles without skew. No attempt was made to correctly scale atmospheric turbulence.

The response of the vehicle is given in figure (4) and, with the exception of the data set corresponding to the turbulence generated by the horizontal bars, there appears to be very little effect of turbulence within the range considered.

The possibility of a turbulence parameter correlating the data was explored by adopting the form used by Bearman[3] - with the power index (*m*) taken to be unity - and evaluating the mean turbulence intensity of the profile over four different heights:

$z = 0$ to $1.5\ h_m$
$z = 0$ to h_m
$z = 0$ to $0.64\ h_m$
$z = 0.64\ h_m$ to $1.5\ h_m$

($z = 0.64\ h_m$ was considered because it corresponds to the approximate height of the centroid of the model side area. $z = 1.5\ h_m$ was included to allow for the influence of the flow above the vehicle on boundary layer growth).

Examples of force and moment coefficients at various yaw angles are given for two of the above turbulence parameters in figure 5. These data appear to support the initial conclusion that for this model and range of turbulence, there is little or no effect of turbulence or the dynamic force and moment data.

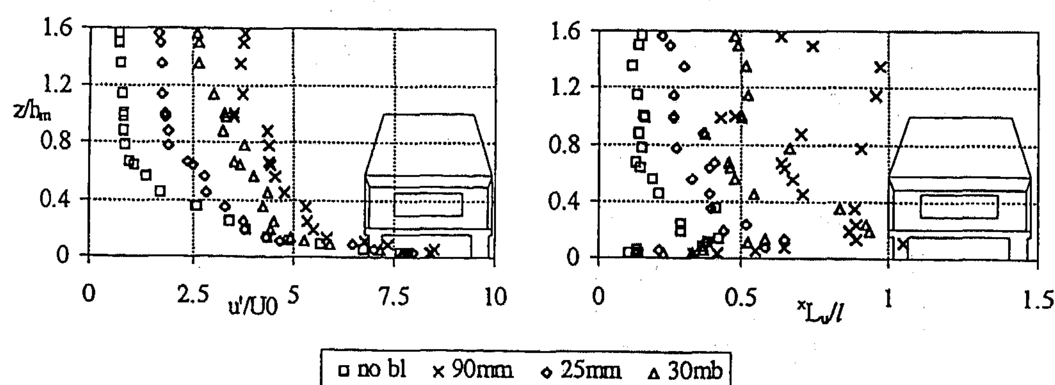

Figure 3
Profiles of turbulence intensity and non-dimensionalised longitudinal length scale for the four gust cases considered

THE INFLUENCE OF VELOCITY SKEW

A number of researchers have considered the effect of skew in crosswind tests on trains and HGV's. There seems to be little if any data relating to passenger cars. The impact of wind fences on the crosswind characteristics of HGV's has been investigated by Coleman[5] and as would be expected, due to the shielding effect, sideforce and lift coefficients were seen to fall compared to the static-static case. Baker[4] produced data from dynamic-static tests on train models which show inconsistencies depending on the force or moment coefficient being considered as a result of simulating either level surroundings or an embankment.

The five different vertical velocity profiles generated for this investigation are shown in Figure 6. These profiles were generated by placing roughness elements ('gravel','egg' and 'lego') on the floor of the wind tunnel upstream of the crosswind track and as a result the turbulence intensity and longitudinal length scale profile in the resultant gust will also be changed. No attempt was made to simulate a specific atmospheric boundary layer. In fact the turbulence profiles associated with the ground boards - in particular the 'egg' and 'lego' boards - show higher values of $u'(z)/U_\infty$ than created for the turbulence tests. (This creates a problem in so far as any conclusions arrived at on the basis of the turbulence data may not necessarily be extrapolated to predict results from the skew tests. As a consequence variations in the coefficients may not be entirely attributable to the change in the skew profile).

The effect of the five different velocity profiles on the aerodynamic characteristics of the squareback model in the yaw angle range 0 to 50 degrees is shown in Figure 7. The influence, compared to both the zero skew and static-static data appears to be greatest for front and rear axle lift and yawing moment. Sideforce and rolling moment do not seem to be influenced to the same extent and this is consistent with the results of Baker[4] for sideforce, but not for lift.

When considering the data from tests of this type the issue of which velocity, or dynamic pressure, to use to non-dimensionalise the coefficients becomes important. Clearly the use of freestream conditions in a boundary layer that may be many times the height of the vehicle does not seem appropriate. Previous work on buildings by Wacker[6] considered the use of a mean velocity evaluated from an integral of the profile over the height of the building, this was seen to significantly reduce the difference between aerodynamic data for different profiles.

As in the case of the mean turbulence characteristics, a number of different height ranges were chosen for the current study to evaluate an effective reference velocity:

(i) $0 < z < 1.5\ h_m$, takes into account the flow on the roof

(ii) $0 < z < 0.6\ h_m$, concentrates on flow over the bonnet and therefore influences front axle lift

(iii) $0.6\ h_m < z < 1.5\ h_m$, concentrates on flow over the backlight area and therefore influences rear axle lift.

In addition, single point reference velocities taken at:

(iv) $z = h_m$

(v) $z = 0.6\ h_m$

and

(vi) $z = \delta^*$ for convenience when working with full scale atmospheric boundary layers.

It should be remembered that changing the reference velocity in dynamic tests changes both the yaw angle (ψ) and the resolved velocity (U_R), while in the static tests it only effects (U_R).

If the alternative non-dimensional velocity is known in terms of U_∞ we can use a factor, B, such that

$$U_B = \frac{U_{ref}}{U_\infty}.U_\infty = B.U_\infty$$

the adjusted yaw angle is then given

$$\psi_B = \tan^{-1}(B.\tan\psi)$$

and the dynamic coefficients should be adjusted

$$C_{F_B} = C_F\left[\frac{1+\tan^2\psi}{1+B^2\tan^2\psi}\right]$$

while the static data is simply

$$C_{F_B} = C_F.B$$

An example of the impact of changing the reference velocity is given in Figure 8 for the squareback model. In this case aerodynamic data normalised using both the freestream dynamic pressure and that obtained from an integral over the height of the model, ie $0 < z < h_m$. It is obvious from Figure 8 that any improvement in collapse of the data will be difficult to quantify for the various reference velocities to be considered and consequently a quantitative measure, Δ_{skew}, was devised.

Δ_{skew} is a measure of the variation between datasets as a percentage of the unaltered data based on the standard deviation of the datasets. As a result

i) if adjustment of the non-dimensionalising velocity improves the data collapse the Δ_{skew} will be +ve. If all the data collapses onto one line, $\Delta_{skew} = 1$.

ii) if adjustment of the non-dimensionalising velocity does not improve the data collapse the Δ_{skew} will be -ve

The influence, in terms of Δ_{skew}, of each of the seven different non-dimensionalising velocities or aerodynamic coefficients, is given in Figure 9. It is seen that no one alternative reference velocity universally improves the collapse of the data. This is obviously a disappointing result, but it may well be that the most 'ideal' non-dimensionalising velocity was not included in those evaluated, since clearly a freestream value is not ideal. However, it is not possible from this data set to predict what the best value would be for passenger cars.

CONCLUSIONS

Dynamic tests using a scale model traversing a wind tunnel on a crosswind track are recognised as being an effective means of investigating the influence of both freestream turbulence and skew on the aerodynamic characteristics of passenger cars. The results from a series of tests on a generic squareback scale model vehicle suggest that, within the range of turbulence intensity and scale considered there was little effect of turbulence on the vehicle's aerodynamic characteristics. The possibility of a single turbulence parameter correlating the data was explored but proved inconclusive. Further tests in which the mean vertical velocity profile of the gust was varied to introduce 'skew' into the effective velocity profile confirmed that the 'non skew' profiles give conservative results in terms of crosswind stability assessment, particularly at yaw angles below 15 degrees. Analysis of several alternative reference velocities did not reveal a suitable position or integral that gave a universal collapse of the data. The vehicles lift characteristics were better correlated with a reference velocity taken as the mean velocity over the height of the vehicle.

ABSTRACT

This paper deals with the correction of aerodynamic interference effects taking place between the nozzle of an open jet wind tunnel and a test model. In order to deduce correct aerodynamic coefficients these interference effects have to be allowed for in the determination of the correct wind tunnel speed. In open jet wind tunnels basically two different methods are used to determine the tunnel speed. One is the so-called nozzle-method, utilizing the pressure difference down the nozzle to determine the nozzle exit velocity or tunnel speed. The other procedure is the so-called plenum-method, where the pressure difference between the settling chamber and the surrounding plenum chamber of the test section is measured and used. In this paper it is shown that both methods yield a systematic error, since the velocity distribution in the nozzle differs from the velocity distribution in an unbounded stream measured at the same distance from the model. In order to compensate for this effect a correction factor is derived with the aid of a simple potential flow model.

INTRODUCTION

When comparing aerodynamic results measured in different open jet wind tunnels it is important to consider interference effects imposed upon the test results by the test section, the nozzle and the collector. On the assumption of small perturbation theory E. Mercker and J. Wiedemann [1] identified four different interference effects occurring in open jet wind tunnels. Neglecting higher order terms, they derived an overall correction factor by summing up the interference resulting from the proximity of the model to the nozzle and the flow collector, the limited extent of the jet dimensions and the horizontal buoyancy effect due to the static pressure gradient often present in empty test sections.

Applying the correction formula to a number of data sets, measured in a large number of wind tunnels, they showed that the correction procedure works for scale models as well as for full scale passenger cars of various sizes. On average a standard deviation between 2 and 3 drag-counts (1 drag-count is CD = 0.001) was attained between the different wind tunnels after correction. Considering that all possible measuring errors and model set-up errors are included, this result can be regarded as satisfactory. Additionally, the results were compared with blockage-corrected data measured in closed wall wind tunnels. The agreement between the two types of wind tunnels was remarkably good.

However, the universal application of the correction formula of Mercker and Wiedemann is restricted to data which are obtained in wind tunnels where the test section reference speed is measured with the so called nozzle-method. This method uses the pressure difference between two cross-sections of the nozzle to determine the tunnel speed. A second method for stipulating the free stream speed is the so called plenum-method. In this method the pressure difference between the settling chamber of the wind tunnel and the plenum hall surrounding the open jet is measured. The plenum-method has not been considered in the correction procedure of Mercker and Wiedemann.

Since a model exposed to a flow generates a pressure gradient in the axial direction, the velocity

distribution in the nozzle of an open jet wind tunnel is affected and tends to deviate from the distribution of an infinite flow. Therefore, the reference velocity of the test section may be evaluated falsely. Apparently, independently of which method is used to determine the tunnel speed, both methods need to be corrected due to this nozzle effect.

This fact is in opposition to statements given in the published literature. For instance, A. Kuhn [2] and R. Künstner et al. [3] claim that either the nozzle-method or the plenum-method is the only correct way to determine the tunnel speed and both authors disregard completely any correction of the tunnel speed with respect to the nozzle effect.

The subject of this paper is to give a new detailed physical explanation of the two methods to determine the tunnel speed. Due to the fact that both methods entail a correction, the procedure of Mercker and Wiedemann is extended here to wind tunnels where the plenum-method is employed.

CORRECTION METHODOLOGY

The dominant effect of interference in wind tunnels is usually taken to be equivalent to a simple modification of the free stream velocity expressed by a perturbation velocity ε

$$U_{cor} = U_\infty + \Delta U = U_\infty (1+\Sigma\, \varepsilon) \qquad (1)$$

where U_{cor} denotes the velocity corrected for interference effects and $\Sigma\, \varepsilon$ is the algebraic sum of all perturbation velocities originating from different fluid dynamic interactions. Expressed in the form of the dynamic pressure q_{cor}, this leads to

$$q_{cor} = q_\infty(1+ \varepsilon_S + \varepsilon_C + \varepsilon_N)^2 \qquad (2)$$

where ε_S denotes the perturbation velocity due to jet expansion, ε_C represents the collector blockage effect and ε_N is the nozzle blockage factor. In this equation, it is assumed that the magnitude of a single interference effect is small and thus higher order terms due to coupling of different interference effects may be neglected. Therefore, the different effects can be simply superimposed and a total perturbation velocity comprising all interactions can be defined. Furthermore, the so-called "invariance under constraint" has to be assumed, which implies that the flow pattern about the model remains unaltered, even with interference effects present. Comparing, for instance, the velocity profiles in front of a vehicle in an infinite stream with those in a wind tunnel, it is assumed that the profiles remain self-similar. In other words, it is assumed that the distribution of the velocity is invariant under constraint and the velocity vectors deviate only by a constant scaling factor.

As mentioned above, this paper deals with the detailed analysis of nozzle interference effects or nozzle blockage. Therefore, for a detailed deduction of ε_S and ε_C as well as for the effect due to a static pressure gradient reference is made to [1]. In this context, it is noteworthy that the effect of the empty test section pressure gradient $\Delta C_{D\,HB}$ has to be treated differently and is introduced into the correction procedure before any dynamic pressure corrections are applied. Regarding the drag coefficient, the entire correction formula for open jet tunnels can be expressed as:

$$C_{D\,cor} = (C_{Dm} + \Delta C_{D\,HB})/(q_{cor} / q_\infty) \qquad (3)$$

Here $C_{D\,cor}$ denotes the corrected and C_{Dm} denotes the measured drag coefficient.

For convenience, the total correction formula comprising all necessary geometrical and fluid-dynamic properties will be given at the end of this paper.

DETERMINATION OF WIND SPEED

The wind speed in the test section of a wind tunnel is determined by measuring the static pressure difference Δp between the settling chamber p_{SC} and a second pressure located either somewhere downstream on the nozzle contour (p_N) or in the plenum chamber (p_P) surrounding the open jet. If the downstream pressure tap is installed in the nozzle contour, the method is called "nozzle-method". With the reference measured in the plenum chamber, the method is called "plenum-method". Fig.1 shows the general set-up for both kinds of measurements.

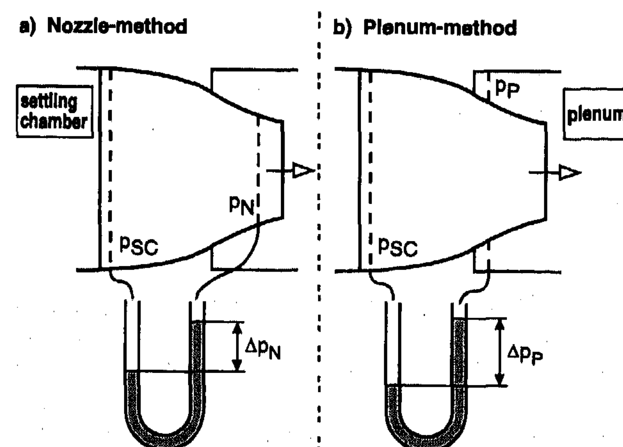

Fig. 1 General set-up for nozzle-method and plenum-method

The procedure for determining the dynamic pressure q_∞ of the jet is in principle the same for both cases.

The pressure difference of the nozzle (Δp_N) or plenum-method (Δp_P) is related to the pressure difference of a Pitot-static tube measured at the center of the jet of the empty test section:

$$q_\infty = \rho/2\ U_\infty = k\ \Delta p \qquad (4)$$

Usually, the numerical value of the nozzle factor k is greater than unity, because the wind speed in the settling chamber is not exactly zero and hence the local static pressure there is below the total pressure. Furthermore, due to the fact that the reference static pressure is measured at different locations, k is different for both methods. For a more accurate determination of k, it is recommended that the relation between Δp and q_∞ is approximated by a third degree polynomial. The reason for the slightly non-linear behaviour of k, especially in the low velocity regime, is observed in the Reynolds-number dependency of the nozzle wall boundary layer.

The decision, of which method should be used in a wind tunnel for determining the tunnel speed, is largely dependant upon the wind tunnel dimensions and the dimensions of the model. Due to the fact that an adverse pressure gradient in front of a model may extend into the nozzle, the measurement of the static reference pressure may be falsified with the nozzle method.

Therefore, for small wind tunnels used for full scale automotive testing, the plenum method is recommended, because the reference pressure is located in the surrounding plenum chamber which usually is ventilated to the ambient air. Thus, for this method the reference pressure is constant and independent of the model size and model position inside the test section. Strangely enough, for some existing automotive wind tunnels the situation is somewhat reversed. For wind tunnels with a large nozzle and often larger distance between pressure tap and test vehicle the plenum method is sometimes advocated, whereas for wind tunnels with small nozzle sizes the nozzle-method is often applied. As mentioned above, both methods need a correction because the presence of the model affects the nozzle exit flow to some extent.

However, it is important to realize, that once the pressure at the tap location (speed holes) is contaminated by the adverse pressure gradient originating from the test vehicle, a correction procedure is no longer meaningful and incorrect aerodynamic coefficients will result.

The problem may be by-passed by locating the static reference pressure tap at a more upstream position until the model influence has vanished. However, this may take place at the expense of a smaller pressure signal and thus a smaller resolution for the tunnel velocity. Fig. 2 shows experimental data measured in one of DNW's model scale wind tunnels. Depending on the model position in the test section, a different streamwise static pressure distribution is measured at the nozzle wall. In this example it is depicted that the pressure distribution converges and is independent of the model location if the downstream pressure tap is located at the position indicated by N.

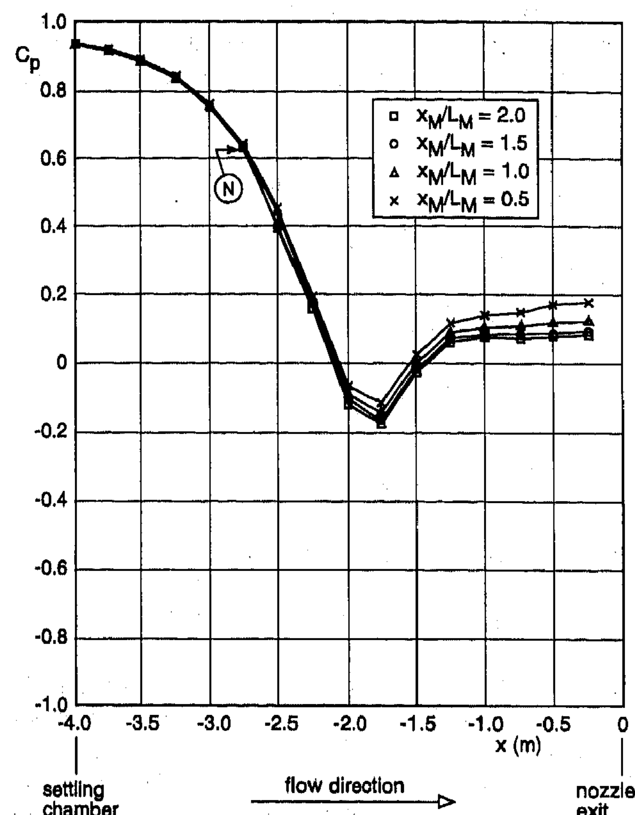

Fig. 2 Static pressure distribution in the nozzle for different model positions; L_M = model length; x_M = distance model center/nozzle

BLOCKAGE EFFECT FOR THE NOZZLE METHOD

As mentioned above, one way to determine the wind speed in an open jet wind tunnel is the nozzle-method, utilizing the pressure difference over the nozzle, see Fig 1a. Assuming that the model influence does not contaminate the downstream pressure reading, the volume flux through the nozzle is constant, regardless of where the vehicle is placed inside the test section and regardless of the geometrical dimensions of the model.

The test section length of an open jet wind tunnel is often limited due to jet stability reasons and due to a decreasing streamwise potential core length of the jet. Therefore, the vehicle is usually placed relatively close to the nozzle exit. As a consequence, the

adverse pressure region in front of the vehicle disturbs the flow inside the nozzle exit plane. In the next chapter this effect will be quantitatively determined with the aid of a simple flow model.

PRESSURE INDUCED BLOCKAGE EFFECT - With a constant volume flux through the nozzle, a blockage effect occurs due to a displacement effect of the flow, and locally a velocity higher than the calibrated tunnel speed is attained in the nozzle exit plane. This situation has to be compared with the flow of an infinite stream.

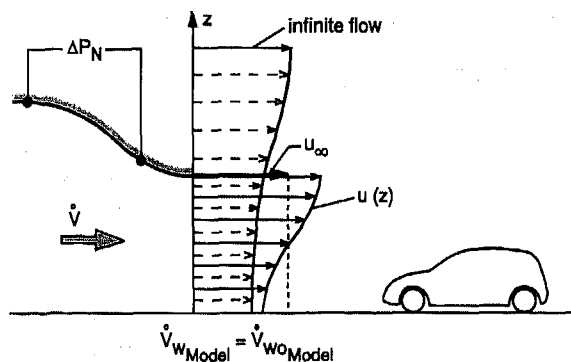

Fig. 3 Qualitative velocity distribution for nozzle-method. ($\dot{V}_{W_{Model}}$ = Volume flux with model; $\dot{V}_{WO_{Model}}$ = Volume flux without model)

Fig.3 shows qualitatively the velocity distribution in front of a vehicle for both cases at the same axial position. Whereas for an infinite flow the free stream velocity will be reached at a large lateral distance only, an appreciably higher velocity is attained at the edge of the nozzle exit for the wind tunnel flow. Consequently, the model experiences a higher aerodynamic force which is non-dimensionalised with a tunnel-q, that is too small. Therefore, a correction has to be applied to compensate for this effect.

Apparently, the drag correction of a model depends on the ratio of the momentum flux of an infinite flow I_∞ and an increased momentum flux I_N due to blockage. As momentum flux is proportional to the dynamic pressure of the flow, it can be written:

$$C_{D\,cor} = (C_{D\,m})_N\,(q_N/q_{cor}) = (C_{D\,m})_N\,/\,(1+\Sigma\,\varepsilon)^2 \qquad (5)$$

with $q_{cor} = q_N\,(1+\Sigma\,\varepsilon)^2$

The index N denotes that the quantities are measured with the nozzle method (at a later stage, when we are dealing with the plenum method the index will be changed to P). The index m denotes the uncorrected measured aerodynamic quantity.

In order to evaluate the nozzle blockage effect, we first look at the interference effects taking place at the nozzle. In a second step we evaluate the reaction of these effects upon the model which is placed in the test section further downstream.

Taking now the interference effect at the nozzle to be equivalent to a modification of the tunnel speed U_∞, a perturbation velocity ε_{QN} can be defined in the nozzle exit plane of the wind tunnel:

$$\varepsilon_{QN} = \Delta U/\,U_\infty = [\,U_\infty - (U_N\,)_N\,]\,/\,U_\infty \qquad (6)$$

where $(U_N\,)_N$ denotes velocity of the unconstraint flow, integrated over the fictitious nozzle cross sectional area A_N.

$$(\,U_N\,)_N = 1/A_N \int u(z)\,dA \qquad (7)$$

A simple potential-flow model consisting of a point source and a parallel flow is used to calculate the velocity distribution of an infinite stream at the nozzle location. The flow model will result in a half infinite body of revolution which represents the test vehicle plus its mirror image. The same approach has been followed by E. Mercker and J. Wiedemann [1] . Only the resulting equation for ε_{QN} will therefore be cited:

$$\varepsilon_{QN} = [A_M\,/(2\,A_N)][1 - x_S/(\,x_S^2 + R_N^2\,)^{1/2}] \qquad (8)$$

where

$$x_S = x_M - L_M\,/2 + [\,A_M/\,(2\,\pi)]^{1/2} \qquad (9)$$

denotes the distance from the nozzle to the source point. Furthermore, x_M and L_M denote the distance from the nozzle to the model center and the vehicle length, respectively. A_M denotes the frontal area of the model and A_N is the cross-section of the nozzle. Finally, R_N denotes the equivalent duplex nozzle radius (for symmetry reason the duplex lateral wind tunnel dimensions are used in the corresponding formulas):

$$R_N = (\,2\,A_N/\pi\,)^{1/2} \qquad (10)$$

As already mentioned in the paper of Mercker and Wiedemann [1], the suggested potential-flow model is a simple representation of the test vehicle. However, as we are dealing with far-field effects in a potential-flow environment, the model may be adequate, nevertheless. For trucks, busses and light vans with a blunt fore-body a more refined flow model may be advisable, however.

Beside the interference effect due to an adverse pressure gradient extending into the nozzle, two other interference effects occur. Again, the reason for these flow effects has to be seen in the interaction between model and nozzle:

1. Due to the solid walls of the nozzle the streamlines will be confined compared to an infinite flow.
2. Due to flow displacement about the model the flow will be deflected at the nozzle contour.

STREAMLINE CONSTRAINT CORRECTION - First, we look at the effect due to streamline constraint and, Fig. 4 illustrates this effect schematically for an arbitrary chosen body of revolution. It can be seen that the free expansion of the streamlines for an infinite flow is confined due to the fact that the flow is

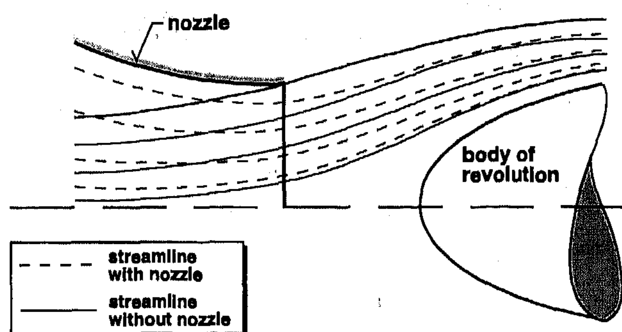

Fig. 4 Streamline constraint due to nozzle proximity

constrained by the nozzle.

It is important to realize that in principle the "invariance under constraint" is no longer fulfilled in this case. However, it will be assumed that this effect can be restricted to the flow-field at nozzle position and therefore the flow field about the model can be considered invariant under constraint

In order to quantify the interaction between nozzle and model a simple flow model shall be employed. For this purpose the nozzle-flow is replaced by a vortex ring superimposed on a parallel flow at the nozzle position. For illustration see Fig. 5.

Herein, the parallel flow represents the undisturbed stream conditions and the vortex flow represents the streamline constraint of the nozzle, which has to be seen in combination with the effect of the adverse pressure gradient in front of the vehicle, because flow constraint occurs only if an interference effect between model and nozzle is present. Therefore, it is assumed that the strength or circulation Γ of the vortex is proportional to the perturbation velocity ε_{QN} at the center of the vortex-ring cross-section. For the circulation Γ it can be written:

$$\Gamma = 2\, R_N\, U_\infty\, \varepsilon_{QN} \qquad (11)$$

where R_N denotes the radius of the nozzle.

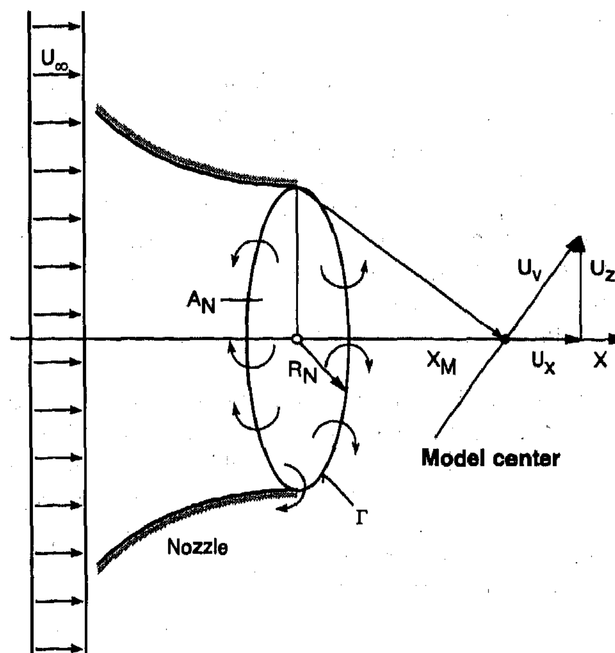

Fig. 5 Induced velocity U_V due to vortex ring with circulation Γ

Applying Biot-Savart principles, it is now possible to calculate an induced velocity U_V of the vortex flow at the model position. The streamwise component U_x of this velocity will be used for correction.

$$U_x = [\Gamma/2]\, [\, R_N^{\,2} / (\, R_N^{\,2} + x_M^{\,2})^{3/2}] \qquad (12)$$

The perturbation velocity at the model position x_M can then be calculated:

$$\varepsilon_N = \varepsilon_{QN}\, R_N^{\,3} / (\, R_N^{\,2} + x_M^{\,2})^{3/2} \qquad (13)$$

Thus, for the example of the drag coefficient, the following correction formula can be derived. With respect to Equation (2) and (3) it can be written

$$C_{D\,cor} = [\, (C_{D\,m})_N + \Delta C_{D\,HB}] \,/\, (1 + \varepsilon_S + \varepsilon_Q + \varepsilon_N\,)^2 \qquad (14)$$

It is noteworthy that ε_N is smaller in magnitude than ε_{QN}, depending on the distance x_M between model and nozzle. The reason for this has to be seen in the fact that the vortex ring induces a vertical velocity component U_z at the model position which tends to widen the jet. For continuity, the axial velocity has to decrease accordingly. In other words, the effect of streamline constraint at the nozzle in combination with the adverse pressure gradient of the model generates an interference effect at the nozzle location that attenuates in the downstream direction.

BLOCKAGE EFFECT FOR THE PLENUM-METHOD

For the plenum-method the pressure difference between the settling chamber and the plenum chamber surrounding the open jet is measured, see Fig. 1b. Since the plenum chamber is vented to the ambient air, the static pressure is constant there and independent of the model arrangement inside the test section. Additionally, since the most upstream pressure tap in the settling chamber is usually far ahead of the vehicle the second pressure location is also not affected by the vehicle. Thus, although the velocity distribution in the nozzle exit plane may be disturbed by the model, the velocity at the circumferential contour of the nozzle exit will be equal to the free stream velocity due to Bernoulli's principles. Consequently, regardless of model size and model position the calibrated tunnel speed of the empty test section can not be exceeded at the boundary of the jet and remains constant. Within the jet, however, the velocity can assume any arbitrary value depending on the model geometry and its distance from the nozzle.

It is important to note that the constancy of the static pressure is fulfilled only for sufficiently large plenum chambers. For a small plenum, strong flow recirculation may take place when a model is placed into the test section, if due to the so called "Coanda-effect" the jet attaches to the walls or the roof of the plenum. This tends to lower the static pressure in the plenum hall. R. Deutenbach [4] has evaluated the Coanda effect for open jet wind tunnels experimentally. In his work criteria are derived for the minimum size of the plenum chamber needed to prevent significant recirculation.

Fig. 6 shows model scale measurements, confirming the constancy of the velocity versus model position for the plenum-method. During this experiment the model was moved towards the nozzle in steps. The wind tunnel speed V_T was determined either by the plenum-method or by the nozzle method. Simultaneously the velocity V_{vane} at the outer contour of the nozzle exit was measured by a vane anemometer. Apparently, with the nozzle-method the velocity ratio varies gradually with the model position, whereas with the plenum-method a more or less constant value is attained.

In order to assess the model/nozzle interaction for the plenum method, the situation in the wind tunnel has to be compared again with the flow in an infinite stream. Fig. 7 shows schematically the velocity distribution in front of a vehicle for the free stream case and for the wind tunnel flow. It is interesting to note that for the plenum-method the volume flux through the nozzle is now smaller with the model installed than the volume flux of the empty test section.

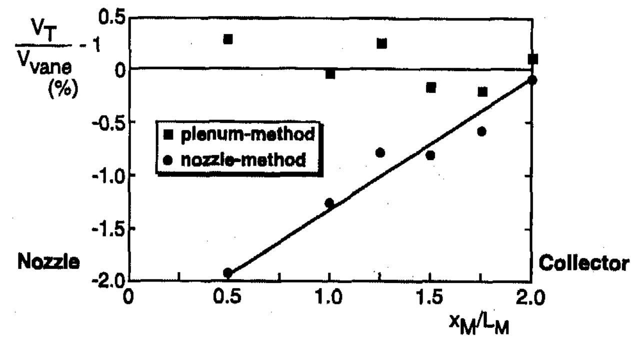

Fig. 6 Relative variation of measured V_{vane} and calibrated V_T tunnel speed versus model position x_M

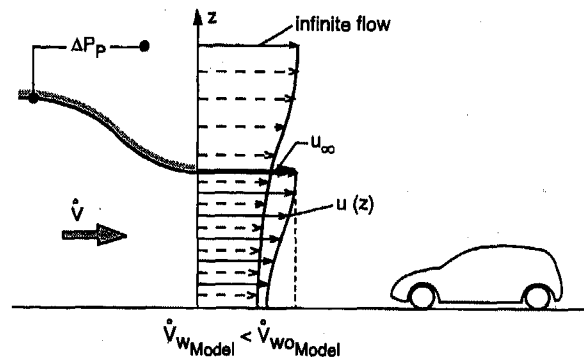

Fig. 7 Qualitative velocity distribution for plenum-method. ($\dot{V}_{W_{Model}}$ = Volume flux with model; $\dot{V}_{WO_{Model}}$ = Volume flux without model)

The magnitude is dependent on the model size and the model position inside the test section. In contrast, the volume flux for the nozzle-method is constant and independent of the model and its position, as explained above. Similarly to closed wall wind tunnels, it is the latter property which eventually enables the correction of the streamwise aerodynamic quantities.

Assuming self-similar velocity profiles at the nozzle position also for the plenum-method, a perturbation velocity ε_{QP} can be defined by the ratio of the velocity vectors between the infinite flow and the flow in a wind tunnel.

$$\varepsilon_{QP} = \Delta U / U_\infty = [\, U_\infty - (U_N)_P] / U_\infty \qquad (15)$$

where $(U_N)_P$ denotes the horizontal velocity component at the edge of a fictitious nozzle in a non-constraint flow. - Since, for the plenum method, at the outer contour of the nozzle the free stream velocity U_∞ is yielded, see Fig. 7, integration over the cross-section of the nozzle is not necessary. The perturbation velocity ε_{QP} can then be determined with the aid of the same potential flow model, also used for the nozzle-method, by calculating the horizontal velocity component at a

distance x_S and a radius R_N from the source point. With

$$(U_N)_P = U_\infty [1 - A_M/(2\pi)] [x_S/(R_N^2+x_S^2)^{3/2}] \quad (16)$$

and Equation (15) it can be written:

$$\varepsilon_{QP} = [A_M/(2\pi)] [x_S/(R_N^2+x_S^2)^{3/2}] \quad (17)$$

For distinctness it should be noted that for the nozzle-method the integration of the velocity over the fictitious nozzle is necessary to evaluate ε_{QN} because through the volume flux only the averaged velocity of the wind tunnel flow is known. In contrast, for the plenum-method merely the velocity at the edge of the fictitious nozzle has to be calculated to evaluate ε_{QP}. As shown above, in a wind tunnel U_∞ will always be attained at the outer edge of the nozzle, regardless of where the model is placed in the test section.

Furthermore, it is important to realize that for the same dynamic pressure adjusted either by the nozzle-method or by the plenum-method different aerodynamic forces will be experienced by the car. These forces are proportional to the momentum flux discharged by the nozzle (I_N = momentum flux for the nozzle-method, I_P = momentum flux for the plenum-method). Assuming self-similar velocity profiles in the nozzle exit plane, in terms of the drag coefficient it can be written:

$$(C_{D\,m})_N / I_N = (C_{D\,m})_P / I_P \quad (18)$$

Due to the fact that the momentum flux is proportional to the square of the volume flux or the dynamic pressure of the flow, it can be concluded that, compared to an infinite flow, the momentum flux I_{inf} through the cross-section of the nozzle is increased by a factor $(1 + \varepsilon_{QN})^2$ for the nozzle-method and $(1 + \varepsilon_{QP})^2$ for the plenum-method:

$$I_N = I_{inf} (1 + \varepsilon_{QN})^2 \quad \text{and} \quad I_P = I_{inf} (1 + \varepsilon_{QP})^2 \quad (19)$$

With Equation (5) the corrected drag coefficient for the plenum-method can then be expressed by:

$$C_{D\,cor} = [(C_{D\,m})_P / (1+\Sigma\,\varepsilon)^2][(1 + \varepsilon_{QN})^2/(1 + \varepsilon_{QP})^2] \quad (20)$$

Finally, by neglecting higher order terms $O(\varepsilon^2)$, Equation (20) reduces to

$$C_{D\,cor} = (C_{D\,m})_P / (1 + \varepsilon_{QP} - \varepsilon_{QN} + \varepsilon_S + \varepsilon_C + \varepsilon_N)^2 \quad (21)$$

Considering buoyancy forces as well, to a good order of approximation it can be written:

$$C_{D\,cor} = [(C_{D\,m})_P + \Delta C_{D\,HB}] / [(1+2(\varepsilon_{QP}-\varepsilon_{QN}+\varepsilon_S+\varepsilon_C+\varepsilon_N)] \quad (22)$$

JET DEFLECTION CORRECTION

Besides the confinement of the flow due to the nozzle, the streamline will be further deflected. This takes place at the nozzle due to flow displacement originating from the model. Whereas the vortex model is designed to fulfil the fluid dynamic boundary condition at the center of the jet, the flow tends to be deflected at the outer contour of the nozzle to assume larger flow angles. This effect is not taken care of by the vortex model. In the work of Mercker and Wiedemann it was shown that jet deflection also tends to widen the jet at the model position. Further it was shown that the nozzle may be replaced by one of reduced cross-section, so that its effective area is smaller than the geometrical area. The jet deflection can then be treated the same way as the jet expansion effect, which occurs due to the limited lateral extent of the jet. Details about how Mercker and Wiedemann derived the appropriate perturbation velocity can be taken from their SAE paper [1].

APPLICATION OF THE CORRECTION FORMULA

In the following a complete correction scheme will be outlined for the nozzle-method as well as for the plenum method. All geometrical and fluid dynamic properties needed in order to execute the correction procedure are listed.

However, in the first instance the various correction terms are summarised in Fig.8 in order to provide a better understanding and a convenient overview of the applied flow models used to deduce the different interference effects. Starting from the ideal situation of a body placed in an infinite stream, the open jet wind tunnel consisting of jet, nozzle and collector is attained in four steps. In the left hand column this situation is sketched for an idealised flow around a sphere. The center column shows how the wind tunnel flow situation can be replaced by superimposing different potential flow models. Finally, the last column yields the appropriate correction factors for the different flow cases.

In this overview, the effect of horizontal buoyancy is not included. As mentioned above, from a physical point of view this effect is treated differently. Furthermore, the effect of streamline deflection is included in the jet expansion correction.

The effect of jet expansion due to the finite width of the jet (ε_S) and the interference effect of the flow collector (ε_C) are not examined in detail in this paper. However, for completeness they are included in the overview of Fig. 8. More detailed information can be taken from [1]. At this stage it will only be mentioned that jet expansion can be evaluated with the

	Idealised flow situation		potential flow model		correction
step I		body in an infinite flow field		dipol in translatory flow	$\frac{q_{corr}}{q_\infty} = 1$
step II		body in a jet of infinite length but finite width		jet boundary modelled by image planes with alternating signs	$\frac{q_{corr}}{q_\infty} = (1+\varepsilon_S)^2$
step III		the nozzle at finite distance of the body (streamline constraint by solid walls of nozzle)		local flow modification by a vortex ring to simulate streamline constraint of nozzle	$\frac{q_{corr}}{q_\infty} = (1+\varepsilon_S+\varepsilon_N)^2$
step IV		the collector at finite distance behind the body (second streamline constraint)		second vortex ring behind the model for collector effect	$\frac{q_{corr}}{q_\infty} = (1+\varepsilon_S+\varepsilon_N+\varepsilon_C)^2$

imaging technique whereas the flow collector effect can be quantified with the aid of a ring-vortex model, similar to the one for the nozzle effect.

The entire correction formula for the drag coefficient measured in open jet wind tunnels can be expressed as:

$$C_{Dcor} = (C_{Dm} + \Delta C_{DHB}) / (q_{cor} / q_\infty)$$

For nozzle-method:

$$q_{cor} / q_\infty = (1 + \varepsilon_S + \varepsilon_C + \varepsilon_N)^2$$

For plenum-method:

$$q_{cor} / q_\infty = (1 - \varepsilon_{QN} + \varepsilon_{QP} + \varepsilon_S + \varepsilon_C + \varepsilon_N)^2$$

C_{Dm} = measured drag coefficient
q_{cor} = corrected dynamic pressure
q_∞ = calibrated dynamic pressure
ε = perturbation velocity

ΔC_{DHB}= **horizontal buoyancy force** (details see Ref.[1])

$$\Delta C_{DHB} = [1.75 / A_M][0.5\ V_M\ G] \text{ with}$$

$$G = [(dc_p / dx)_N + (dc_p / dx)_C]$$

$(dc_p / dx)_N$ = static pressure gradient from the nozzle of empty test section, taken over the length of half the model volume V_M.
$(dc_p / dx)_C$ = static pressure gradient from the collector of empty test section, taken over the length of half the model volume V_M.
A_M = frontal area of vehicle or model

ε_S = **jet expansion correction factor** (details see Ref.[1]).

$$\varepsilon_S = \tau\ (V_M / L_M)^{1/2} A_M / (A^*)^{3/2}$$

τ = tunnel shape factor. Constant for each tunnel. Can be extracted from published charts, see for instance Ref.[5].
V_M = vehicle/model volume
L_M =vehicle/model length
A_M = frontal area of vehicle/model
$A^* = A_N / (1+ \varepsilon_{QN})$
ε_{QN} = q-correction factor, see below

ε_C = **collector blockage correction factor** (details see Ref.[1])

$$\varepsilon_C = [\varepsilon_W R_C^3] / [(L_{TS} - x_M)^2 + R_C^2]^{3/2}$$

$\varepsilon_W = [A_M / A_C] (C_{Dm} / 4 + 0.41)$ = wake blockage factor

$R_C = (2\,A_C/\pi)^{1/2}$ = equivalent duplex collector radius
A_C = collector cross section
L_{TS} = test section length
x_M = distance nozzle - model center

ε_N = **nozzle blockage factor**

$$\varepsilon_N = \varepsilon_{QN}\, R_N^{\,3} / (R_N^{\,2} + x_M^{\,2})^{3/2}$$

$\varepsilon_{QN} = [A_M/(2\,A_N)][1 - x_S/(x_S^{\,2} + R_N^{\,2})^{1/2}]$ = blockage factor for nozzle-method
$\varepsilon_{QP} = [A_M/(2\pi)]\,[x_S/(R_N^{\,2} + x_S^{\,2})^{3/2}]$ = nozzle blockage factor for plenum-method
$x_S = x_M - L_M/2 + [A_M/(2\pi)]^{1/2}$ = distance model-source point
x_M = distance nozzle - model center
$R_N = (2\,A_N/\pi)^{1/2}$ = equivalent duplex nozzle radius
A_N = nozzle cross section
A_M = frontal area of vehicle/model
L_M = vehicle/model length

VERIFICATION OF THE CORRECTION METHOD

In order to verify the correction method, especially with respect to the nozzle blockage effect for the plenum-method, a rather limited set of data was available. In a data set, provided by EADE (European Aerodynamic Data Exchange Committee) and some other full scale wind tunnels, only two wind tunnels used the plenum method. The data set consists of full scale measurements of 10 different passenger cars in 8 different wind tunnels. In the original data set, the uncorrected data for the two wind tunnels employing the plenum method were adjusted to the nozzle method according to experimental evidence, because at that stage a correction for the plenum-method was not available. After extending the correction method of Mercker and Wiedemann to the plenum-method, the original data set was reanalysed.

Table 1 shows the uncorrected data for the drag coefficient of the 10 cars denoted by V1 to V10. The different wind tunnels are denoted by WT1 to WT8. Details about the vehicles and the wind tunnels can be found in the paper of Mercker and Wiedemann [1]. It is noteworthy that the standard deviation of the results in the different wind tunnels varies between 8 and 1 drag-count. The mean standard deviation is therefore only about 6 drag-counts, however with a variation of ± 3 drag-counts. This means, depending on the test vehicle, that it is possible to attain fairly consistent results in different wind tunnels without any correction. However, this result is rather arbitrary and therefore unreliable.

Table 2 shows the corrected data for all data measured either with the nozzle-method or with the plenum-method.

Table 2 Corrected drag coefficient

tunnels has now largely decreased. An averaged standard deviation of approximately 3 drag-counts can be calculated and the variation of the standard deviation is now only ± 1 drag count. This demonstrates how well the results measured in different wind tunnels will compare after the new correction has been applied. Table 2 also includes the corrected results from two solid wall wind tunnels. These wind tunnels are denoted by $WT_{sw}(9)$ and $WT_{sw}(10)$. The agreement between the mean values of the open jet wind tunnels and the closed wall wind tunnels is remarkably good.

SUMMARY

A correction method for open jet wind tunnels, as suggested by Mercker and Wiedemann, has been extended for use in wind tunnels in which the plenum-method is used to determine tunnel speed. For this purpose the physics of both methods, the nozzle and the plenum-method, have been reconsidered. It has been shown that, for both methods, a correction has to be applied because the adverse pressure gradient in front of a model extends into the nozzle to some extent and therefore influences the velocity distribution in the nozzle exit plane. This generates a deviation from the velocity distribution that would be measured in an infinite stream at the same axial distance from the model. As a result of the nozzle interference a perturbation velocity is generated at the model position, which has to be corrected.
Application of the method to full scale passenger cars tested in a large number of different wind tunnels showed good agreement among the corrected data.

ACKNOWLEDGEMENT

The authors wish to express their thanks to Mr. Geoffrey Carr, Mr. Mark Gleason, Mr. Jim Hackett and Dr. Jorg Vagt for reviewing the paper. Their comments and constructive criticism improved the paper greatly.

ABSTRACT

The sensitivity of cross-winds in reducing the engine cooling ability in motor cars is highlighted. Tests on three different motor cars were conducted in the Monash University full-scale wind tunnel at different yaw angles under different wind velocities. The test results show that motor car engine cooling capability decreases with an increase in yaw angles. For a wind velocity of 14 m/s, a 13% decrease in radiator cooling capability was found at a yaw angle of 20^{o} compared to a zero yaw angle. The effect of yaw angles on the engine cooling also depends on the motor car front-end configuration, but this becomes less important with increasing wind velocity. The effect of cross-winds on car engine cooling was also evaluated by on-road engine cooling tests. A convenient experimental method to measure wind velocity and yaw angle relative to a moving car is also described.

INTRODUCTION

The fuel consumption of cars is one of the major global issues. For the average car, aerodynamic drag takes a large share of useful engine power. The reduction of aerodynamic drag is important to lower the fuel consumption and this has been achieved by cars becoming more rounded in plan view and having lower front ends. Consequently, the effect of the more streamlined plan-form of modern cars has often been to reduce the yawing moment stability. With these changes to the airflow around the vehicle front end it was desirable to investigate the sensitivity of the cooling system to yaw angle.

Though many papers have been published on the subject of radiator heat transfer and design, relatively few papers have discussed the effect of wind velocity and direction on the engine cooling. Schaub and Charles [6] in 1980 investigated the ram air effect on air side cooling system performance. They found that, under ram conditions, front-end loss could be divided into a basic front-end loss measured at zero approach air velocity, which depended on the radiator-fan cooling air flow rate, and a ram-air loss which varied with the vehicle speed. Saunders and Kolodziejczyk [5] tested the effect of tailwinds on a modified full-scale car. Their tests showed that exiting hot-air recirculating through the radiator from under the car at a 1 m/s tailwind velocity reduced radiator heat rejection by 16%. At 7 m/s, the reduction increased to 28%. Due to the complexity of engine cooling wind-tunnel simulation and the commercial sensitivity of experimental results, little information on the effect of cross-winds on the engine cooling has been published. This paper addresses the effect of cross-winds on the performance of engine cooling.

SPECIFIC DISSIPATION

In order to measure the effect of cross-winds on the motor car engine cooling, a convenient parameter is required. The parameter used is called Specific Dissipation (SD). SD is defined as the heat transfer rate of a heat exchanger divided by the maximum temperature difference across the heat exchanger [7]. SD can be expressed as:

$$SD = \frac{Q}{T_{hot,in} - T_{cold,in}} \qquad (1)$$

where $T_{hot,in}$ and $T_{cold,in}$ are the hot and cold fluid inlet temperatures of the heat exchanger, and Q is the heat exchanger heat transfer rate. The application of SD on evaluating engine cooling was given by Lin et al [4]

In essence if all experimental conditions are maintained constant except for a change in front-end configuration, a 10% improvement in SD corresponds to a 10% increase in the heat rejection by the radiator.

WIND-TUNNEL ENGINE COOLING TESTS

WIND-TUNNEL TEST INSTRUMENTATION

The Monash full-scale wind tunnel has been used as a joint RMIT and Monash aero-acoustic facility. The vehicle test section is shown in Figure 1. The maximum wind velocity is about 50 m/s. The turntable provides an opportunity of investigating the cross-wind effect on engine cooling.

The vehicles used for engine cooling tests at the Monash wind tunnel were three locally-made vehicles (Vehicle A to C). The test set-up is shown in Figure 2. During engine cooling tests, the car engine was not in operation and the electric cooling fans were disconnected. The hot coolant through the radiator was provided by a heat bench located outside of the wind tunnel. The maximum coolant temperature in the heat bench was controlled by a thermostat. The coolant flow rate was measured by a magnetic flowmeter (Fischer & Porter Mini-Mag 10D1475), which had a system accuracy of within 1%. The radiator coolant inlet and outlet temperatures and radiator approach air temperature were measured by six calibrated T-type thermocouples. Signals from the magnetic flow meter and thermocouples were recorded by a host computer through a Fluke 2620A Hydra Data Acquisition Unit.

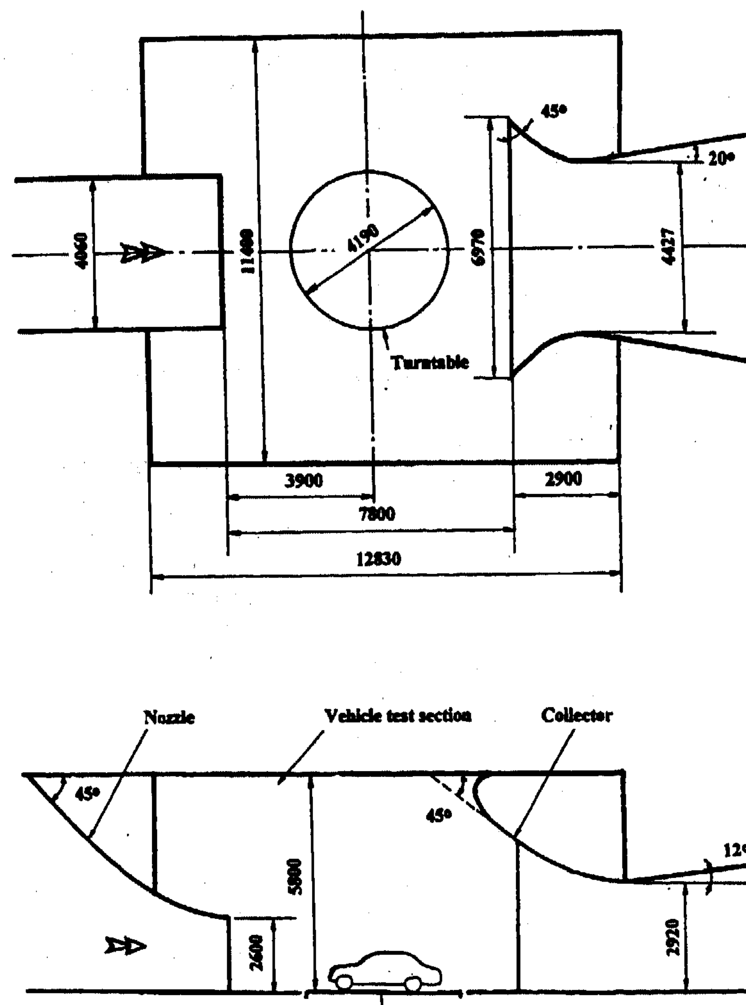

Figure 1. The vehicle test section of the Monash University wind tunnel

WIND-TUNNEL TEST RESULTS AND DISCUSSION

Tests were conducted at relative wind velocities of 14, 19, 28 and 33 m/s, and yaw angles varying from 0^{o} to 20^{o} with an interval of 5^{o}. Test results are plotted in Figures 3 to 5.

Mean SD values plotted in Figures 3(a), 4(a) and 5(a) have a standard deviation of less than 0.5%. The change of SD with yaw angle, is normalised to $[100 \times (SD_{yaw} - SD_{yaw=0}) / SD_{yaw=0}]$ and plotted in Figures 3(b), 4(b) and 5(b). Results suggest that Specific Dissipation significantly:

(a) decreases with the increase of yaw angles when other parameters (e.g., resultant wind velocity, coolant mass flowrate, etc.) are maintained constant; for example, about 13% decrease of SD is shown at a yaw angle of 20 degrees and a wind velocity of 14 m/s;
(b) depends on the car front-end configuration; and, as expected,
(c) increases with an increase in wind velocity.

The above test results indicate that tests in full-scale wind tunnels:

(a) can show the effect of cross-winds on engine cooling, and
(b) enable the automotive cooling engineers and stylists to evaluate the ranking of their designs.

ON-ROAD ENGINE COOLING TESTS

TEST INSTRUMENTATION

The effect of cross-winds on engine cooling was also investigated by testing Vehicle A on the road. During on-road engine cooling tests, radiator approach air, and coolant radiator inlet and outlet temperatures were measured by six calibrated T-type thermocouples. Coolant flowrate was measured by a calibrated system which measured the pressure differences across a fully open thermostat [3]. Wind velocities and yaw angles were measured with a system specially developed for on-road vehicle tests. Signal outputs from all sensors were recorded by a Lap-top PC through the same Fluke data acquisition system used at the Monash wind tunnel.

Wind Velocity and Yaw Angle Measurement

Different methods to measure the relative wind characteristics (velocity and yaw angle) have been addressed by several authors. Buckley et al [1] measured wind velocity and angle during on-road tests with a Gill propeller-vane anemometer which was mounted on a mast fitted to the test car's roof rack. Watkins et al [9] also used a Gill anemometer but supplemented the measurement with cross-wire anemometers to give information at higher frequencies. In both cases the anemometers were calibrated in-situ (in-situ calibration of velocity and angle is required when anemometers are influenced by the proximity of the vehicle). Schaub and Charles [6] measured approach air velocity with a five-point Pitot-static probe rake supported one metre in front of the vehicle based on a proximity profile calibration factor established during earlier road tests. However, all those methods need to attach measuring sensors external to the vehicle. Generally this is not convenient and additionally those instruments interfere with the flow field of the car, incurring a drag penalty and generating aerodynamic noise. One of the objectives of this study was to develop a method to measure the relative wind velocity and yaw angle in a non-obtrusive manner.

Ignoring compressibility effects, then from the stagnation pressure equation for an incompressible fluid, the velocity, V, may be calculated from measurements of stagnation and static pressures [8].

$$V = \sqrt{2(P_t - P_s)/\rho} \qquad (2)$$

where P_t is the stagnation pressure, P_s is the static pressure of the undisturbed flow and ρ is local air density. However, when Equation (2) is applied to measure the air velocity near the intake cooling air slot of a car front bumper bar it is very difficult to locate the stagnation point and also static pressure positions which reflect the undisturbed flow static pressure, accurately. Consequently, if the pressure difference is measured between two points, one of which is close to the stagnation point and another close to a point which has a similar static pressure as the undisturbed flow and then calibrated against wind velocity in a full-scale wind tunnel, the pressure difference may be used to measure wind velocities during on-road tests. Crosswinds and the resultant yaw angle significantly move the stagnation point and influence the other static pressures around the vehicle. Therefore to calculate the yaw angle, an additional set of pressure taps are needed which are sensitive to yaw angle and velocity.

Experimental Set-up and Procedures

The experiments were conducted in the vehicle test section of the Monash full-scale wind tunnel. The test vehicle (an Australia-made Ford Fairmont) was placed on a turntable, as shown in Figure 6. The main instruments used for this program were two pressure transducers (Honeywell 160PC), the Fluke 2620A Hydra Data Acquisition Unit, and a host-computer. Experimental procedures consisted of the determination of pressure-tap positions on the car bumper bar and the calibration of those pressure taps, including dynamic calibration.

Determination of Pressure Tap Positions - In order to measure both wind velocity and angle it is convenient to drill four pressure tap holes through the bumper bar. For many modern cars, the bumper is a large removable one-piece plastic moulding which is easily machined and transportable between many vehicles and is frequently one of the first components to be manufactured in the production of a new car. A single instrumented bumper bar is convenient for car manufacturers as it can be used on several different test vehicles. For example, it can be used for aerodynamic studies on cooling, drag, noise, etc.

To estimate the best positions on the bumper bar without an extensive pressure tapping exercise, a static pressure tap was made from a thin washer as shown in Figure 7 which was connected to a pressure transducer via 1.5 mm diameter plastic tubing. The pressure transducer measured the difference between local pressures and the pressure inside the vehicle. The pressures at pre-marked spots on the bumper bar (as shown in Figure 8) were measured at zero yaw angle and a tunnel speed of about 19 m/s. Results are plotted in Figures 9 and 10. Figure 9 shows the variation of pressure with position around the sides of the bumper bar and Figure 10 shows that point 3' seems to be the closest point to the stagnation point on the centre of the bumper middle cross-bar. Point 7 was located opposite point 3 and these two points were chosen as they exhibited good repeatability and sensitivity to yaw angle. Point 6' was chosen on the flat surface of the slot to measure local static pressure of the flow through the slot. Finally, pressure taps were inserted in the bumper bar at those four positions and connected to two pressure transducers through 1.5 mm

diameter plastic tubing. One pressure transducer measured the differential pressure between locations 3 and 7 and the other measured the differential pressure between 3' and 6'.

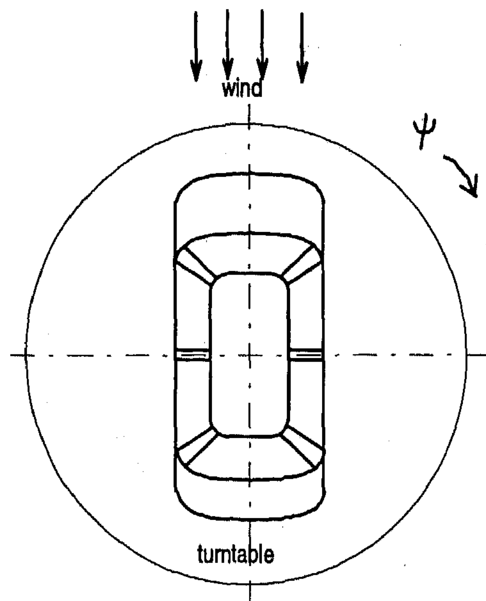

Figure 6. Test car on the turntable at the Monash wind tunnel

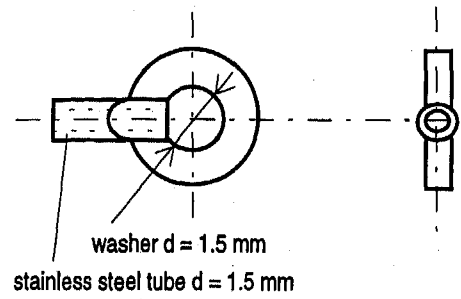

Figure 7. Washer-shaped pressure tap

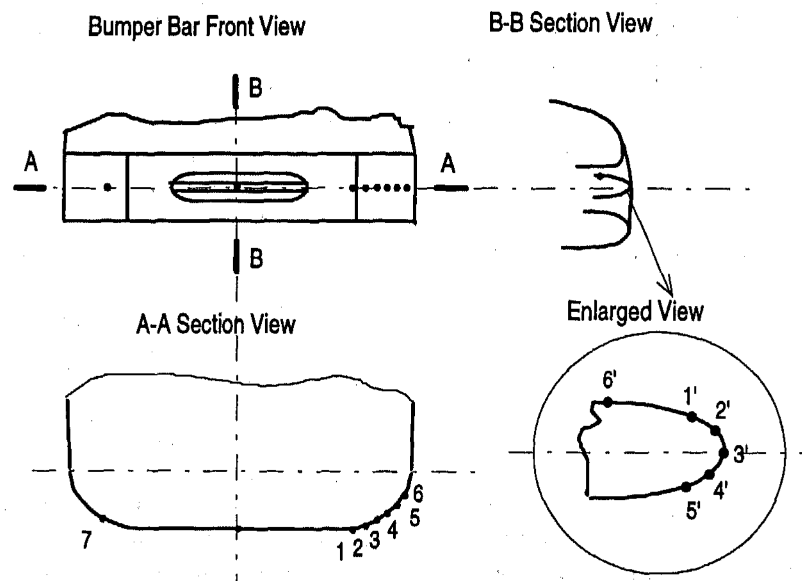

Figure 8. Partial view of a car bumper bar

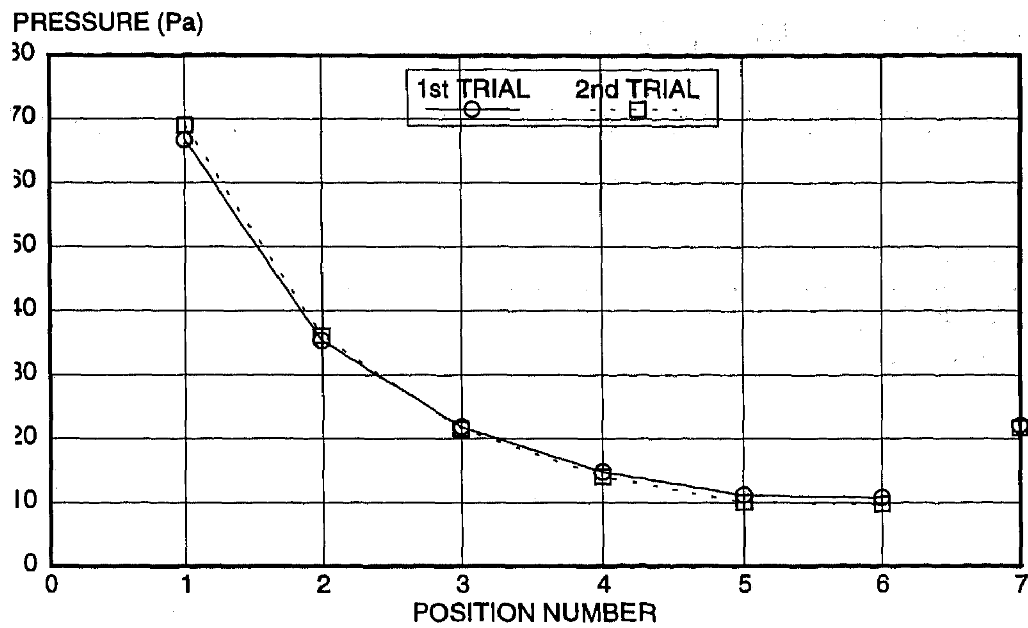

Figure 9. Pressure profile for the determination of side pressure taps

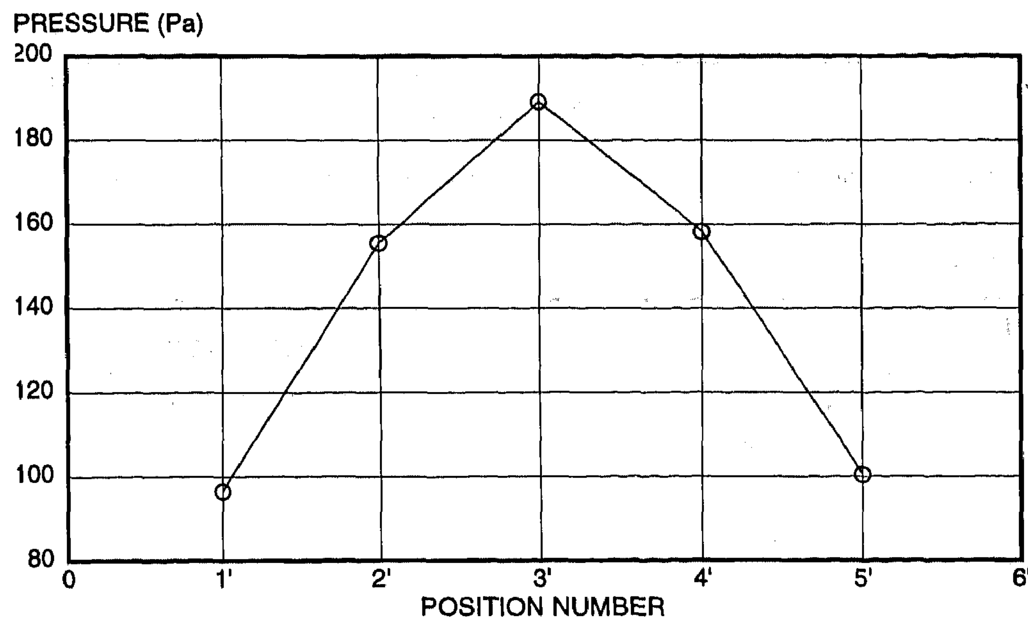

Figure 10. Pressure profile for the determination of centre pressure taps

Calibration of Pressure Taps - The calibration of pressure taps was performed at tunnel velocities of 17.8, 22.5, 28.3, and 33.9 m/s and yaw angles from -15° to +15° with an interval of 3°. The voltage outputs from those two pressure transducers were recorded by the host computer. Then correlations between the differential voltage output of v_c between 3' and 6' and v_s from 3 and 7 with velocity, V, and yaw angle, ψ, were established using polynomials with constants determined via regressions. The polynomials are seen in Equations (3) and (4). Thus in the wind tunnel or on the road, measurements of v_s and v_c can be inserted into Equations (3) and (4) and from those simultaneous equations, V and ψ can be calculated. Comparisons of results from both tests and prediction with regression equations at a wind velocity of 28.3 m/s are plotted in Figures 11 and 12. The figures indicate that both experimental and correlated results match with each other very well. The comparison of predicted results with experimental results is also listed in Table 1.

$$v_c = (a_1 + a_2 V + a_3 V^2) + (b_1 + b_2 V + b_3 V^2)\psi + (c_1 + c_2 V + c_3 V^2)\psi^2 \quad (3)$$

$$v_s = (a_1' + b_1' V + c_1' V^2) + (a_2' + b_2' V + c_2' V^2)\psi + (a_3' + b_3' V + c_3' V^2)\psi^2 + (a_4' + b_4' V + c_4' V^2)\psi^3 \quad (4)$$

12.0	12.5	-0.5	28.4	-0.1
15.0	15.5	-0.5	28.4	-0.1

Dynamic Response - For certain types of testing, a rapid response of a system to relative velocity changes is needed. Examples include coastdown testing (to establish aerodynamic drag and rolling coefficients) and the estimation of effects of turbulence in relative wind on stability and noise. The limiting factor for the system described here is the response of the pressure tubing system. Because pressure transducers (Honeywell 160PC) were mounted inside the test car, about 2 meters of 1.5 mm diameter thin plastic tubing was required. In the resulting dynamic system, a strong amplification of pressure fluctuation around a frequency of 200 Hz may occur and in order to damp out the resonant peak a capillary tube restrictor of internal diameter 0.4 mm and length 5 mm developed according to the procedures of Holmes [2] was located symmetrically about the centre of each plastic tubing. Dynamic calibration of the system, involving step changes to the local airflow around the pressure tappings and monitoring the output on a storage oscilloscope, indicated that the typical time constant was about 40 ms.

ON-ROAD TEST RESULTS AND DISCUSSION

The on-road tests were conducted under following car conditions:

(a) thermostat fully open,
(b) cooling fan disconnected, and
(c) air conditioning off.

On the test day the average atmospheric wind velocity was 6.7 m/s and the direction was 68° from right side of the road (as shown in Figure 13). Tests were conducted at car speeds of 22, 28 and 30.6 m/s. The car was driven in both directions on the road. Typical road test results are listed in Table 2. The results indicate when cars are driving into the wind the engine cooling ability appears to increase and, as expected, and similarly to decrease when downwind.

The on-road test results were also compared with the results from wind-tunnel tests (from Figure 3a). The on-road test results were found to be very similar to the finding from the tests conducted at the Monash wind tunnel, see Figure 14.

Whilst the reduction in cooling is relatively small under the yaw angles tested, a more critical on-road condition is under strong tailwinds which can also generate larger yaw angles and lower relative velocities for the vehicle than tested here. Under such conditions further work is needed, which should be performed with an active cooling fan (if normally fitted to the vehicle) and this may indicate the need to yaw vehicles in cooling tests.

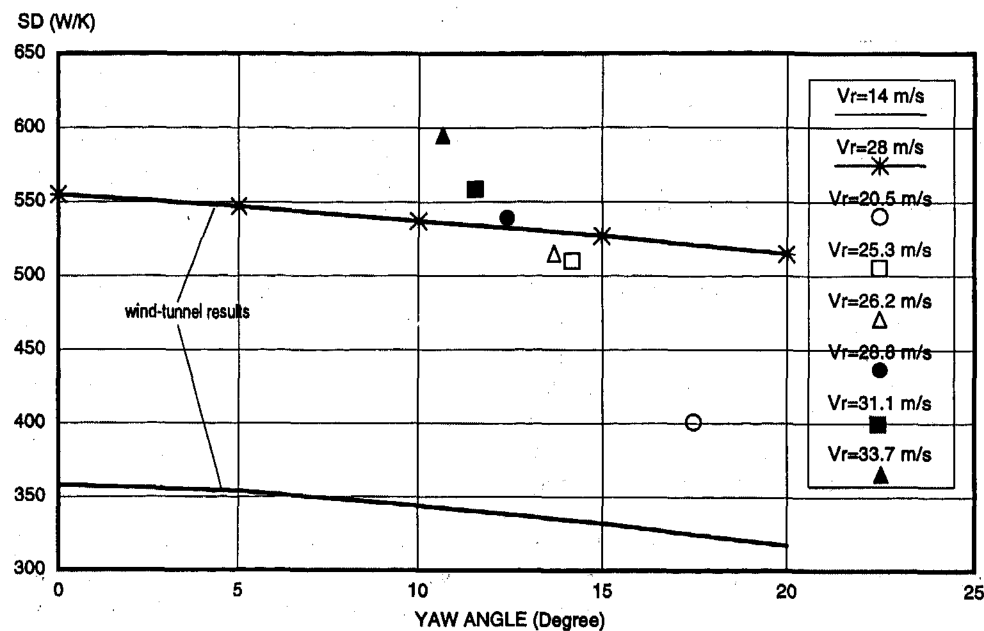

Figure 14. Effect of cross-wind on motor car engine cooling: on-road versus experimental results

CONCLUSIONS

Within the restrictions of the full-scale wind tunnel investigation on three locally-made motor cars and on-road evaluation, the following conclusions can be made:

1. Cross-winds can significantly reduce motor car engine cooling. The reduction increases with increasing yaw angle.
2. On-road tests under yawed conditions gave closely similar results to similar conditions in the wind tunnel.
3. As expected:
   (a) at the same yaw angle, the effect of cross-winds will decrease with the increase of resultant wind velocity; and
   (b) the effect of cross-winds will vary with the motor car front-end configuration.
4. A convenient experimental method to measure wind velocity and yaw angle relative to a moving car was found.

FUTURE WORK

Additional work should be undertaken under conditions that are closer to the maximum capacity of the cooling system. These should include the effects of strong atmospheric winds with significant tailwind components, giving high yaw angles and low relative wind speeds.

DIGITAL PHYSICS™ Analysis of the Morel Body in Ground Proximity

Andrew Anagnost, Ales Alajbegovic, Hudong Chen, David Hill, Chris Teixeira, and Kim Molvig
Exa Corporation

ABSTRACT

Presented is a study of the air flow over the Morel body [1] in ground proximity which was obtained using a discrete particle method, referred to as *DIGITAL PHYSICS*. The results were computed at several back-light angles and will be compared to experimental observations. Separation and reattachment along the angled section at a back-light angle of 30 degrees, and complete separation at 35 degrees, were both accurately predicted.

INTRODUCTION

The aerodynamic forces on vehicles can have a significant impact on overall performance. One major contributor to vehicle drag is the external shape. Janssen & Hucho [2] were the first to note the importance of the rear window slant on the overall drag when they observed that relatively low slant angles (between 25 and 35 degrees) resulted in a substantial increase in drag. This important result pointed out that improper design can substantially degrade vehicle performance by producing unnecessarily high drag.

The Morel body [1], shown in Figure 1, is one of the most fundamental test cases for determining the capability of an analysis methodology for predicting the basic fluid flow phenomena common in automotive vehicle aerodynamics. It represents a significant test case because it exhibits physical dependencies which are common in vehicle aerodynamics and allows the study of the affect of back-light angle on overall forces. Another body with characteristics similar to the Morel body, and used for the same purpose, is the Ahmed body [3]. The differences between the Ahmed and Morel bodies are minimal. Ahmed's body is slightly longer and thinner than the Morel body and Morel kept the slant section aspect ratio constant at 1.5, whereas Ahmed used a value of 1.9. However, the behavior of the flow over the two bodies is essentially the same.

For the purposes of this study a minor simplification to the Morel geometry was made. Specifically, Morel smoothed some of the edges of his geometry with a small radius round. Since the exact dimensions of this round were not reported by Morel, the geometry used in this study has squared edges like those of the Ahmed body. However, since all the rounded edges are parallel to the flow direction, or on the blunted forebody, their effect on the flow behavior is quite negligible.

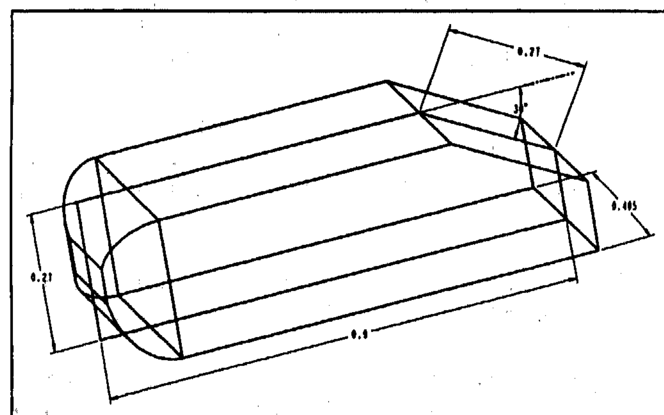

Figure 1. The Morel body (Morel, 1978); all dimensions in meters, back-light angle set to 30°.

The flow structure can be divided into three well distinguished regimes. Figure 2 shows the dependence of the drag coefficient on the back-light angle. The sub-critical regime is strongly three-dimensional. At low back-light angles drag is decreased due to a boat-tailing effect, and the minimum is reached at about 10 degrees. By increasing the back-light angle, two strong vortices at each of the side edges are formed and tend to roll up over the slanted surface. The rolled-up vortices decrease the base pressure and drag starts to increase. At about 25 degrees the flow separates at the upstream edge of the slant and reattaches downstream to form a separation bubble. A slight increase in angle above 30 degrees causes the separated region on the slant surface to join the separation bubble of the base flow. The merging of the separation regions destroys the vortical flow and increases the base pressure

resulting in a considerable decrease in drag. This behavior is then retained for all higher angles.

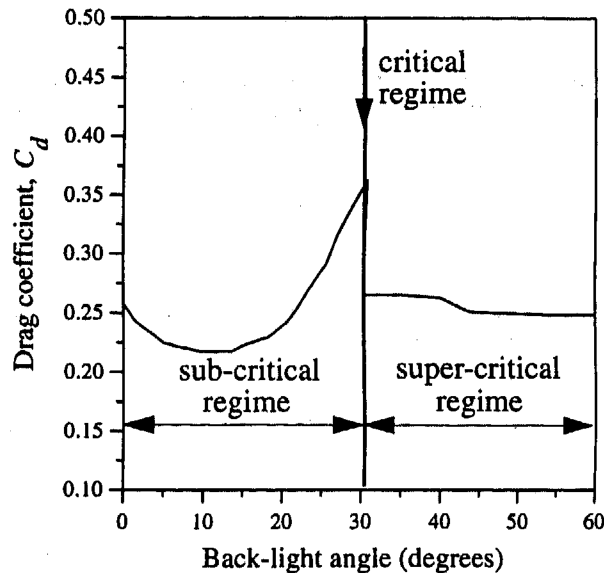

Figure 2. Measured drag coefficient of the Morel body (Morel, 1978).

The complexity of the fluid flow over the Morel and Ahmed bodies has defied many attempts to predict the experimentally observed behavior using traditional computational fluid dynamics (CFD). Han (4) used the k-ε model to compute flow over the Ahmed body. The difference between the predicted and measured drag coefficient was around 30% for slant angles between 0 and 30 degrees. However, the computational approach completely failed to predict the phenomena of vortex breakdown, and the formation of a large separation bubble, for slant angles beyond 30 degrees. There was also an extensive experimental and computational effort at MIRA to investigate the flow over the Ahmed reference model [5]. They obtained excellent experimental results, and an attempt was made to reproduce them using two commercially available CFD codes. Drag coefficient trends were qualitatively predicted, but the values were about 30% too high in the sub-critical and critical regimes. Enormous difficulties were encountered in the super-critical regime. Several mesh resolutions were used with limited success. The complete separation at 35 degrees was never predicted. In addition, the pressure coefficient at the stagnation point had values larger than one. More recently, Bickerton *et al.* [6] attempted to use different turbulence models and mesh structures around the corner at the top edge of the back-light. The results show strong dependence on the gridding technique and question the generality of the solution scheme.

This paper will present results for the Morel body in ground effect which have been obtained from a discrete particle method, a novel extension of lattice gas theory, which yields accurate fluid dynamics using a simple rectilinear lattice; this method is referred to as *DIGITAL PHYSICS*. The results for the Morel body will be described at several back-light angles. The results are remarkably accurate and include the prediction of separation and reattachment along the angled section at a back-light angle of 30 degrees. This phenomenon was observed experimentally by Ahmed *et al.* [3], but has never been computed numerically until the current results. In addition, the phenomena of vortex break down and the subsequent drop in drag was adequately predicted. Included in the discussion will be a presentation of the underlying technology of *DIGITAL PHYSICS*.

THEORETICAL FOUNDATIONS OF *DIGITAL PHYSICS*

DIGITAL PHYSICS extends lattice gas theory to allow application of the method to high Reynolds number flows over external geometries. The lattice gas automata (LGA) method can be viewed as a discrete version of kinetic theory for a dense gas. The mean behavior of the microscopic model of a digital fluid can be shown rigourously to agree with the macroscopic governing equations of fluid dynamics, the Navier-Stokes equations. In the past, lattice gases suffered from the presence of discreteness artifacts and other problems which prevented the quantitative prediction of fluid dynamic lift, drag, and flow structures. The techniques employed in *DIGITAL PHYSICS* remove these artifacts and produce accurate quantitative predictions [7], [8], [9], [10]. The motion of particles is simulated on a face-centered-hypercubic (FCHC) lattice which ensures macroscopic isotropy [11]. The method used has three-speeds with one rate coefficient which moderates the equilibrium in order to remove the lattice artifacts [8]. In addition, the algorithm is unconditionally stable, inherently parallel and computationally very efficient.

The microdynamics of the discrete particle system simulated using *DIGITAL PHYSICS* are described by the masters equation:

$$N_{ji}(\mathbf{x}+\mathbf{c}_{ji}, t+1) - N_{ji}(\mathbf{x}, t) = C_{ji}\{(N_{ji})\} \tag{1}$$

where $\mathbf{c}_{ji}$ is particle velocity, N_{ji} is the number of particles having speed j $(1/2c_j^2=\{0,1,2,...\})$ and moving in direction i; all particles have unitary mass. $C_{ji}\{(N_{ji})\}$ is a sequential series of valid binary collisions that transfer an integer number of particles from one pair of states to the other pair. A valid collision exactly conserves the mass, momentum, and energy at the node. It can be proven that the sequential multilinear collision process monotonically drives the particle distribution towards a stable equilibrium distribution [9], [10]. This equilibrium can be calculated using $C_{ji}\{\left(N_{ji}^{eq}\right)\} = 0$ and has Maxwell-Boltzmann form:

$$N_{ji}^{eq} = R_j^{-1}\exp\left[\left(-\alpha+\gamma\cdot\mathbf{c}_{ji}+\beta\frac{c_{ji}^2}{2}\right)\right] \tag{2}$$

where the coefficients α, γ and β are associated with the conservation of mass, momentum and energy. The energy dependent factors R_j^{-1} are the transition rates.

The hydrodynamics equations are obtained by using the same tools developed from continuum kinetic theory

applied to the discrete lattice gas [11], [12]. The terms in the ensemble averaged microdynamical equation are expanded about a given cell location (x, t) and the 2nd order Chapman-Enskog expansion is performed. The solutions of the resulting equations are found order by order for the deviation from the equilibrium, N_{ji}^{eq}. It can be shown that the macroscopic conservation equations simulated by *DIGITAL PHYSICS* reproduce the well known mass and momentum conservation equations obtained from continuum mechanics to the indicated order in velocity [8]:

$$\frac{\partial\rho}{\partial t} + \nabla \cdot \rho \mathbf{v} = 0 \quad (3)$$

$$\frac{\partial\rho \mathbf{v}}{\partial t} + \nabla \cdot \rho \mathbf{v}\mathbf{v} = -\nabla p + \nabla \cdot \rho\nu\left(\nabla \mathbf{v} + \nabla \mathbf{v}^T - \frac{2}{D}(\nabla \cdot \mathbf{v})\right) + O\left(v^3\right) \quad (4)$$

where,

$$\nu = \left(\frac{1}{\lambda} - \frac{1}{2}\right)T \quad (5)$$

T represents the temperature of the system and D the dimension of the flow. The quantity λ is the relaxation time scale which is used for the adjustment of the viscosity. In the simulations reported in this paper isothermal behavior is assumed. An appropriate energy equation could be derived in a manner similar to that used for equation (4), but it would be contaminated by the presence of discreteness artifacts. As a result, the current methodology is limited to flow Mach numbers below 0.3. The scaling between the lattice and physical units is done through the nondimensional Reynolds number, *Re*.

In order to capture the physics of high Reynolds number flow without resolving all of the relevant physical scales in the boundary layer, a simple wall boundary condition is employed which accounts for the effect of the unresolved boundary layer. The wall boundary conditions are specified through the wall shear stress as:

$$\tau_w = C_f''\frac{1}{2}\rho U_s^2 \quad (6)$$

where U_s is the instantaneous velocity on the surface where the local boundary conditions are applied and C_f'' is a local friction coefficient. Note that this definition of skin friction coefficient is different from standard definitions based on free stream or potential flow velocities. The friction coefficient is calculated by using the local resolution, the global Reynolds number, and the *DIGITAL PHYSICS* equivalent of the law-of-the-wall.

This law-of-the-wall is derived directly from fundamental turbulent boundary layer theory and is derived as follows. First we define a friction velocity, u_τ, such that:

$$\tau_w = \rho u_\tau^2 \quad (7)$$

For sufficiently large Reynolds number (as is the case for the external flow over automobiles), the following well known scaling law is appropriate within the region of logarithmic behavior.

$$\frac{\partial u}{\partial y} = \frac{u_\tau}{\kappa y} \quad (8)$$

where κ is the VonKarman constant($\kappa = 0.4$). Integrating this relation to some height y_s at which the velocity is U_s yields the following:

$$\frac{U_s}{u_\tau} = \frac{1}{\kappa}\left[\ln\left(\frac{u_\tau y_s}{\nu}\right) + B\kappa\right] \quad (9)$$

Where B is a constant of integration with an empirical value of approximately 5. Using equations (6) and (7) we note that

$$\frac{U_s}{u_\tau} = \sqrt{\frac{2}{C_f''}} \quad (10)$$

Hence,

$$C_f'' = \frac{2\kappa^2}{\left(\ln\left(\frac{u_\tau y_s}{\nu}\right) + B\kappa\right)^2} \quad (11)$$

We next eliminate y_s and u_τ from the equation by matching the lattice viscosity to the turbulent eddy viscosity at a height y_s in the logarithmic region of the boundary layer. That is,

$$\nu_T = \kappa u_\tau y_s = \nu_{lat} \quad (12)$$

where ν_T is the turbulent eddy viscosity and ν_{lat} is the lattice viscosity. Hence, we have assumed that there exists a y_s such that the lattice viscosity matches the turbulent viscosity at some point in the logarithmic region of the boundary layer. If this is to be strictly true, then y_s must be of the order of the boundary layer displacement thickness. For Digital Physics, this implies that the near wall voxel size is of the same order. In practice, excellent results are obtained for simulations where the near wall voxels size is much greater than the appropriate boundary layer displacement thickness.

Using the results of (11) and (12) we obtain the basic form of the friction law:

$$C_f'' = \frac{2\kappa^2}{\left(\ln\left(\frac{Re}{\kappa Re_{lat}}\right) + B\kappa\right)^2} \quad (13)$$

where Re is the flow Reynolds number, and Re_{lat} is Reynolds number of the lattice based on the freestream lattice velocity, viscosity, and number of voxels along the characteristic length. This form is strictly valid as long as the near wall voxel size is within some practical limit of the boundary layer displacement thickness.

However, it is well known that adverse pressure gradients decrease the extent of logarithmic behavior within the

boundary layer and that the thickness of the logarithmic region goes to zero at separation. As a result, the value of y_s should decrease in the presence of an adverse pressure gradient. This decrease in y_s can be modeled by altering the viscosity matching of equation (12). Specifically,

$$\nu_T = \kappa u_\tau y_s = \nu_{lat}\left(1 + f\left(\frac{\partial p}{\partial x}\right)\right) \quad (14)$$

where the pressure gradient function is negative in an adverse pressure gradient and zero otherwise. Utilizing (14) yields the final form of the friction coefficient:

$$C_f'' = \frac{2\kappa^2}{\left(\ln\left(\left(\frac{Re}{\kappa Re_{lat}}\right)\times\left(1 + f\left(\frac{\partial p}{\partial x}\right)\right)\right) + B\kappa\right)^2} \quad (15)$$

The results presented in the next section will demonstrate the utility of this simple model for predicting the behavior of high Reynolds number, turbulent, external fluid flow. The accuracy of the results can be directly attributed to the high temporal and spatial resolution which is employed across the entire flow domain.

SIMULATION

The simulation of the flow over the Morel body was performed in a digital wind tunnel similar to that shown in Figure 3. Simulations were run in both fully three dimensional and with a symmetry plane splitting the body in half. There were no significant differences between the two types of simulations. The parameters used in the simulation were the same as the ones reported by Morel [1]. The ground clearance between the Morel body and the floor was 0.0445 m. The inlet (source) was set to a uniform air speed of 58 m/sec. The size of the wind tunnel was set to produce an area weighted blockage of 1.7%; identical to the blockage of the experimental set up. The total stream wise extent of the tunnel was twelve body lengths and the body was placed four lengths from the inlet.

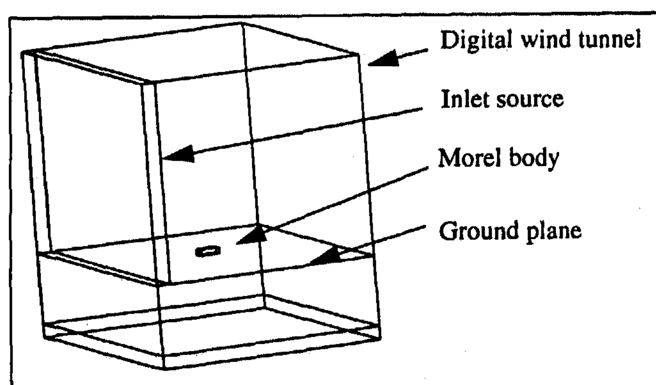

Figure 3. The Morel body in the digital wind tunnel.

The inlet flow was uniform and a modest boundary layer was allowed to grow along the tunnel floor as a result of an imposed friction force on the ground plane.

Since Morel's experimental data had been corrected for the presence of struts, no mounting struts were modeled for the simulation.

The computation advanced time-accurately to a final state which is steady in the mean. Although thousands of time steps are required to reach a quasi-steady state, the computational efficiency of the method ensures that the simulations are completed in relatively short periods of time (a few days) with enough samples to minimize sampling errors. It is interesting to note that the method of collecting and evaluating data from the digital wind tunnel is quite analogous to the procedures and methods employed in sampling data from a real wind tunnel.

The simulation required approximately 8 million voxels (or volume elements) to represent the wind tunnel, and 800 000 surfels (or surface elements) to represent the surface of the Morel body. Figure 4 provides an illustration of the computational lattice. The same lattice configuration was used for each back angle; the only difference being the additional cells required to fill the volume as the back angle increases. Less than one hour was required to prepare the geometry and prescribe boundary conditions. The simulations were run on a four processor SUN UltraSparc server and required approximately 4 days for each back-light angle.

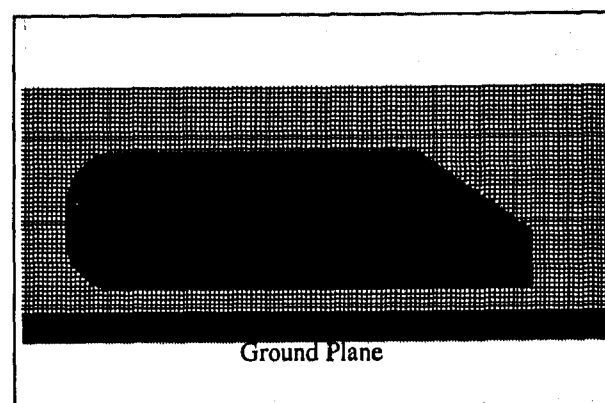

Figure 4. Computational lattice.

RESULTS AND DISCUSSION

LIFT AND DRAG COMPARISON - Drag and lift are major parameters of interest for any flow study over bluff bodies. Simulations were performed for the Morel bodies with back-light angles at 5, 12.5, 25, 30, and 35 degrees. The corresponding drag and lift coefficients as a function of back-light angles are shown in comparison to experiments in Figures 5 and 6.

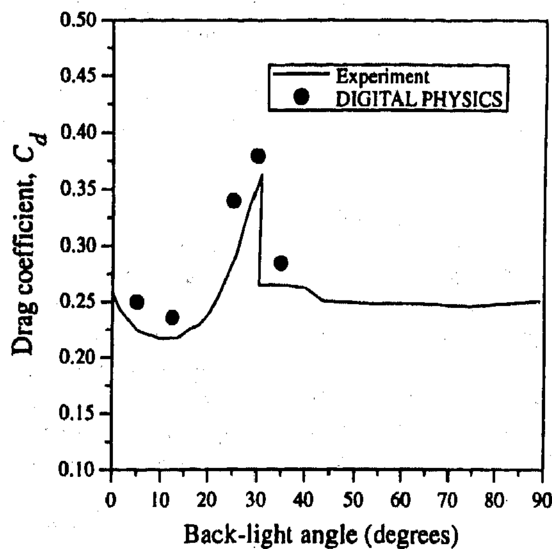

Figure 5. Comparison between the measured and predicted drag coefficient as a function of the back-light angle.

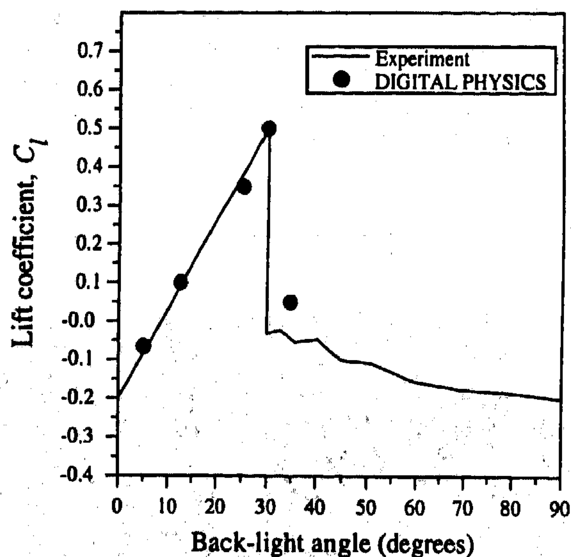

Figure 6. Comparison between the measured and predicted lift coefficient as a function of back-light angle.

The simulation predicted a sharp drop in both drag and lift coefficients for angles between 30 and 35 degrees. This indicates that *DIGITAL PHYSICS* captures the important physics of the flow and is able to duplicate the observed flow structures in the critical and super-critical regimes. There is also good agreement between the measured and predicted values for drag and lift coefficients. The difference varies between 10% (5 degrees) and 5% (30 degrees) for drag. In addition, the change in drag coefficient from one angle to the next is well predicted.

At 30 degrees the simulation exhibited the bi-stable behavior indicated by Ahmed [3]. Ahmed noted that the drag at 30 degrees could be either low or high depending on the initial state of the flowfield. The high drag result presented above persisted for several thousand time steps before suddenly transitioning to the low drag result indicative of high back light angles. This is consistent with Ahmed's observations of the dual nature of the critical angle.

Figures 7 to 8 show the spatial distribution of the pressure coefficient, C_p, on the upper surface centerline of the Morel body at three different back-light angles. Pressure distribution is a convenient indicator of the flow structure. Note that for all slant angles the stagnation pressure coefficient is always unity. At 5 degrees back-light angle there is no separation (Figure 7). However, at 30 degrees the C_p distribution suggests the existence of a separation bubble over the back-light (Figure 8). Previous computational efforts by other authors failed to predict this behavior. Further increase in back-light angle (35 degrees) results in a complete separation at the back (Figure 9). The back pressure recovers considerably and the drag is reduced.

Dips in the C_p distributions at the top edge of the slanted section for angles of 30 and 35 degrees indicates a slight delay in separation which is indicative of a finite resolution effect. Increasing resolution near the start of the back-light angle shifts the separation point further toward the sharp edge and decreases the magnitude of the pressure dip.

Additional finite resolution effects are visible at the pressure minimum over the nose of the body. In this region the surface pressures are "noisy" near the point of maximum velocity. This is due to inadequate surface resolution in a region of large tangential velocity. As resolution is increased along the rounded edge, the spatial oscillation of the surface pressures disappear.

Figure 10 shows the pressure distribution in two regimes in comparison with the experimental data. Regime I is the high drag 30 degree result and regime II is the low drag 35 degree result. The agreement is qualitatively good. It is clearly seen that the flow structure has been captured for the two regimes. The major discrepancy is the absence of the bowing of the pressure coefficient across the slanted section which was observed experimentally for regime I.

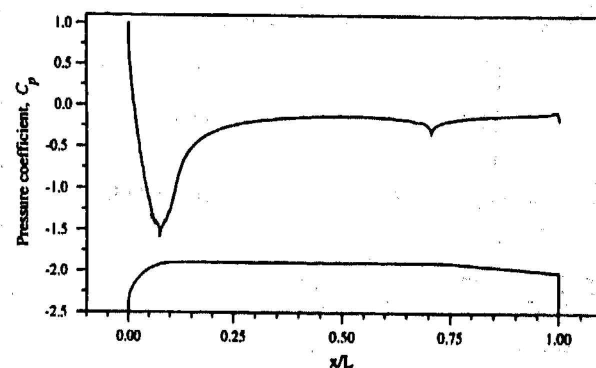

Figure 7. Pressure coefficient at 5 degrees back-light angle (upper surface centerline).

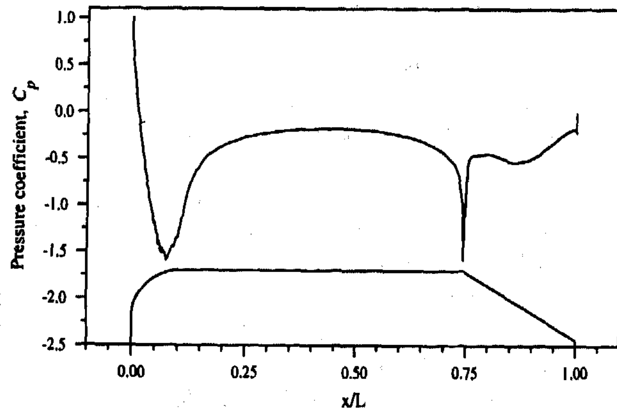

Figure 8. Pressure coefficient at 30 degrees back-light angle (upper surface centerline).

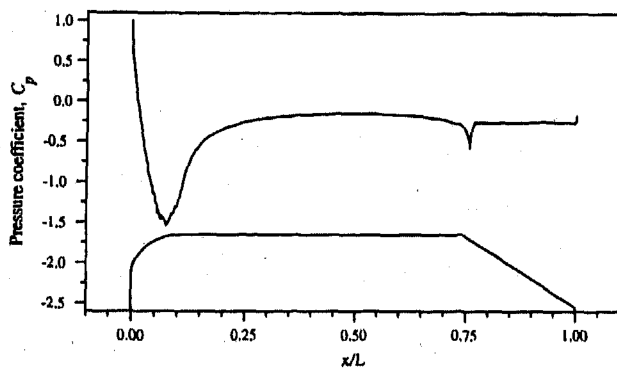

Figure 9. Pressure coefficient at 35 degrees back-light angle (upper surface centerline).

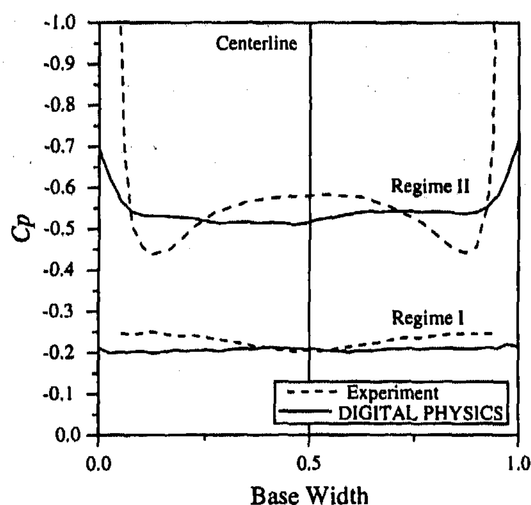

Figure 10. Pressure distribution on the middle of the back light in comparison with the Morel's data.

FLOW STRUCTURE - Typical flow structure in the critical regime can be inferred from Figure 11. The separation bubble which is formed on the back-light surface can be clearly seen. The flow separates right after the top edge and reattaches at the bottom edge of the back-light. The separation and reattachment lines are shown in Figure 12. Beyond 30 degrees the drag drops dramatically and maintains a relatively constant value for higher angles. At 35 degrees there is complete separation at the back (Figure 13) and the final state is free of vortical flow; the resulting rise in base pressure produces the abrupt decrease in drag.

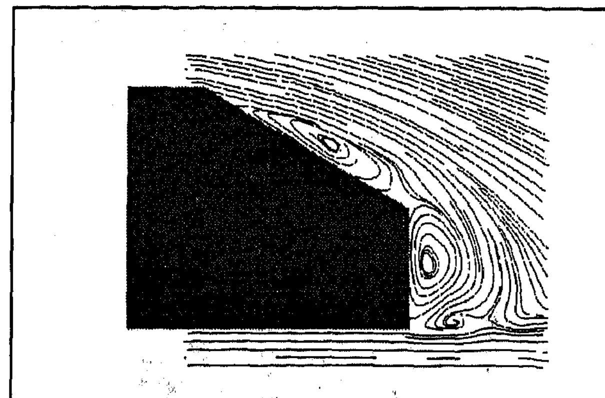

Figure 11. Centerplane streamlines showing separated region; back-light angle = 30°.

Figure 14 shows the comparison between the simulated back flow structures for 30 and 35 degree back-light angles. A clear distinction can be observed between the two cases. At 30 degrees can be observed well formed side vortex and separation babble. The case at 35 degrees clearly shows the complete separation.

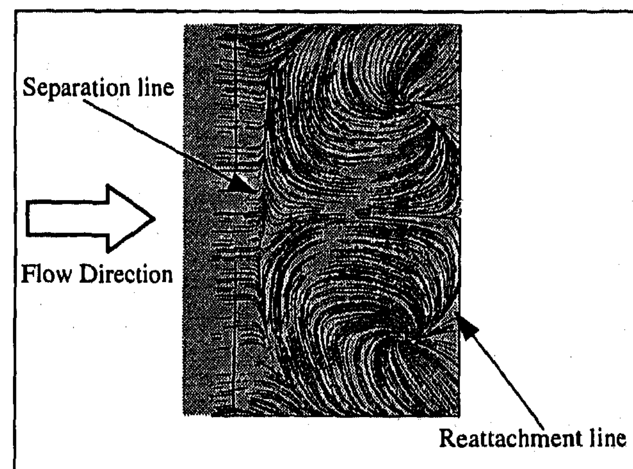

Figure 12. Simulated surface oil flow patterns showing reattachment line; back-light angle = 30°.

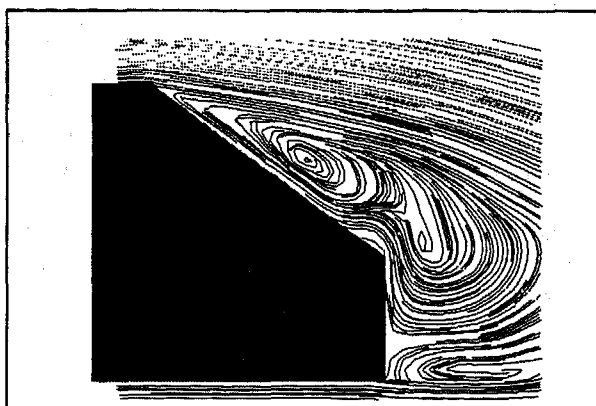

Figure 13. Centerplane streamlines showing separated region; back-light angle = 35°.

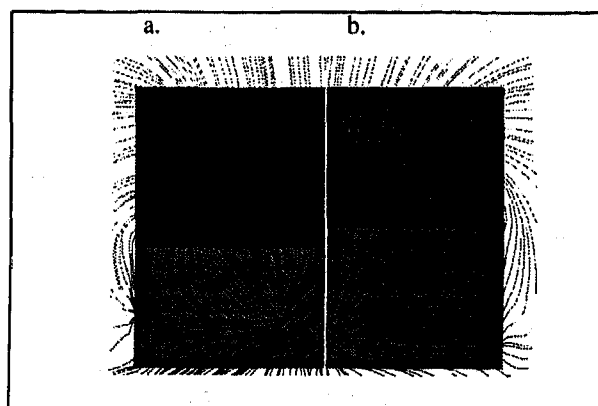

Figure 14. Backplane streamlines; a.) back-light angle = 35°, b.) back-light angle = 30°.

CONCLUSION

The present study illustrated the simulation of fluid flow over the Morel body at several different back-light angles. The computed drag and lift coefficients are in very good agreement with experimental data. Vortex breakdown phenomena were accurately predicted. Furthermore, the obtained flow structures clearly agree with the experimental observations by Morel [1] and Ahmed *et al.* [3]. The agreement between the predictions and measured values clearly demonstrate the capability of *DIGITAL PHYSICS* to simulate high Reynolds number external fluid flows.

ACKNOWLEDGMENTS

The authors would like to thank Jonathan Rothstein and Mark Casella for their considerable effort in the completion of the figures presented in this paper. The authors would especially like to thank Steve Remondi for his contribution to this project.

Driver Car Following Behavior Under Test Track and Open Road Driving Condition

R. Wade Allen, Raymond E. Magdaleno

Advanced Vehicle Technology, Ford Motor Co.

ABSTRACT

This paper describes the results of an experiment concerning driver behavior in car following tasks. The motivation for this experiment was a desire to understand typical driver car following behavior as a guide for setting the automatic control characteristics of an ACC (Adaptive Cruise Control) system. Testing was conducted under both test track and open road driving conditions. The results indicate that car following is carried out under much lower bandwidth conditions than typical steering processes. Dynamic analysis shows driver time delay in response to lead vehicle velocity change on the order of several seconds. Typical longitudinal acceleration distributions show standard deviations of less than 0.05 g (acceleration due to gravity). Distributions of time headway (following distance divided by following vehicle speed) show conservative behavior by some subjects while others had median values on the order of 1.0 second, and significant occurrences of following between 0.5 and 1.0 seconds.

INTRODUCTION

The driving task can be broadly categorized according to control, guidance and navigation functions that determine vehicle path and speed profile. Control covers psychomotor functions that stabilize vehicle path and speed against various aerodynamic and road disturbances and assist in traffic interactions such as car following. Guidance involves perceptual and psychomotor functions coordinated to follow delineated pathways, adhere to implied speed profiles, interact with traffic and avoid hazards. Traffic control devices, including road markings and signs provide a significant input to the guidance level in path following and speed selection. Navigation involves higher level cognitive functions applied to path and route selection and decisions regarding higher level traffic interactions (e.g., avoiding congestion).

A considerable range of past research has focused on driver steering control and following delineated pathways with more limited attention to speed selection and control. The research discussed in this paper concerns driver headway and speed control during car following. The speed control aspects of car following can relate generally to driver closed loop response to aerodynamic disturbances and roadway geometry. The guidance aspects of car following include perception of lead vehicle headway and relative velocity and closed loop control of following distance. This research was motivated by a desire to understand the dynamics of driver headway control as a guide for setting the automatic control characteristics of Adaptive Cruise Control (ACC) Systems.

BACKGROUND

Past research on car following has dealt with driver headway control models and measurements of driver behavior. Pipes [1] carried out fundamental work in this area, and Bekey, et al. [2] provided a useful summary of past work and further analysis on the general problem of driver lead car following. These early control models assumed that during car following the driver attempts to minimize velocity differences with a lead vehicle (i.e., a well defined stimulus). Recent work on ACC (Adaptive Cruise Control) systems by Fancher, Bareket, et al., (3) and Sayer, Fancher, et al., [4] has produced some data on velocity, range and range rate distributions of drivers during car following.

Data collected by Chandler, et al. [5] has shown that the driver can be characterized according to a closed loop bandwidth (gain or crossover frequency) of 0.37 rad/sec and a time delay of 1.5 seconds in responding to changes in lead vehicle velocity. Note that this bandwidth is a factor of 10 slower than compensatory steering bandwidth, e.g. Allen [6]. Torf and Duckstein [7] also have collected data on driver detection times for several levels of lead car acceleration. They found detection times of 1.9 seconds for a lead car acceleration of 2.5 ft/sec^2, and 2.5 seconds at an acceleration of 1.6 ft/sec^2. By regression analysis they also determined that response time decreased by 0.8 seconds for each increase of 1 ft/sec^2 in lead car acceleration. This may relate to the amount of time required to sense a velocity change (i.e., higher accelerations give more rapid change in lead car range and range rate).

SIMPLE CROSSOVER MODEL — The early speed control models cited above [1,2,5] can be summarized with the classical Crossover Model of McRuer and Krendal [8] as illustrated in Figure 1. Here, the driver responds to velocity errors with throttle commands such that vehicle longitudinal acceleration is proportional to the error. In this model the driver/vehicle response is simplified to a gain (the proportionality constant between velocity errors and longitudinal acceleration), time delay between velocity error and acceleration, and a pure integration to derive vehicle speed from longitudinal acceleration.

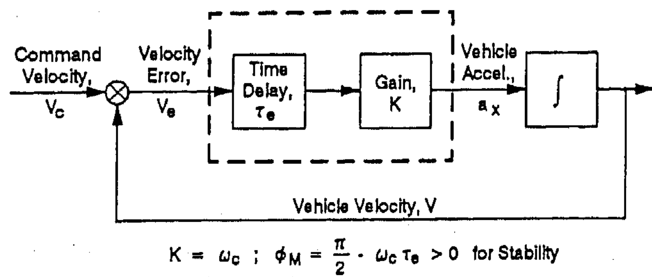

Figure 1. Simple "Crossover" Control Model for Speed Control

The Crossover Model for human control systems is efficient for experimental measurement as it can be compactly characterized by two parameters, the gain or crossover frequency (ω_C) and the time delay (τ_e)[8]. If we take the Fourier transform, e.g. Truxal [9], of the equations describing the Figure 1 system we have the following transfer function:

$$F\left(\frac{V}{V_e}\right)_{j\omega} = \omega_c e^{-j\omega\tau_e}$$

where (1)

$$\omega_c = K \text{ and } j = \sqrt{-1}$$

In the crossover model characterization of manual control system dynamic behavior, crossover frequency is a measure of the system (driver/vehicle) bandwidth, and the product of crossover frequency and time delay is a measure of system damping:

Crossover Frequency = $\omega_c \approx$ Bandwidth

Phase Margin (system damping) = $\phi_M = \pi/2 - \omega_C \, x \, \tau_e$ (2)

In the above equation ω_C is given in radians/second, τ_e is expressed in seconds and ϕ_M is given in radians. When Phase Margin goes much below unity (1.0 radian or about 60°), the system response is oscillatory. Phase Margin goes to zero, the system becomes unstable.

The Crossover Model is a convenient means for simply characterizing manual control system behavior that can easily be derived from FFT transfer function data. Even though we may postulate more complicated engineering control system models, the crossover model provides a simple basis for summarizing the dynamic behavior of a compensatory system. These two key parameters, crossover frequency (ω_C) and phase margin (ϕ_M), provide a means for characterizing the bandwidth and damping of the closed loop manual control system that can be conveniently statistically analyzed to provide a summary of typical behavior and variation across a group of subjects.

In this research it is of interest to simply characterize the dynamic coupling between the following and lead vehicles. The above crossover model parameters can also be interpreted in terms of a closed loop natural frequency by using the Pade approximation for a time delay, e.g. Truxel [9]:

$$e^{-j\omega\tau_e} = \left(j\omega\tau_e +\right)^{-1}$$

where (3)

$$j = \sqrt{-1}$$

Given the above approximation, we can then derive the closed loop transfer function which is given by:

$$\frac{\omega_c / \tau_e}{(j\omega)^2 + j\omega / \tau_e + \omega_c / \tau_e} \qquad (4)$$

where the closed loop natural frequency (ω_n) and damping ration can be expressed as follows:

$$\omega_n = \sqrt{\omega_c / \tau_e}; \zeta_n = 1/2\sqrt{\omega_c \tau_e} \qquad (5)$$

EXTENDED CROSSOVER MODEL — The above simple crossover model can be extended to include maintenance of a desired headway as illustrated in Figure 2. Here, a command feed-forward for headway has been added with the additional parameter a which is low frequency (i.e., long time constant) effect. The extended crossover model controls to minimize velocity errors (V_e) just as with the simple crossover model. In addition, the extended crossover model also develops an additional headway error term (R_e) which is also minimized, but at a much slower rate than the velocity errors.

The extended crossover model has a bandwidth that is approximately equal to the simple crossover model. Because of the higher frequency dynamics of the low frequency a term the phase margin now has an extra component:

Phase Margin = $\phi_M = \pi / 2 - \omega_c x \tau_e - \alpha / \omega_c$ (6)

In the above formula, α is expressed in the units 1/second and can be interpreted as the low frequency bandwidth for headway distance control. This extra phase component allows a simple means for identifying the α parameter in transfer function phase data.

APPROACH

The data processing and analysis used in this paper involves frequency domain procedures designed to identify transfer functions and parameters for crossover models desribed above. These procedures start with time histories of key

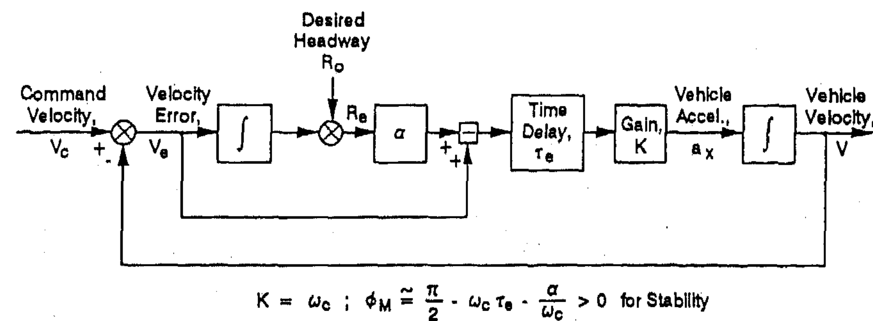

Figure 2. Extended Crossover Model for Speed and Headway Control

variables (e.g., throttle, speed, range) that define the basic human/machine system dynamic response. These time histories are then transformed using FFT (Fast Fourier Transform) procedures to give frequency domain transfer functions between key variables as discussed in Bendat and Piersol [10] and Randall [11]. The FFT procedures are analogous to linear regression analysis procedures that define the relationship between a dependent variable and an independent variable in terms of correlated and uncorrelated components.

With FFT analysis the correlated response between independent and dependent time histories then defines a transfer function that expresses an input/output relationship (e.g. driver throttle response to changes in lead vehicle headway) between key system variables. Given a transfer function, parameter identification procedures can then be used to identify key system characteristics such as driver/vehicle time delay and gain in response to lead vehicle velocity changes.

Measured time histories of key variables were recorded during experimental runs and converted to binary form including scaling constants to allow for maximum efficiency in processing and storage. The time histories were initially manually screened to locate regions of artifact free response, and to screen out segments containing drop outs in sensor response. This was particularly important regarding the range sensor data in both the test track and open highway experiments. The range signal would drop out if range became too large or a combination of lateral position and road curvature caused the lead target vehicle to exceed the limits of the sensor azimuth field of view.

Good sections of time history response were identified for further FFT processing. Additional preprocessing was carried out by applying taper windows to minimize transient artifacts associated with selecting data time windows where the time histories are abruptly started and stopped. The data were then processed by an advanced FFT routine that provided power spectra and transfer functions and coherence functions between selected variables. The coherence function is the equivalent of a linear correlation function, and defines what percentage of an output signal in a given frequency region is linearly correlated with an input signal. Typically the coherence values are used to select transfer function points that are reliable (high coherence) and reject unreliable measurements (low coherence) as indicated in the example transfer function plot in Figure 3.

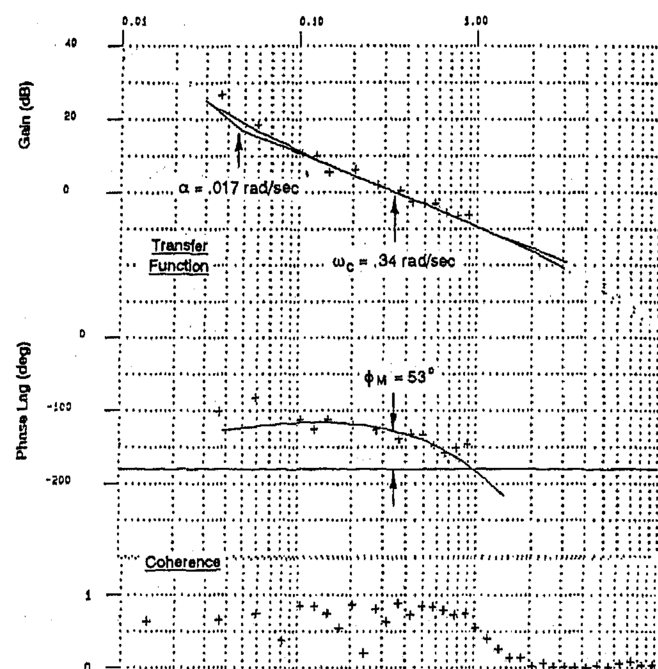

Figure 3. Example Plot of FFT Results and Crossover Model Parameter Identification

Transfer function and coherence data were plotted as indicated further on to highlight reliable transfer function data and to allow for simplified parameter identification. If it is assumed that the driver/vehicle system can be described by the simple gain and time delay model used by previous investigators, then these parameters can be easily identified from transfer function plots such as Figure 3. The gain is identified from the amplitude plot at the zero dB crossover point, and the time delay is obtained from the phase plot in the region of crossover. The α parameter in the extended crossover model is identified in the low frequency region well below crossover based on increased phase shift with decreasing frequency. The Figure 3 transfer function was derived by taking the ratio between the range signal FFT (driver input) and following vehicle velocity (driver/vehicle response) and analytically accounting for the kinematic integration between velocity and range

An example of the vehicle dynamics for longitudinal speed control are illustrated by the transfer function plot in Figure 4. This vehicle transfer function was derived by taking

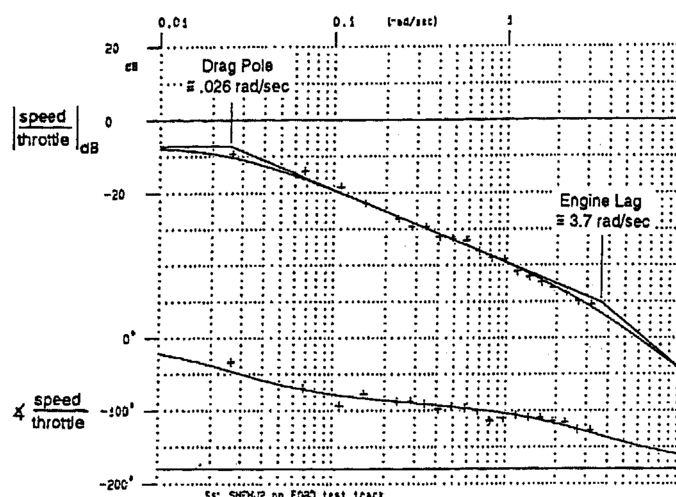

Figure 4. FFT Identification of Longitudinal Vehicle Dynamics Transfer Function

the ratio between the vehicle velocity FFT (output) and the throttle signal (input). The transfer function model fit to the FFT data involves a low frequency pole associated with vehicle aerodynamic drag and a high frequency pole associated with engine throttle response lag. The Figure 4 data show that longitudinal vehicle dynamics can be approximated over a wide frequency range by a pure integration as assumed in the crossover models of Figures 1 and 2.

Distributions of longitudinal acceleration and time headway (lead vehicle range divided by following vehicle headway) were derived directly from any artifact free time history data. In long test track or open road runs, the time series were screened for artifacts (mainly range dropouts), and the distributions were based on the remaining data.

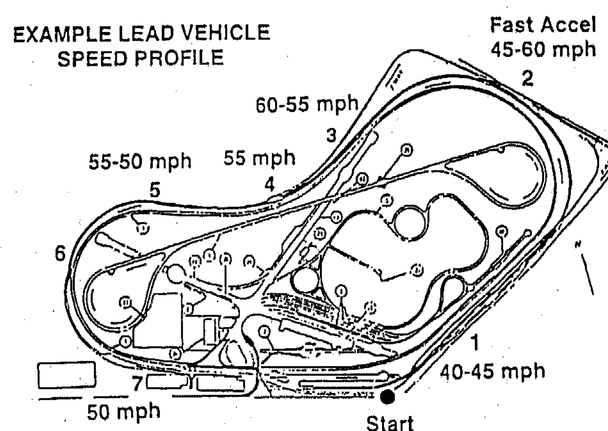
METHODS AND PROCEDURES

TEST TRACK EXPERIMENT — Twelve Ford employees (seven men and five women) took part in the study. The human use research protocol for this study required the participants to be company employees. A reasonable distribution of age and gender was achieved as indicated in Table 1a.

Two test vehicles with automatic transmissions were utilized in the study; the lead vehicle was a midrange four door sedan and the follow vehicle was a midrange sport coupe. The follow vehicle was instrumented with a radar sensor mounted on the center of the front bumper to measure the distance of the lead vehicle with respect to the follow vehicle. Throttle angle (degrees), brake pressure (psi), and velocity (mph) of the follow vehicle were also recorded. Custom-written data acquisition software was used to collect and record data at a frequency of 20 Hz on an IBM PC-compatible computer located in the trunk of the follow vehicle. During testing, an IBM Thinkpad was used to view the data as it was collected. Interference from other vehicles on the test track as well as lap completion times and the time at which climate control tasks were performed (as explained below) were recorded and time-synched with the data file.

The low speed test track at the Ford Dearborn Proving Grounds, shown in Figure 5, was used in the study. The track is 4.3 kilometers long and has six curves varying in radii from 606 to 241 meters. Participants were greeted by the experimenter at their workplace and driven to the test track in the follow vehicle. They were first given a brief overview of the study and then filled out a consent form indicating their willingness to participate in the study and a biographical form which provided the experimenter with information regarding personal characteristics (e.g., date of birth, occupation, etc.) and driving habits (e.g., vehicle driven, annual mileage, etc.).

The test participants were instructed to follow the lead vehicle as they normally would as if they were driving in traffic. They were told that the objective of the study was to evaluate the usability of a climate control system in order to encourage natural car following behavior. The driver of the lead vehicle produced what appeared to be a random speed profile during the study. A majority of the time the lead vehicle driver used cruise control inputs to maintain uniform acceleration and deceleration rates; brake pedal and accelerator pedal inputs were used three times. The speed of the lead vehicle ranged from 30 to 60 mph for all of the laps. The number of speed changes per lap ranged from two to five. An example lead vehicle speed profile for a lap is indicated in Figure 5.



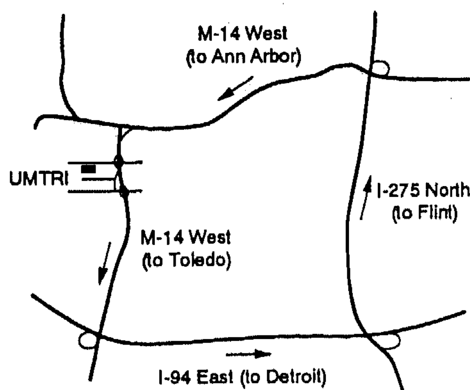


Figure 5. Ford Low Speed Test Track

Each participant drove six laps around the test track. On the final three laps, each participant performed a total of nine tasks using the climate control system as instructed by the experimenter. Examples of some of the tasks included increasing the temperature three degrees, checking the outside temperature, and decreasing the fan setting to the minimum output. At the end of the session, participants were driven back to their workplace. Each test session lasted approximately one hour.

OPEN ROAD EXPERIMENT — Researchers at the University of Michigan Transportation Research Institute (UMTRI) collected manual control data under open highway conditions. The manual control condition was one of three that was investigated; the other two conditions involved driving using conventional cruise control and driving using adaptive

cruise control where vehicle speed and headway is controlled relative to a forward vehicle in the same lane.

Thirty-six drivers (18 men and 18 women equally divided into three age groups (20-30 years, 40-50 years, and 60-70 years), were recruited from a local driver and vehicle licensing office to serve as participants. The subjects drove a 1993 compact imported sedan, instrumented with an infrared headway sensor, around a 88.5 kilometer (55 mile) route in Southeast Michigan that took approximately 50-60 minutes to complete. The highway route and average traffic density conditions are summarized in Figure 6. The study was run

Segment	Average Volume	Lanes
US 23 (South)	44,000 - 56,000	2
I-94 (East)	60,000 - 91,000	2-3
I-275 (North)	45,000 - 112,000	3-4
M14 (West)	43,000 - 70,000	2-3

Source: Michigan Department of Transportation (1993)

Figure 6. Open Road Test Route

during non-peak travel times, and due to the open road conditions was less controlled than the Ford test track study. While a variety of data were recorded, the following six measures were supplied for analysis herein: acceleration, engine throttle position, brake pedal depression and velocity of the instrumented test vehicle, and range and range rate to lead vehicles

RESULTS

DATA ANALYSIS — Data on vehicle speed, longitudinal acceleration and lead vehicle range and range rate were collected on a lap top computer and stored in data files. This data was subsequently analyzed using several time series analysis programs. Figure 7 shows a time series for a good test track data set. This time series was analyzed with FFT procedures which resulted in the transfer function data shown previously in Figure 3. The transfer function estimates represent frequency points that reached a coherence value of .65 or greater in the analysis procedure. The transfer function estimates span the crossover frequency region (.34 rad/sec). The model fit gives reasonable representation of the FFT data, and is consistent with both simple and extended crossover model interpretations.

Figure 8 a) shows a typical time trace of one subject's data during the open road experiment. Range dropouts are apparent in the data which limit FFT analysis. However, time windows were identified as indicated where reasonable FFT analyses could be obtained. Figure 8 b) shows a time expansion of data selected for FFT analysis. Data quantization can be noted here, which illustrates digital resolution in range, range rate and speed. The range drop outs plus quantization place some limitation on the quality of subsequent FFT analysis of the open road data.

Ffigure 8. Example Open Road Time History Data

DYNAMIC COUPLING — Simple crossover model (crossover frequency, phase margin and time delay) data is summarized for both the test track and open road experiments in Table 1. Note that the average crossover frequency is .21 rad/sec and phase margin is 0.7 radians for the test track data and 0.76 radians for the open road data. Equivalent time delays, as derived from the crossover frequency and phase margin, are 3.28 and 4.96 seconds respectively for the track and road data. If the open road time delay data outlier at 11.47 seconds is ignored, the track and road data sets are quite comparable. The phase margins indicate loop closures that range from critically damped to slightly under damped. The closed loop bandwidth and damping defined by Equation 5 were calculated for the track and road data and are also summarized in Table 1. Here we see that the closed loop damping is quite stable across subjects for both sets of data and indicates a slightly under damped condition.

For the test track data there is some tradeoff between driver dynamic behavior and performance. Figure 9 illustrates that driver time delay decreases and crossover frequency increases with decreasing headway time. This result is consistent with more aggressive control for shorter headway times. Multiple regression analysis was performed with headway (T_H) as the dependent variable and crossover frequency (ω_c), phase margin (ϕ_M) and effective time delay (τ_e) as independent variables. The results are summarized in Table 2, which shows that the slopes of crossover frequency and time delay are a significant function of headway time, while phase margin (a measure of closed loop control damping) is not dependent on headway time. These results indicate that driver dynamic behavior is generally related to headway time, with shorter headways leading to more aggressive driver control.

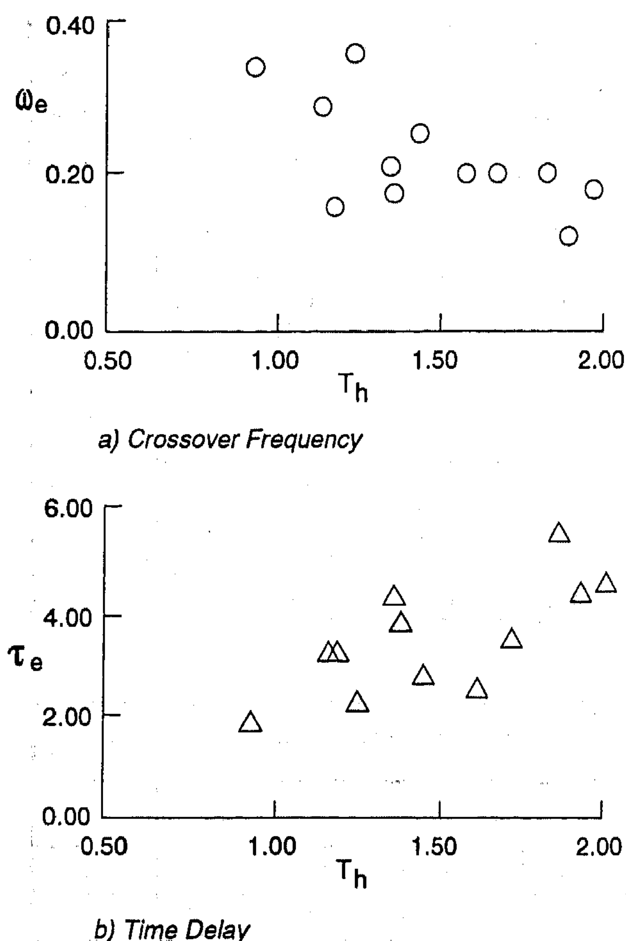

Figure 9. Test Track Crossover Frequency and Time Delay Data vs. Headway Time

The test track FFT data was also used to fit the low frequency parameter α (Figure 2) associated with outer loop hadway control (low frequency data quality was too variable in the road set to permit reliable α identification). Since a accounts for some of the open loop phase lag, the associated driver time delays are somewhat reduced as summarized in Table 3. Here we see that α, which is the equivalent of the bandwidth of the headway or range control loop, is an order of magnitude lower than the inner velocity control loop bandwidth given by the crossover frequency ω_c.

CONTROL AND HEADWAY DISTRIBUTIONS — Distributions of longitudinal acceleration for both the track and road experiments are summarized in Figure 10. Here we see that the acceleration distributions during car following are remarkably similar between subjects and between test track and open road. Maximum values are less than 0.3 g, and standard deviations are less than 0.05 g (1.0 g equals the acceleration due to gravity or 32.2 ft/sec^2). The variation is greater on the open road probably due to the more varied driving conditions. The closed throttle deceleration of modern aerodynamically designed passenger cars is on the order of 0.1 g which probable explains the lower distribution limit. The distributions appear to be reasonably symmetrical, and the upper distribution limit indicates conservative use of engine throttle to match lead vehicle velocity and maintain headway.

Given the longitudinal acceleration described above, the driver can still choose to follow a lead vehicle at any desired distance. Typical time headway distributions are shown in Figure 11. Here we see more variability between drivers in headway time than in their longitudinal acceleration distributions. We also note that the open road drivers exhibit more variability than the test track drivers. Some subjects spend a significant portion of their car following exposure at headway times of less than 1.0 seconds which might be considered fairly risky behavior. The oft stated rule of thumb of a minimum of one car length (approximately 15 feet) for each ten miles per hour of speed (approximately 15 feet/sec) gives an equivalent headway time of 1.0 seconds.

Range and velocity limits were applied to the open road headway data in Figure 11b in order to make the following conditions more consistent with the test track conditions. In Figure 12 we show open road distributions without any range or velocity limits. Here we see that occurrence of large time headways increases dramatically. In Figure 12 we also compare our instrumented vehicle headway distributions with data collected on the highway with loop detectors as presented by Farber [12]. Here we see that the open road instrumented vehicle data is generally consistent with the ensemble data collected at a single location. The instrumented data presented here does show significant variations between drivers, which may be an important consideration when analyzing the effectiveness of crash avoidance systems.

CONCLUSION

We have successfully analyzed open road car following data and validated the general findings of a test track experiment of driver car following behavior. The overall objective of the manual headway control experiment was to measure the dynamic coupling drivers achieve with respect to a lead vehicle. We have a consistent measurement of this coupling under both test track and open highway driving conditions. The open road data appears to be less constrained which may be due to the influence of more uncontrolled variables such as the occurrence of interacting traffic and the drivers' general task demands.

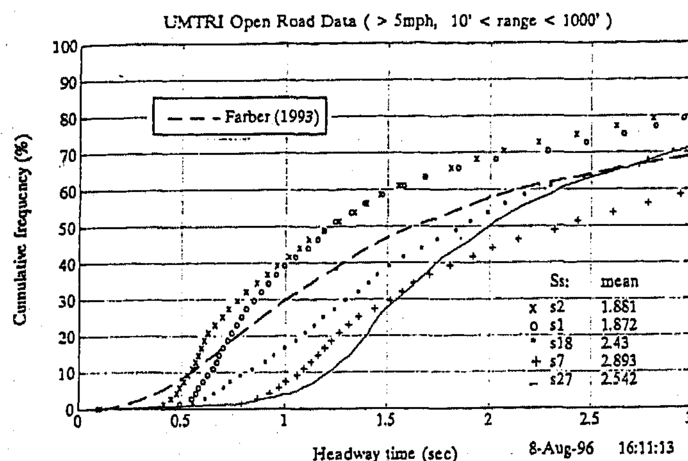

Figure 12. Open Road Headway Time Distributions Under Near Full Range Conditions: Speed Greater than 8 kph (5mph) and Range Interval 3-300 m (10-100 ft)

This study has identified driver headway control characteristics that are quite slow compared to other control processes such as steering for path following and maintaining lane position. The driver exhibits time constants and time delays on the order of several seconds to tens of seconds that limit the stable control bandwidth that can be achieved in maintaining headway. These continuous control time constants and time delays are probably due to processes associated with range and range rate perception, and should not be confused with discrete reaction times associated with braking which are considerably shorter.

ACKNOWLEDGMENTS

This work was sponsored by the National Highway Traffic Safety Administration. Mr. Michael Perel of the Office of Crash Avoidance Research served as the Contracting Officer's Technical Representative. We gratefully acknowledge the open road car following data provided by Dr. James Sayer of the Human Factors Division of the University of Michigan Transportation Research Institute.

Virginia Tech

ABSTRACT

The Unmanned Ground Vehicle Competition is jointly sponsored by the SAE, the Association for Unmanned Vehicle Systems (AUVS), and Oakland University. College teams, composed of both undergraduate and graduate students, build autonomous vehicles that compete by navigating a 139 meter outdoor obstacle course. The course, which includes a sand pit and a ramp, is defined by painted continuous or dashed boundary lines on grass and pavement. The obstacles are arbitrarily placed, multi-colored plastic-wrapped hay bales. The vehicles must be between 0.9 and 2.7 meters long and less than 1.5 meters wide. They must be either electric-motor or combustion-engine driven and must carry a 9 kilogram payload. All computational power, sensing and control equipment must be carried on board the vehicle. The technologies employed are applicable in Intelligent Transportation Systems (ITS).

A written design report and an oral presentation are required from each team, and expert judges evaluate these along with inspecting the actual vehicles. Design judging focuses primarily on the design process rather than the implementation of that design in the actual vehicle. The latter feature is evaluated by performance on the obstacle course. The team winning the design contest receives a $1000 award from SAE and is offered the opportunity to present their design paper at the SAE World Congress. The 1996 competition was held at Walt Disney World in Orlando on July 13- 15.

This paper presents the conceptual design of the vehicle and its components. Innovative aspects of the design are highlighted, along with descriptions of the electronics, software, computers, actuators, sensors, and the means of system integration. The steps followed in the design process are described along with the use of computer-aided design. Considerations of safety, reliability, and durability are included. The analyses leading to the predicted performance of the vehicle (speed, ramp climbing, reaction times, etc.) are also documented. Although not a factor in judging, the paper also includes a cost estimate (not counting student labor) for the final product if it were to be duplicated.

INTRODUCTION

CALVIN (Computerized Autonomous Land Vehicle with Intelligent Navigation), shown in Figure 1, is a battery powered three-wheeled vehicle with a computer vision system for line following and ultrasonic sensors for obstacle avoidance. CALVIN was one of two vehicles entered by the Virginia Tech Team in the 4th Annual International Autonomous Ground Vehicle Competition.

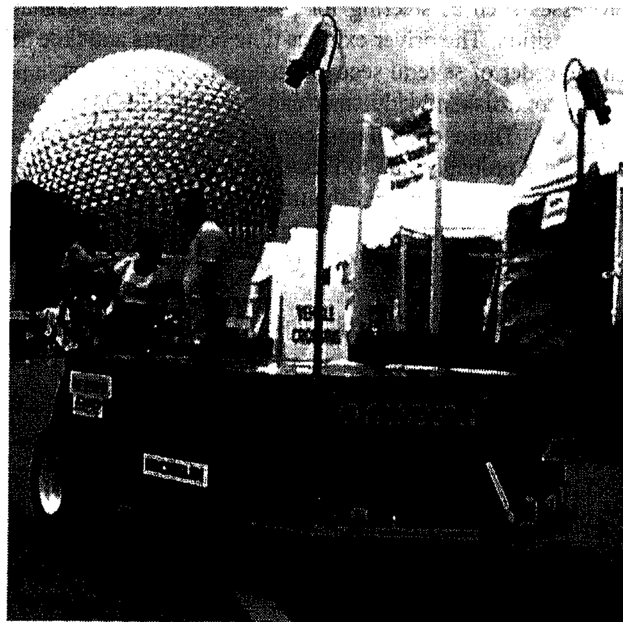

Figure 1 : Overview photo of CALVIN

This is the first year that Virginia Tech has participated in the competition. As part of our preparation, team members reviewed technical papers written by recent competitors and video tapes from the past two competitions. It became clear that the contest presents a formidable task and that a robust, well-developed and carefully tested design would be a basic requirement for success. With this in mind, the team made a concerted effort to pursue simple, reliable, cost-effective designs for the base components and subsystems. This is also the approach recommended by Gifford, et. al., [1995] as part of their winning philosophy in the 1995 competition. Keeping this approach in mind, CALVIN's design incorporates many of the features that have been used successfully in recent competitions. For example, like several past entrants, CALVIN is based on the chassis of a three-wheel golf cart.

Although this platform is larger than the ideal vehicle, it does provide a rugged, stable base with ample space for equipment and payload. Also following past successes, CALVIN uses a computer vision system for line following and ultrasonic sensors for obstacle avoidance. The innovative elements of the design can be found in those areas that caused failure or were recognized as problems in otherwise successful vehicles from past competitions. These innovative features are discussed in detail later in this paper.

PROJECT ORGANIZATION

PROJECT TEAMS - As one of the largest technical universities in the country, Virginia Tech has a talented and diverse student population from which to draw. Although many large projects (such as the SAE Mini-Baja and Solar Car) have been run in the past, this autonomous robotic project generated unparalleled excitement among students and faculty. A small team of volunteers began working to organize the project in the summer of 1995. By the fall semester, the combined team working together on the two vehicles had grown to almost 50 students from across the Colleges of Engineering and Arts and Science. To direct the efforts to build CALVIN, four separate groups were formed to cover Mechanical Design, Sensing & Control, Computer Vision, and Project Organization with each group subdivided to distribute the work. To facilitate group communication, meetings were held twice a week with monthly presentations given by each group.

PROJECT TIMELINE - Organization and scheduling is a key ingredient in the success of a project of this scope and duration. Although many intermediate objectives have been achieved along the way, major project milestones are shown on the general project timeline at the end of the paper.

DESIGN PROCESS OVERVIEW

GENERAL DESIGN DESCRIPTION - The general overall design of CALVIN will be described with reference to the photographs shown as Figures 2 and 3. Figure 2 shows a top view of CALVIN with the weather-protective top cover removed. The general layout of the base vehicle, along with a number of the major components, are visible in this picture. These components include the 24 volt drive motor, timing-belt drive and differential; the 12 volt linear steering actuator with integral feedback potentiometer; the microcontroller; the on-board emergency stop (e-stops); the three 12-volt batteries and the antenna for emergency stop and radio control when not in competition. The microcontroller and electronics mount to a hinged shelf that opens to give access to the pentium-based PC and power supplies. Figure 3 is a front view of CALVIN that shows the five bumper-mounted ultrasonic sensors and the two side-viewing cameras, along with some of the weatherproof Lexan used to encase the vehicle.

DESIGN TOOLS - As with all aspects of our design, the tools used in the creative process were dictated by the overall objective of producing a safe, competitive vehicle. All Virginia Tech engineering students are trained in the use of either AutoCad or Cadkey, and both were used extensively in the design process. The uses of computer-aided design ranged from preparing a test course layout with a shape similar to the sample course shown in the contest rules, to detailed layout of the vehicle systems and subsystems. As an example, AutoCad was used to produce a layout (Figure 4) of the existing base frame of the golf cart. Attachments and modifications were then based on these drawings. Other software used during the course of the project included

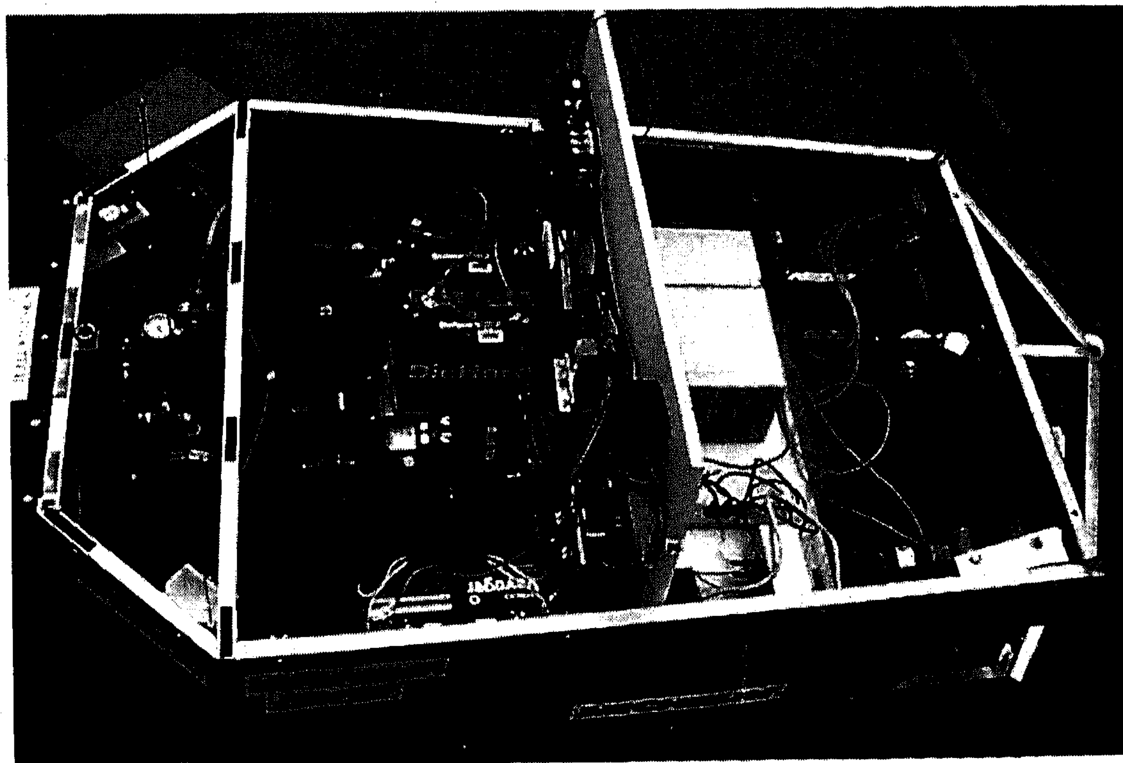

Figure 2: Top view photograph

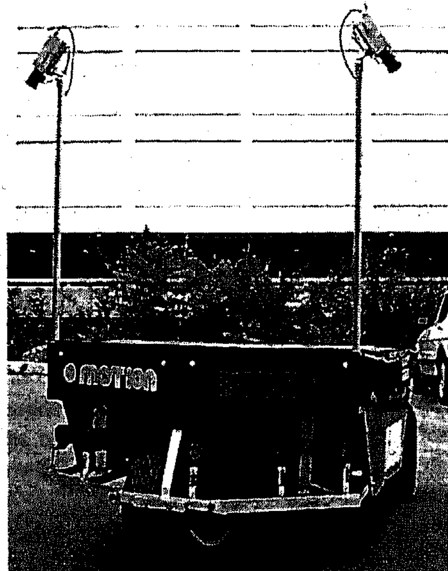

Figure 3: Front view photograph

spreadsheets, TKSolver!, MathCad and Mathematica for general mathematical modeling and MatLab for control and vibration analysis. Specialized software was also written to aid with steering kinematics and vision system modeling.

DESIGN CRITERIA (SAFETY, RELIABILITY AND DURABILITY) - The most critical design criteria were those that involved safety and those necessary to meet contest rules. Beyond these fundamental requirements, a continuing effort has been made to incorporate reliability and durability into the final design. This goal has been pursued both through the careful specification of proven, reliable components and through extensive field testing during every phase of the design. In subsequent sections, brief discussions will help to highlight the effort to produce an inherently safe, reliable vehicle. Safety was also a top priority in all shop work and during field testing.

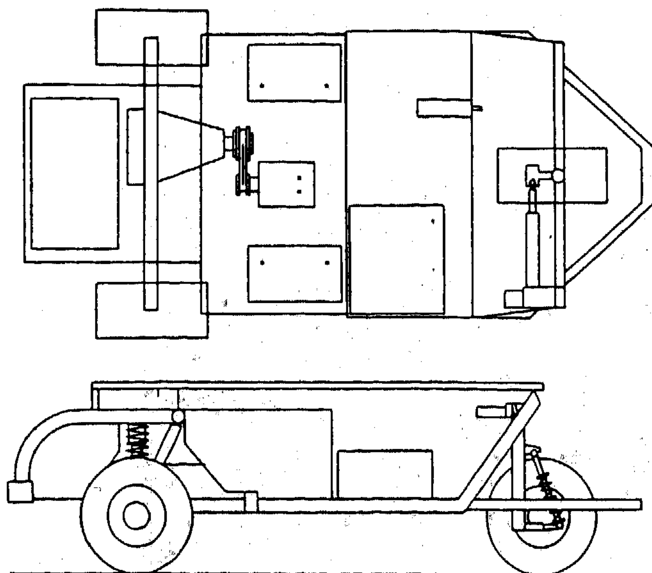

Figure 4: AutoCad Layout

FAIL-SAFE BRAKES - Acceptable braking performance was assured by using the primary components from the original golf-cart braking system. The only difference is that the actuating force normally applied by the user through the foot pedal has been replaced by a fail-safe input force from a pneumatic actuator. An electro-mechanical valve and relay system control the operation of the pneumatic actuator. While the vehicle is in operation, the main power bus closes the relay, powering the valve, thus keeping the brakes disengaged. When the circuit loses power, valve power is lost and the brakes are engaged. This condition occurs when either the onboard E-stop or the remote E-stop is activated.

STEERING ACTUATOR AND CONTROLLER - The rack-and-pinion steering system on the original golf cart was replaced with a 12-volt DC linear actuator with integrated position feedback. The motor in this system is controlled by a Pulse Width Modulation (PWM) controller. The input signal to this controller can be generated by either the microcontroller, in autonomous mode, or a radio control receiver in manual override mode. Manual override mode is used for transportation of the vehicle.

DRIVE MOTOR AND CONTROLLER - CALVIN's primary drive system uses a 0.746 kW, 24V DC motor with tachometer feedback for precise velocity control. Power is delivered to the rear wheels through a 1.8 to 1 timing belt reducer and the existing 6 to 1 golf cart differential. The speed of this motor is controlled using a PWM H-Bridge controller. The controller is capable of adjusting its PWM duty cycle so as to produce an effective continuous output voltage from -24 to +24 volts and a current of 160 amps continuous and 320 amps peak. Like the steering system, the input signal to the controller can be generated by either the microcontroller with active velocity control, in autonomous mode, or a radio control receiver in manual override mode.

ULTRASONIC AND TACTILE OBSTACLE SENSORS - CALVIN is equipped with two types of sensors in order to facilitate obstacle avoidance. First, a fan-shaped array of five ultrasonic sensors is used to locate obstacles potentially in the vehicle's path. In the event that an ultrasonic sensor detects an obstacle, an algorthim is run in order to determine how the vehicle's path should be changed. This routine considers the vehicle's distance to the obstacle, and which ultrasonic sensors in the array detected the obstacle.

The tactile sensors consist of three push-bars on the front of the vehicle. These sensors are used to indicate that the vehicle has collided with an obstacle. In the event that a tactile sensor is actuated, an interrupt routine immediately stops the vehicle and performs a reverse maneuver. The reverse maneuver steers the vehicle based upon which tactile sensor was actuated, in order to relocate the vehicle further from the obstacle. The vehicle then returns to normal operation and continues on its path around the track. The ultrasonic and tactile sensor arrays can be seen in Figure 5.

COMPUTER AND SOFTWARE - The vision system is implemented using a pentium 100MHz PC and an FF1 DSP Frame Grabber from Current Technology, Inc. All vision algorithms were developed using standard C and the frame grabber's C libraries. Standard C is also used to code and compile the software necessary to communicate between the computer and the microcontroller.

Figure 5: Ultrasonic and Tactile Sensor Arrays

The vision system is based on two cameras looking to the left and right of the vehicle, but only one camera is active at a time. When the active camera obtains a series of three consecutive poor images, the system switches to the view on the other side. Image processing is performed on a view of the course directly adjacent to the vehicle. Of this whole image, only two smaller regions of interest (ROI) are considered to be significant. All image processing is then performed on these ROIs only, in order to save computation time. The frame grabber first thresholds the gray-scale camera image to convert the image to binary black and white. The thresholding routine is dynamically adjusted for each ROI to recognize the white paint on grass as the brightest portion of the image. This means that the ROI images used to navigate consist of white line segments on an all-black background. The vision code then uses these two ROI to detect a forward and a rear segment of the course line. In order to discern the line, the routine finds the grouped blobs which it extracts as a segment of the line. The location of the centroids of these blobs are then compared to those found when initializing the vehicle in the center of the course. This information is used to determine the vehicle's distance and angle relative to the line defining the course. The superposition of this zeroth order and first order path information results in a desired steering angle. This angle is then processed to be transmitted to the microcontroller.

The microcontroller integrates the desired steering angle (based solely on vision) with information from the ultrasonic and tactile sensors. Priority must be assigned to obstacles potentially in the vehicle's path; therefore tactile and ultrasonic sensor information is, in some cases, weighted more heavily than the vision in determining the actual steering angle. Consequently, the microcontroller combines the three inputs to determine the path of the vehicle. In effect, the microcontroller performs all onboard navigation.

SENSORS, ELECTRONIC LAYOUT AND SYSTEM INTEGRATION - Figure 6 is a schematic diagram showing the general architecture and integration of the sensors, electronics and computers used on-board CALVIN. Once an image has been processed, the PC sends a steering angle to the microcontroller via a serial connection. If the course boundary line is not clearly detected by the vision system in several successive frames, the PC also sends a command to the microcontroller to switch to the second camera, and the vision system begins tracking the opposite line. Ultrasonic signal processing as well as integration and direct control functions are handled by the Motorola 68HC11-based microcontroller. This microcontroller also executes closed-loop control of the steering and drive motors using pulse-width-modulated signals. A schematic layout of the battery connections and power control elements is shown in Figure 7.

DESIGN PROBLEMS AND SOLUTIONS - Throughout the design process for CALVIN, precise design tools and techniques were used whenever possible. Occasionally, however, an event would arise where trial-and-error methods were necessary. The first arose from the imprecise geometry of the base frame. Calvin began as a golf cart, but came with no factory dimensions. Measurements were made and CAD drawings constructed, but the angles of the frame were difficult to accurately measure, and small differences had a great effect on the positioning of integral parts. This forced a trial-and-error technique on mounting the drive motor, steering actuator and tachometer.

Electrical problems are also unavoidable on a vehicle with so many components. Floating grounds and ground loops are primary contributors to these difficulties. During the layout and wiring of the vehicle, an effort was made to keep the wires as short and organized as possible to facilitate quick troubleshooting. Still care had to be taken to reduce the interference in many of the electrical components, most notably the cameras and the monitors. To do this, ground wires were consolidated, and shielded coaxial wire was used when possible.

PERFORMANCE PREDICTIONS

BRAKING AND SPEED CONTROL - The most critical performance issues were those that involved safety requirements and meeting contest guidelines. Braking and speed control, especially on an inclined surface, are obviously of great importance. An earlier section of this paper describes the design of the braking system and how the foot pedal input was replaced by a pneumatic actuator. Acceptable performance was assured by selecting an actuator that supplied the same brake cable tension as a typical user would supply through the brake pedal in an emergency condition (roughly 500N).

Accurate speed control is important for safe vehicle operation and for assuring constant performance of the vehicle on sloped surfaces. Several past contestants reported control problems that were directly attributed to speed variations. Velocity is controlled on CALVIN using a tachometer attached directly to the output shaft of the drive motor to provide a voltage signal proportional to vehicle speed. This signal is fed back to the microcontroller, which issues a pulse-width-modulated control signal to the motor driver. By modeling the vehicle as a mass moving on a frictionless surface, control system gains can be selected to give stable velocity control with an adequate response time.

RAMP-CLIMBING CAPABILITIES AND SAND PIT PERFORMANCE - Competition rules permit ramps or inclined terrain to have a grade of up to fifteen percent. This information, coupled with the 8.04 km/hr maximum allowed speed and the vehicle's estimated weight, can be used to directly compute the minimum required power of the drive motor (since power equals force multiplied by velocity in the direction of the force). A twenty

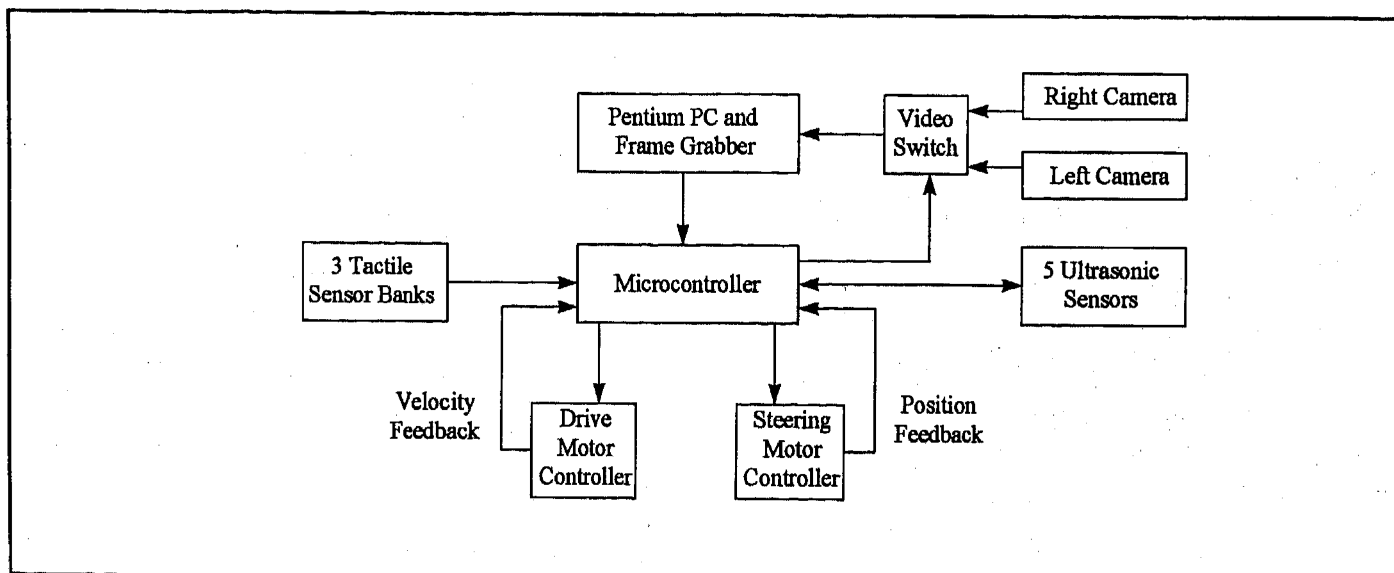

Figure 6: Sensor and control integration

percent grade and a 8.04 km/hr vehicle speed produce a vertical velocity component of 1.61 km/hr. Assuming a 1780 N vehicle weight and no friction results in a required drive motor of about 0.746 kW. Recognizing that steep inclines would be traversed at 1.61 km/hr or less, this was taken to be a conservative estimate. A 0.746 kW continuous, 1.49 kW peak, 24 volt DC drive motor was selected and purchased from a surplus catalog. Using a speed reduction of about 10:1 through a timing belt drive and the golf cart differential, the desired 8.04 km/hr peak speed and ramp-climbing ability were achieved as predicted. Designing a vehicle to traverse a sand pit was a less precise prediction. Goodyear, who donated the vehicle tires, provided assurances that these wide, soft tires would perform well in sand and would not damage the grass portion of the course.

REACTION TIMES AND LINE-TRACKING PERFORMANCE - With any digital control system, the faster the update speed of the controller, the more stable the performance of the controlled device under rapidly changing conditions. The computer vision and ultrasonic acquisition and computation requirements obviously limit the overall update rate of the controller. The team attempted to partially address this issue during conceptual design by separate, parallel processing of the ultrasonic and vision feedback. The vision feedback processing is accomplished directly on the frame grabber card or in the host Pentium 100 MHz personal computer. Operation of the ultrasonic sensors and the associated processing are accomplished in the Motorola 68HC11-based microcontroller. This allows a maximum update rate to the steering and drive motors of about 6 Hz. At peak vehicle speed, this amounts to an update about once every 0.3 m of travel. Through testing, this has been determined to be marginal for robust line tracking; one or two bad images can result in the vehicle traveling out of bounds. Nevertheless, within the constants of the existing equipment, this is a reasonable update rate. At competition, we intended to run CALVIN at peak speeds of about 3.22 km/hr to maintain stable operation.

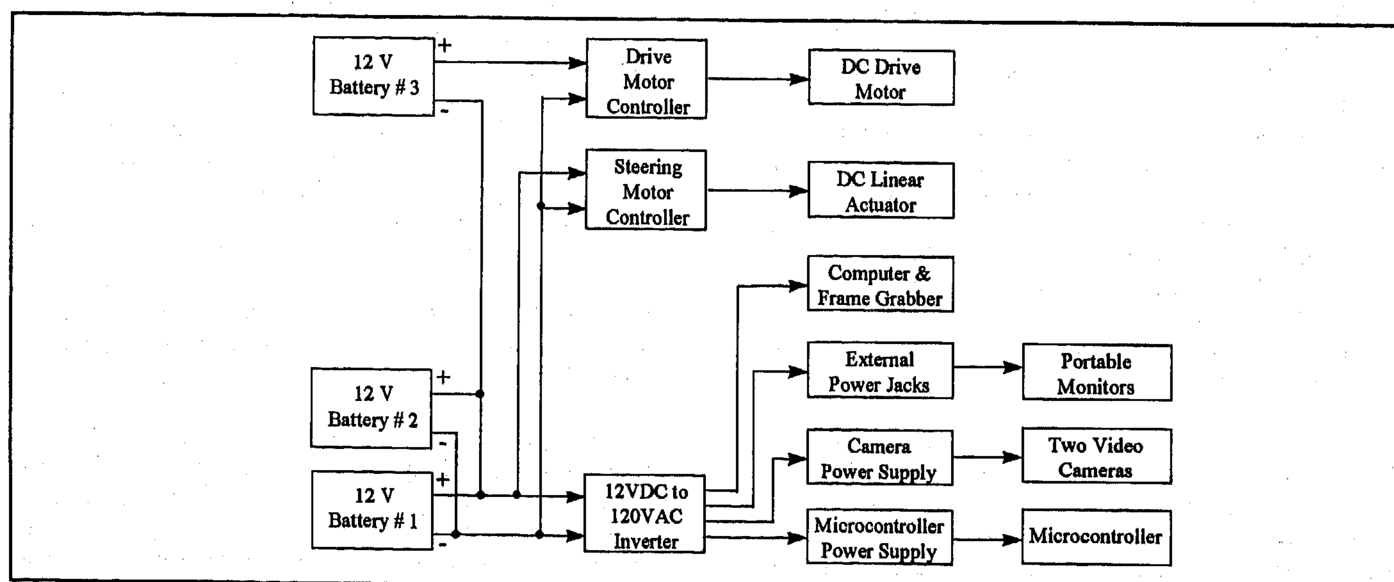

Figure 7: Power supply diagram

INNOVATIVE ASPECTS OF THE DESIGN

The design philosophy used in developing CALVIN did not specifically include innovation as a design objective. Our primary objective was to design the most competitive possible vehicle under the constraints of the governing contest rules and limited financial resources. Nevertheless, the resulting design is believed to be innovative in several significant respects. In all cases, however, the innovative features are intended to address problems or shortcomings reported in similar vehicles from previous competitions.

A simple example of this was the design of a system that uses only three 12-volt deep-cycle batteries as the source for all on-board power. Power for the PC and peripheral equipment was supplied using an 400 Watt inverter to generate 120 volt AC power. Other DC power requirements were met through small on-board power supplies or through series connection of the batteries. This power supply arrangement was previously shown as Figure 7. While this may seem to be a minor issue, a number of previous teams, including the first-place 1995 Colorado team [Gifford, 1995], cited the maintenance of several dissimilar batteries as a significant disadvantage. The University of West Virginia team also cited the weight penalty and potential danger associated with their eight- battery, 96-volt DC bus system [Banta, 1995].

A second, and more significant, innovative feature of CALVIN is the use of two independent cameras for line tracking. This innovation is an attempt to address, in a cost-effective way, the problems noted by 1994 and 1995 competitors with single-camera systems [Murphy, 1995, Gifford, et. al., 1995]. Originally, the team hoped to use two cameras and two independent frame grabbers. With such a system, each camera could continuously track one of the two course oundary lines. Unfortunately, two frame grabber cards or a single multi-input frame grabber proved to be too expensive, and an alternative innovative solution was pursued. The end result was to use a simple relay-actuated video switch to change camera views when the course boundary lines disappeared or became difficult to detect. Using a line-integrity check based on the size and grouping of white image areas, the computer vision system makes three attempts to find a line with the current camera. If two successive attempts fail, the vision software sends a command to the microcontroller to switch to the camera on the other side of the vehicle and begin tracking the opposite line. Based on a video update rate of at least six frames per second (bad images can often be rejected quickly, resulting in a higher rate), and a maximum speed of 8.04km/hr, the vehicle will travel no farther than 0.244 m in this time.

A third innovative feature of CALVIN's design is the use of a radio controller to generate the same PWM signals as the microcontroller for the steering and drive motor controllers. This allows simple switching between autonomous and manual modes, which greatly facilitates vehicle setup and testing. During normal operation, all user interaction with CALVIN is through the radio controller or through a single weather-resistant control panel mounted on the left rear quarterpanel of the vehicle. This control panel is shown in Figure 8 below. While this is again a simple feature, it is a clear improvement over the interfaces used by vehicles in previous competitions, many of which required awkward interactions including manual pushing for placement and setup.

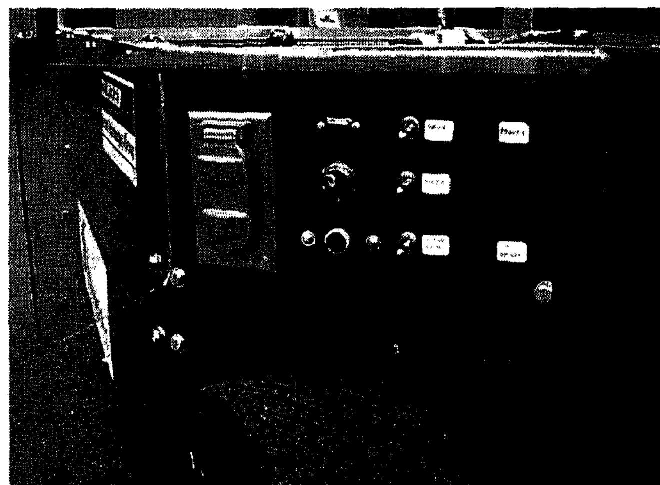

Figure 8: The control panel

A fourth innovative feature of CALVIN is the separation of data processing between the PC and the microcontroller. Since data processing speed has historically limited other vehicles maximum speeds [Cheok, 1994, Nagy et. al., 1995], a system was designed to process data in parallel. By processing closed-loop velocity and steering control, as well as ultrasonic and tactile sensor data on CALVIN's microcontroller, the PC is used solely for the computationally intensive vision algorithms. This separation of data processing greatly reduces the total processing time, therefore increasing the maximum sustainable vehicle speed.

VEHICLE COST AND FUNDING SOURCES - The table at the end of the paper lists the ready-made components that were purchased or donated. Separate columns list both the retail cost and the purchase price of the component. Note that many items were either donated or sold to the project team at a substantially reduced cost. Also note that all fabricated components, such as mounting brackets, sensor housings, framework, bumper and the Lexan outer shell, were built by members of the design team in the student shop of the Mechanical Engineering Department. In addition, team members did a great deal of electronic design and circuit fabrication. It is estimated that approximately 5000 person hours have been invested in this project. This includes time spent on activities such as project organization, fundraising, publicity, and research.

COMPETITION RESULTS

The 1996 Unmanned Ground Vehicle competition held at Walt Disney World, Epcot Center July 13-15, was composed of two sub-competitons. The first was the SAE Design Competition, which evaluated the written report, an oral presentation and a static viewing for each vehicle.

The second competition was the obstacle course race. All vehicles were given three attempts at completing the course, and the vehicle to complete the course in the shortest amount of time, or to proceed the furthest in any one run would be declared the winner of this competition.

Virginia Tech's CALVIN vehicle was declared the winner of the SAE Design Competition. Virginia Tech' s other vehicle, BOB, scored third place in the SAE Design Competiton. The

winner of the obstacle course race was Ohio State University's vehicle. Virgina Tech' s obstacle course race results were 13th and 6th for CALVIN and BOB respectively.

ACKNOWLEDGMENTS

Thanks to the many corporate sponsors and to the Departments of Electrical and Mechanical Engineering for making this project possible. Special thanks to Mr. William Agnew of SAE for carefully reviewing this document before final submission.

New Thermal Infrared Sensor Techniques for Vehicle Blind Spot Detection

John W. Patchell and R. Steven Hackney
A.L.I.R.T. Advanced Technology Products
Toronto, Ontario

ABSTRACT

Vehicle Blind Spot Detection (BSD) represents a logical first step towards a comprehensive Collision Avoidance strategy as envisioned in plans for the Intelligent Transportation System. BSD systems have been developed based on a number of technologies, but cost and performance issues have prevented widespread commercial success, particularly for light vehicles.

This paper presents a new Vehicle Blind Spot Detector. The device is based on a recently developed, novel thermal infrared sensor technology.

A description of the operation of the sensor is provided, together with a brief comparison with existing technologies. Experimental data are also presented, showing results of operation of the sensor.

INTRODUCTION

Collision Avoidance (CA) systems will form an integral part of the Intelligent Transportation System initiative [1]. Stand-alone Blind Spot Detection represents a logical first step in the development of fully integrated CA [2].

Considerable testing has been done on related technologies [2,3], along with evaluation of prototype and commercial systems [4]. While some systems are available for heavy trucks and other large vehicles, BSD systems are not yet common and are not commercially available for light vehicles (passenger cars and small trucks).

Typically, systems with highly reliable performance are unacceptable because of total installed system cost. Conversely, most inexpensive systems cannot provide required performance across all ranges of environmental conditions and target types.

This paper presents a novel approach to infrared sensing technology with application to Blind Spot Detection. This technology appears to be relatively low cost, and holds the potential to be implemented with high operating performance.

OPERATION OF THE NEW SENSOR

The ALIRT BSD uses long wavelength (7 to 14 μm) infrared technology which senses <u>emitted</u> thermal energy of a vehicle. This is in contrast to <u>reflected</u> energy sensed by active sensors (radar, ultrasonic or short wavelength infrared).

The pyro-electric detectors used in the ALIRT BSD respond only to a change in temperature. If the temperature of the object in the sensing field is constant, the output of the

detector is zero. Essentially, the detector is a differentiator that gives an output proportional to the rate of temperature change within the field of view: no temperature change equals no output. Thus, a BSD based on a single simple infrared detector will give zero output (no detection signal) for a vehicle in the host vehicle's blind spot if there is no relative motion, even though both vehicles may be moving. Conversely, a change in the temperature of the target region, for example an overpass shadow, may trigger a "false alarm."

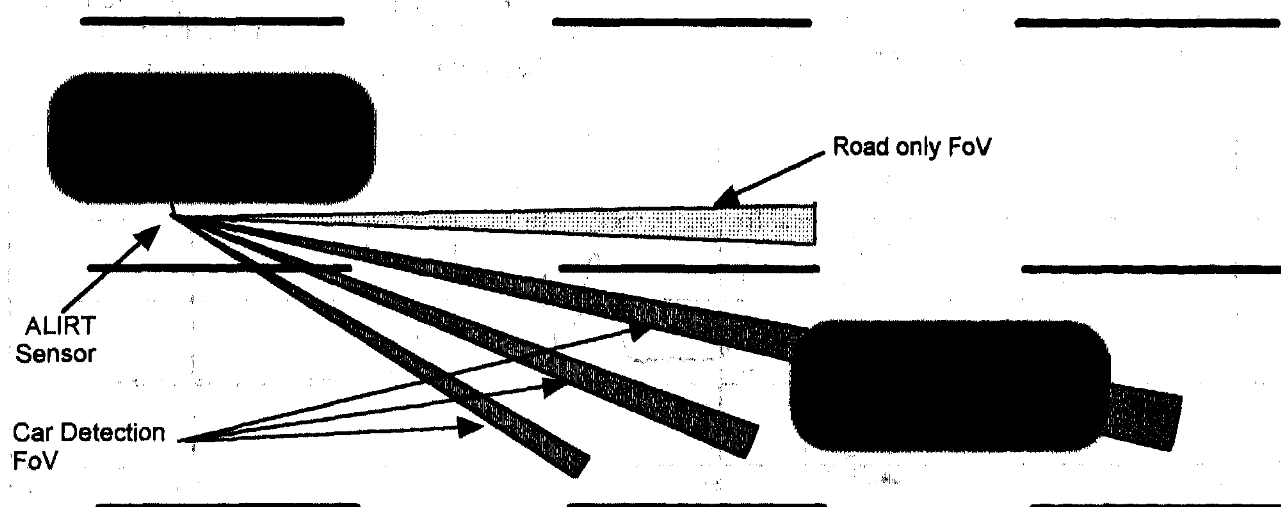
This limitation is overcome by employing fields of view (FoV's) of two types and alternately comparing them using proprietary techniques (international patents pending). One type of FoV is aimed in the conventional manner at the blind spot while the second is aimed so that only a representative sampling of the road surface is visible -- for example immediately behind or below the host vehicle.

If no vehicle is in the blind spot, then both types of fields of view see the road surface. The difference in temperature between the two FoV's is consequently small and the output of the detector is small.

However, when a vehicle is present in one FoV and not in the other, then the output is large. When a vehicle enters the blind spot there is a positive differential between the detection and reference zones of the sensor. This differential is used to trigger an output signal (for example a light or buzzer) to warn the driver of the lane change hazard.

In the case of a change in the road temperature, as generated by the shadow of an overpass, for example, both the reference zone and the detection zone will change temperature at approximately the same time. Therefore the differential will remain zero.

One possible FoV arrangement is shown in Figure 1. The unit is shown mounted on the left side rear view mirror. The road-only element views the road directly behind the car while three lens elements are used to cover the driver's blind spot. In the initial prototype, only one of the three illustrated Detection FoV's has been implemented.



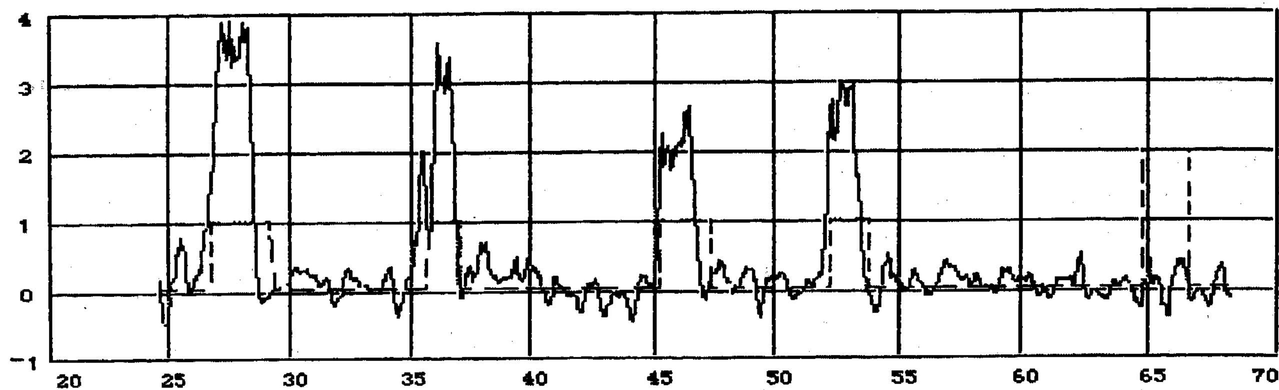


Figure 1 - Arrangement of Fields of View

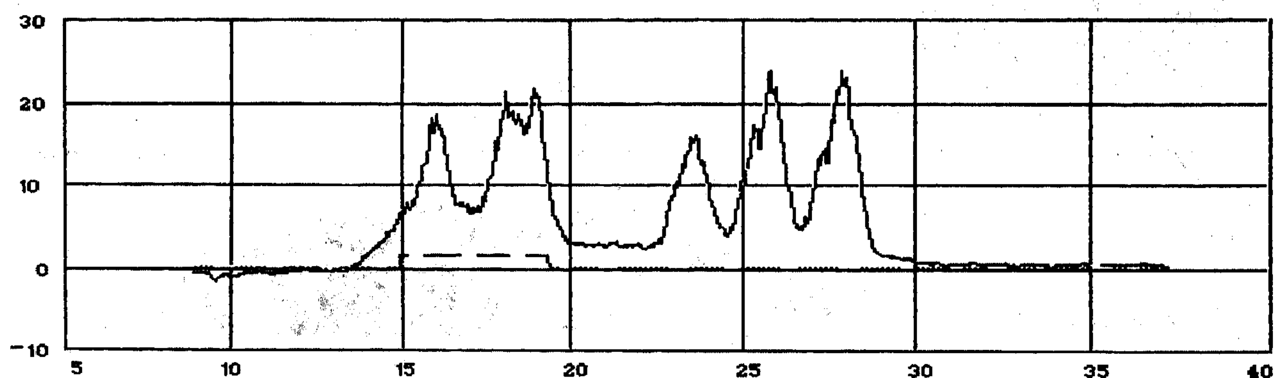

Time: 3:40 PM
Weather: Sunny, 25C
Comment: The first four events are cars. The final event (at about 65 seconds) is a bridge shadow.

Figure 2 - Detection of Cars

EXPERIMENTAL RESULTS

TEST RESULTS ACHIEVED Early testing has indicated that portions of operating vehicles are reliably warmer than the environment by at least 1 to 2C. This has been found to be true of the engine compartment, radiator and exhaust system: testing has also shown that tires will achieve approximately 2C of heating in approximately 1 km of driving in city condition. Therefore, a moving vehicle will emit significantly greater infrared than its surroundings.

Considerable testing has been conducted using a prototype device. The following graphs are typical of the results obtained: similar data have been collected across a range of

Time: 10:00 AM
Weather: 17C, Partly sunny
Comment: Transport truck signal. The first peak at 16 sec is front wheels, 18-19 sec is dual axles on rear of cab and 23, 26, and 28 sec the three axles on the trailer.

temperatures, weather conditions and times of day.

In figure 2 and 3 , the solid line is the BSD output. The broken line is a manually entered "event" channel used as a marker to record the occurrence of a vehicle in the blind spot or other significant occurrence. The horizontal axis is time in seconds.

The above data were collected using a sensor configured with a single detection field of view and a single reference field of view. The detection zone is approximately 300 mm diameter at the road surface.

Consequently, under some circumstances this configuration of the device will not detect large vehicles since the tires of the vehicle actually straddle the detection zone. This can clearly be seen in the case of the trailer of the transport truck. During a portion of the time that the trailer is resident in the blind spot, no detection is registered.

A second implementation of the device has been constructed with revised reference and detection zones . As indicated in figure 4, this version of the BSD features two distinct detection zones. This has largely eliminated the "straddle" problem found with the single-zone implementation of the original prototype.

Figure 5 shows the detection of a passenger bus using this version of the detector. With the current threshold alarm trigger of approximately 0.6C, the vehicle is continuously detected during the entire time it is in the blind spot of the host vehicle.

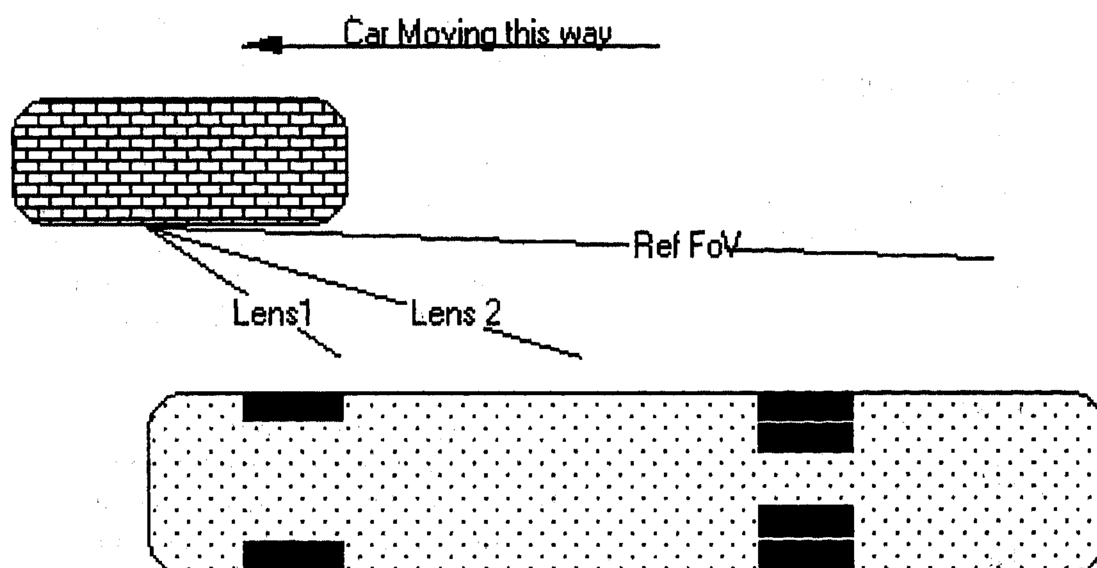

Figure 4 - Configuration of Multiple Detection-Zone BSD

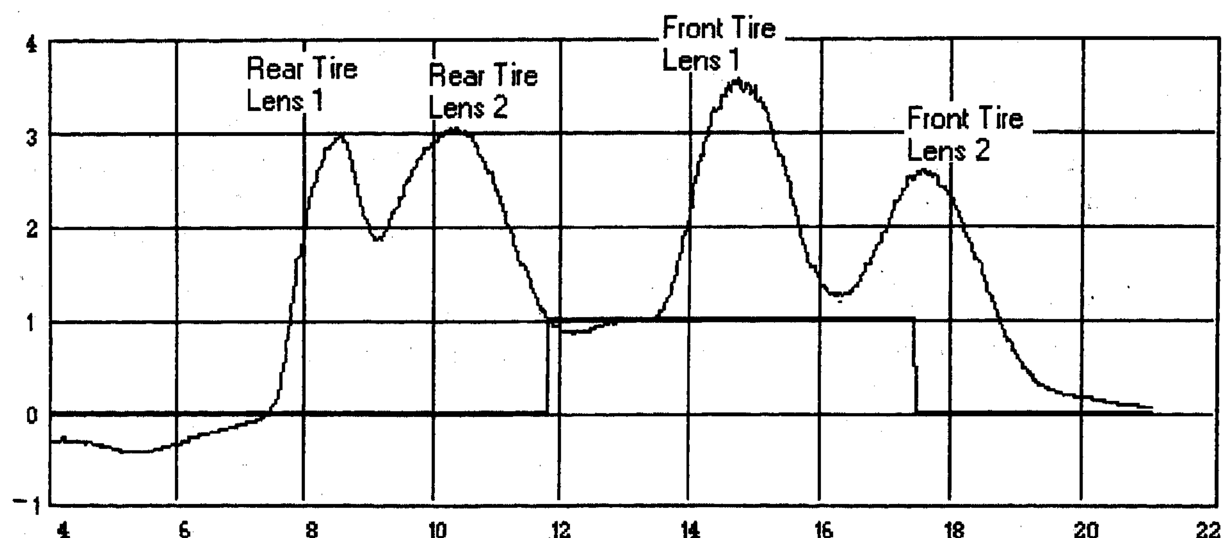

Figure 5 - Detection of a Bus Using Two Detection-Zone BSD

As can be seen from these figures the ALIRT BSD is very effective in detecting vehicles in real road conditions.

COMPARISON WITH EXISTING TECHNOLOGIES

A number of technologies have been employed in attempting to solve the BSD problem, including:

- Ultrasonic
- Active Infrared
- Laser
- Radar

These technologies are all "active" -- that is they all make use of a sensor that detects a signal which is transmitted from the host vehicle and reflected off of the target vehicle.

By contrast, the ALIRT BSD technology is passive. This strategy is expected to offer the following advantages:

System Cost: Because a passive system is inherently less complex than an active system, advantages are expected in the areas of system cost, installation cost and general reliability. Total sensor cost is estimated to be less than twenty dollars with volume manufacture.

Reliability: Near infrared has been generally found to be environmentally stable. Testing has shown the sensor to be effective in conditions of rain, winter and summer temperatures, snow and daylight or darkness. The system detects operating vehicles independently of colour, size or shape. It does not respond to parked vehicles or other non emitting roadside objects. IR transmissions are

relatively unaffected by airborne moisture. Fog will affect the sensor operation less than it will affect the driver's vision.

CONCLUSIONS

A vehicle Blind Spot Detection system has been developed based on a new passive infrared technology. Testing to date indicates that the detector will be able to provide a high level of performance at relatively low cost.

Active Matrix LCD Performance in the Automotive Environment

Mark R. Vincen
Delco Electronics Corp.

Abstract

The environment of the automobile poses severe challenges to AMLCD technology. Among automotive display applications, the primary instrument, or instrument cluster, is the most demanding due to the safety concerns of display shortcomings or failure.

This paper will address and summarize issues involving the application of AMLCD display technology to the primary instrument. The results of environmental testing of ruggedized automotive AMLCD modules will be presented, without revealing the display module manufacturers' names.

The paper will also reveal the results of supplemental testing of these AMLCD modules. Tests that characterize AMLCD display performance such as contrast, brightness, response time and viewing angle performance vs. ambient temperature will be presented.

Introduction

As already mentioned, the primary instrument is the most demanding display application in the automobile. This is the case because safety related information is displayed by the instrument cluster. Vehicle gear position, speed, and critical telltales or warning indications such as brake activation, etc., are examples. The federal government regulates specific aspects of these critical functions via the FMC (Federal Motor Vehicle System Standards) regulations. Aspects such as size, color, functionality, and readability are addressed. Importantly, if the vehicle is derivable, these critical functions must be operative.

Requirements for the Primary Instrument Display

The following requirements for a primary display are the most severe for a display in the automobile. These requirements address optical readability and comfort as well as the environmental performance and durability attributes necessary for high reliability and safety.

Optical Requirements:

DISPLAY BRIGHTNESS (white)	150 Footlamberts
CONTRAST RATIO (CR)	100/1
DISPLAY DIMMING RATIO	100/1
VIEWING ANGLE	+/- 60 deg. H,V
RESPONSE TIME	50 ms @ 25 deg. C
DEFECTIVE PIXELS	1 per display 'ON"
	1 per sq. in. "OFF"
RESOLUTION	80 color groups/in.
HIGH AMBIENT CONTRAST RATIO	10/1 min. white CR
	@ 3000 FC

Environmental Requirements:

OPERATING TEMPERATURE RANGE	-40 to +85° C
PERFORMANCE TEMPERATURE RANGE	-20 to +70° C
STORAGE RANGE	-40 to +95°C
POWERED TEMP	-40 to +85°C
HIGH TEMP ENDURANCE	85°C, 250 hrs.
HUMIDITY	65° C, 94% RH
VIBRATION	3.2 G, Multi-axis
EMC	GM 9114P
ULTRAVIOLET EXPOSURE	500 HRS (Xenon device)

The preceding optical and environmental requirements have been addressed in a set of Pre-validation tests. These tests are based on an actual Validation test set for a production

primary instrument cluster. A primary cluster using the AMLCD technology would be required to pass these Validation tests in order to be qualified for production. The actual Production Validation tests require certain minimum test sample quantities; we used smaller quantities to lower costs and save time. The purpose of this Pre-validation test was to identify potential problem areas with the test modules, not to qualify them for production. AMLCD modules from several manufacturers were tested. The following is a block diagram of the Pre-validation test procedure:

Pre-Validation Test Sequence:

Power Temperature Cycling (PTC)	500 - one hour Cycles -40 to +85 C 15 minute dwells and transitions Device power 5 minutes ON, OFF
High Temperature Endurance (HTE)	+85 C Steady State, 250 hours
Biased Humidity Test (BHT)	+65 C, 94% R.H. Steady State (non-condensing)
Ultraviolet Exposure Test (UVE)	500 hr. Exposure in Xenon-lamp Device
Electro-Magnetic Compatibility (EMC)	GM 9114P Test Profile
Frost Test	-40 C Soak, then +35 C @ 94% R.H device must be operational for 30 minutes
Vibration Test	3.2 g, Multi-axis 0-1000 Hz.

Results of Environmental Testing

The results of the environmental testing on several manufacturer's AMLCD modules revealed problems with the display polarizers and the cold cathode fluorescent tube (CCFT) backlight system. The following summarizes these problems:

Display Polarizers

Our testing revealed polarizer problems in two areas. The first problem identified involved moisture penetration into the polarizer. After the Biased Humidity Test, moisture absorption into the polarizer caused strange optical effects including the appearance of a pronounced "X-Pattern" becoming visible in the display. This pattern moved with the observing angle of the viewer. Some polarizers are more susceptible to this problem than others. One polarizer type showed abnormal front surface reflection patterns in addition to the "X-Pattern" seen through the display.

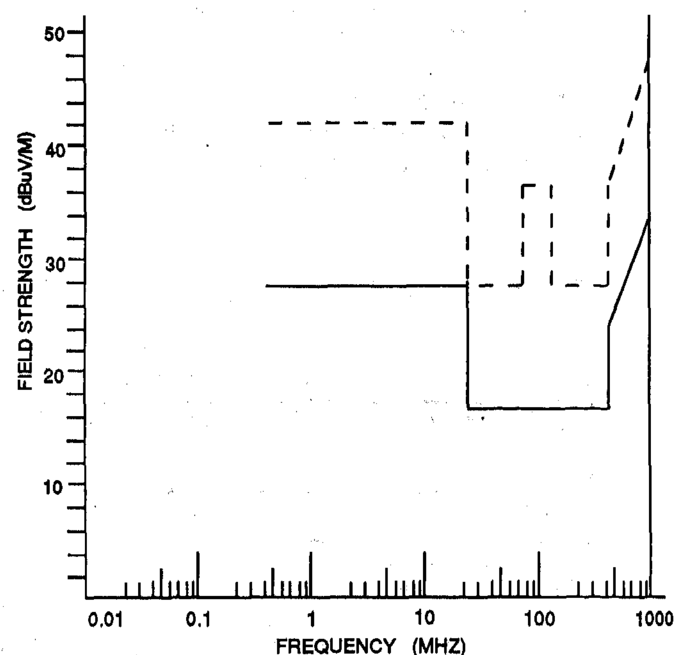
The second problem found was the delamination of the polarizer from the display glass substrate. This problem was found after the High Temperature Endurance Test (+85°C, 250 hrs.). Again, not all of the polarizers used on the various modules tested had this delamination problem. The polarizer adhesive is obviously suspect here.

The polarizers used in these AMLCD modules are the poly-vinyl alcohol (PVA) type. This type of polarizer has good optical performance, including color neutrality, but it has high temperature limitations. We are told the upper temperature limit for PVA type polarizers is about 95°C. This is only 10°C above the +85° C temperature we are testing the modules at. The polarizers, especially the rear one, are being heated by the module backlight system. This temperature rise behind the display is in the 10°- 30° C range. This means the rear of the display can be at 115°C when the module is in a +85°C ambient as it is in the Pre-Validation tests. This temperature is clearly above the maximum temperature of the PVA type polarizer. Interestingly, some of the polarizers tested were able to pass the High Temperature Endurance (HTE) test indicating the PVA polarizer can withstand the high temperatures for a limited period of time. This is greatly helped if the particular module backlight imparts a relatively lower temperature rise to the polarizers.

CCFT Backlight System

The next major problem revealed by the testing involves the cold cathode fluorescent (CCFT) backlight system. The Power Temperature Cycling (PTC) test damaged some CCFT backlight systems, resulting in catastrophic failure. The backlights still functioned, but were

very dim and orange in appearance. Analysis indicated the lamps had been damaged in two significant ways. One, the lamp electrodes were damaged by activation at -40 C when the lamp mercury is in the liquid state. The activation of the plasma flow inside the lamp without the mercury in the gaseous state results in eventual damage to the electrodes. The PTC test took the CCFT lamps down to -40°C 500 times (and activated the lamps) during the test, which is enough to cause failure with some backlight systems. The second failure also involved the mercury in the liquid state. At -40°C the liquid mercury collects at the bottom or lowest section of the CCFT tube. The chances are good that the collection point is coated with phosphor. The liquid mercury can contaminate the phosphor, damaging the lamp's function even after the lamp returns to room temperature.



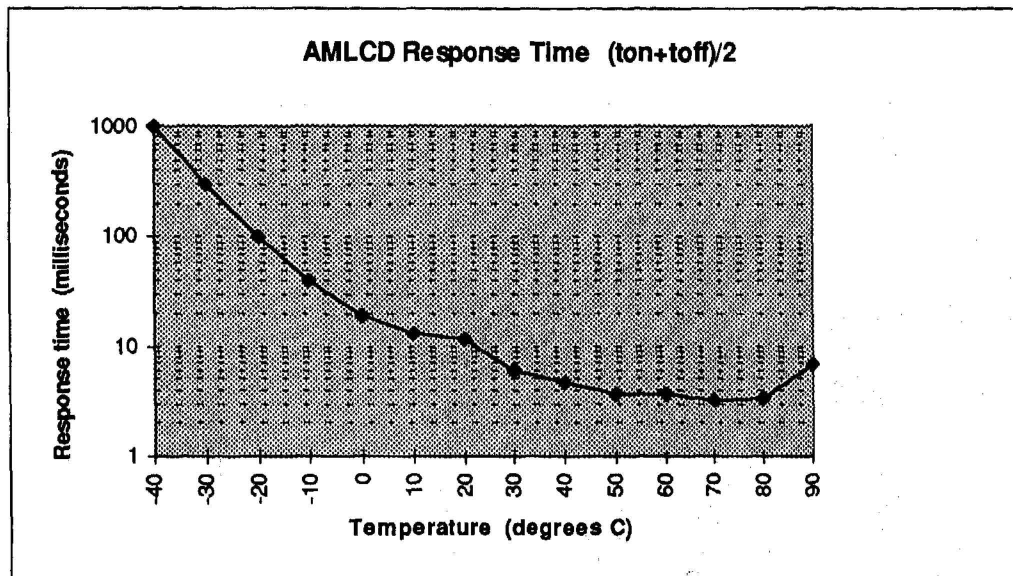
These two failure mechanisms are major drawbacks to CCFT system applications at low temperature extremes. To minimize some of these problems it would be necessary to heat the lamps and delay trying to operate them at these extreme temperatures.

Electro-Magnetic Compatibility (EMC)

All of the AMLCD modules had very high RF emissions; both radiated and conducted through the wiring harness. Figure 1. is a description of the acceptable levels of Radiated Emissions per the GM 9114P specification.

The results of our EMC testing on several manufacturers' AMLCD Modules indicate that RF emissions by these modules is a serious problem. The CCFT backlight system is a major source, contributing to most of the emissions at the lower frequencies including the AM radio band. The remaining module electronics, including the video circuitry and row/column drivers, produce most of the RF emissions at the higher frequencies including the FM and Cellular phone bands.

None of the tested modules used RF suppression techniques (as far as we could determine) which would make a significant reduction in RF noise levels. However, the RF levels are so high without suppression techniques that we have concern that the AMLCD modules will still ultimately have relatively high RF emission levels. This is especially problematic because vehicle manufacturers are requiring lower and lower emission levels.



Frequency Range (MHZ)	Amplitude (dBuV/m) Narrowband	Broadband
0.4 - 75.167	28	41
20 - 75.167	15	28
75.167 - 119.132	15	38
119.132 - 375	15	28
375 - 1000	25 - 34.5	38 - 47.8

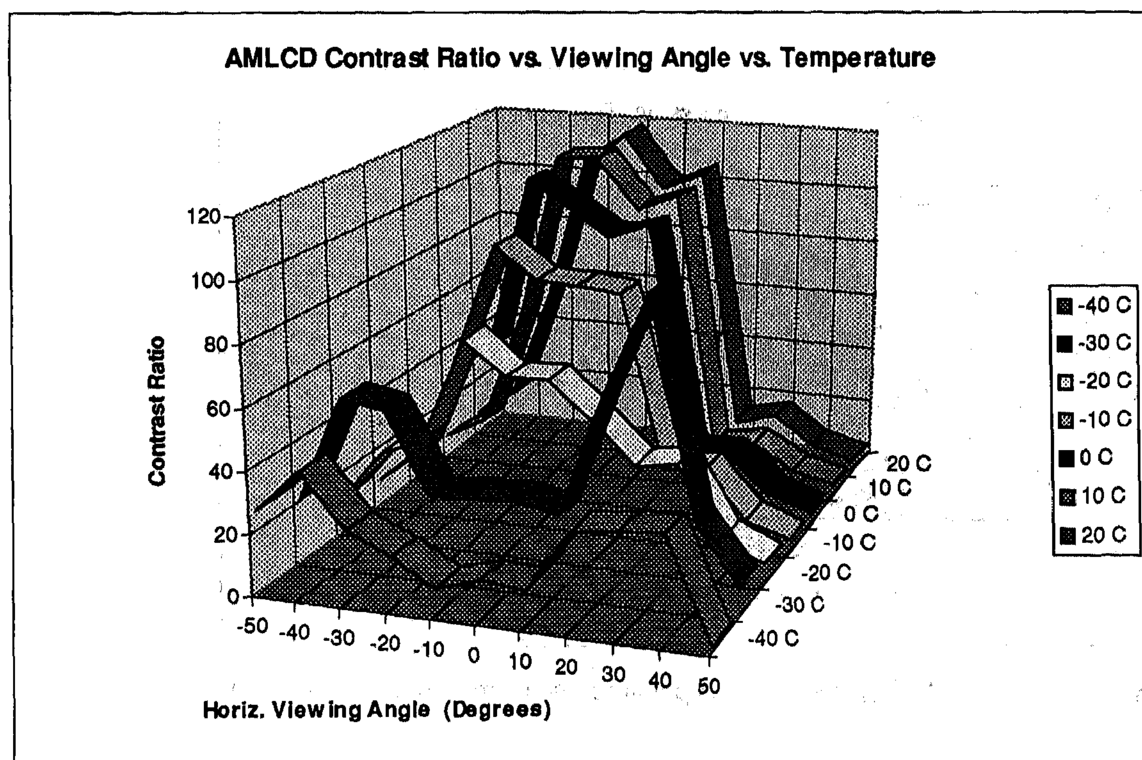


Figure 1. - Radiated Emissions Performance Objectives

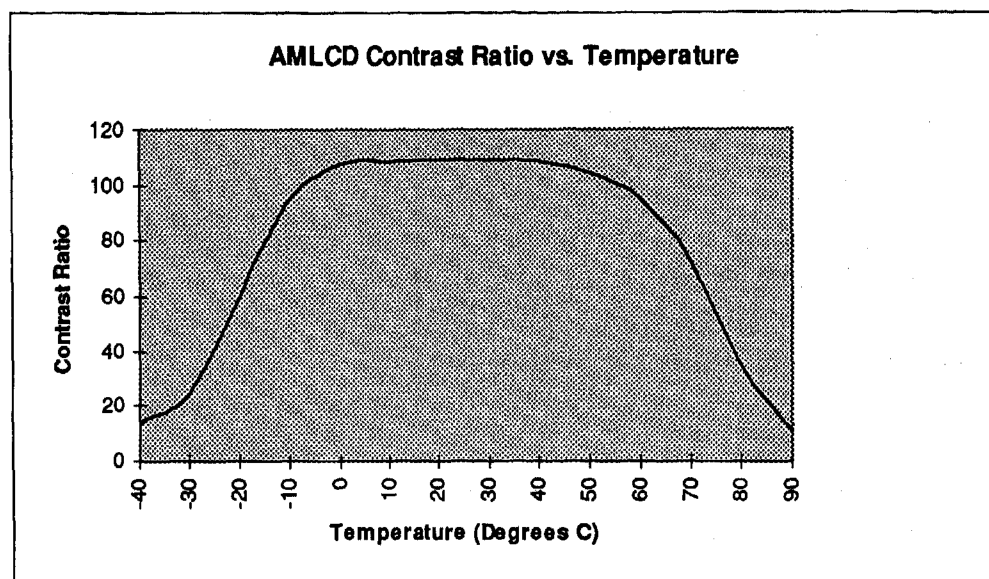
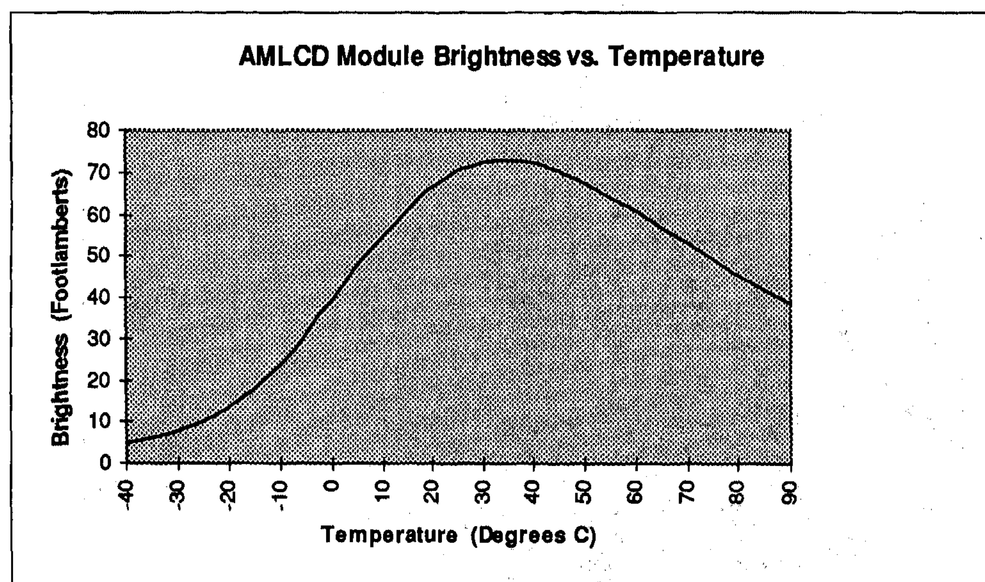
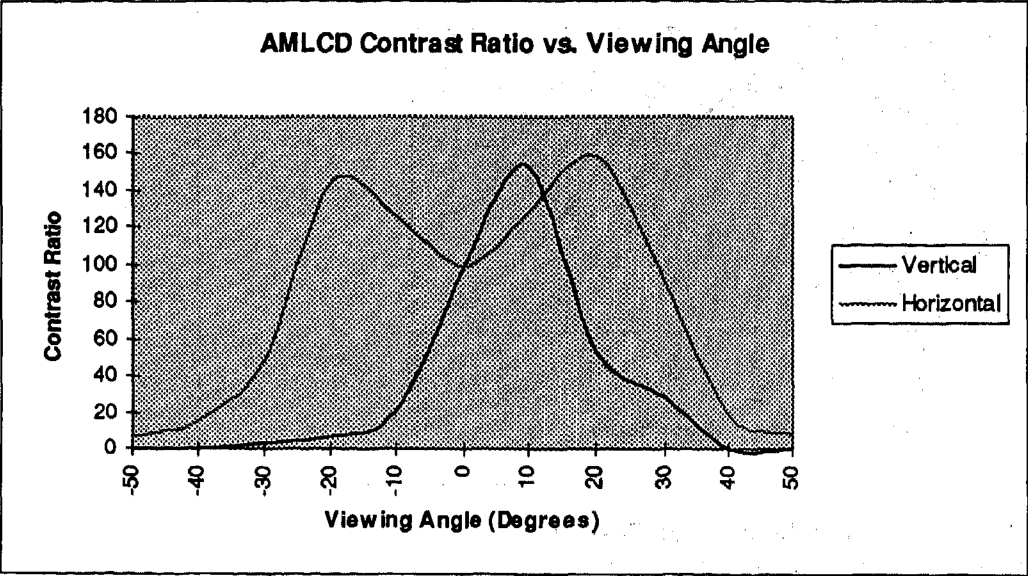
Supplemental Testing and Evaluation



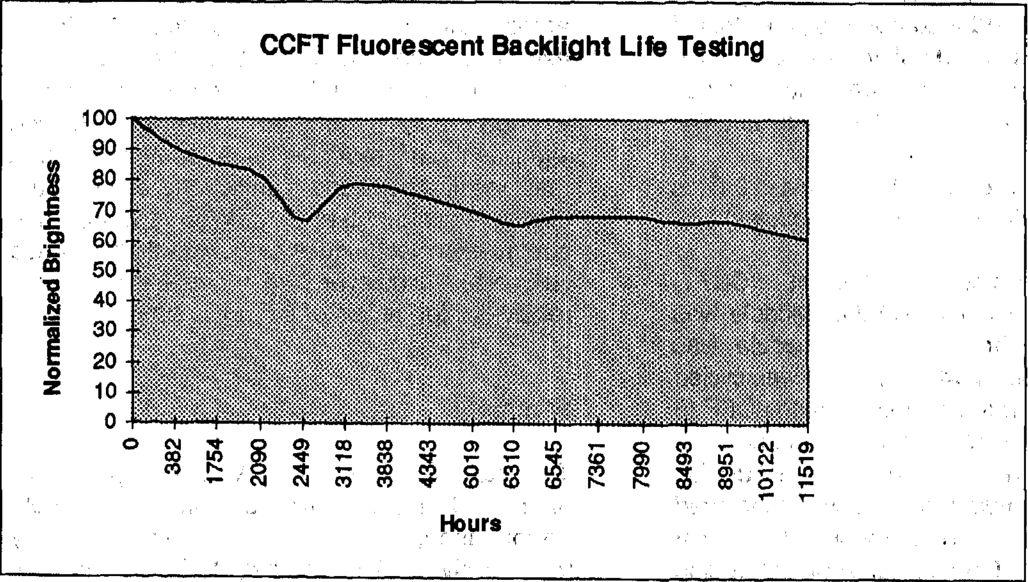
Additional optical and EMC testing was performed on some of the AMLCD modules. The optical testing involved the measurement of display brightness (incl. lifetime), contrast, response time, and viewing angle performance of the display vs. temperature. Graphs 1 - 7 show the results of this evaluation effort. The AMLCD modules that were evaluated did not have the new wide-angle optical film. Ruggedized AMLCD modules with this film were not available at the time of this writing.



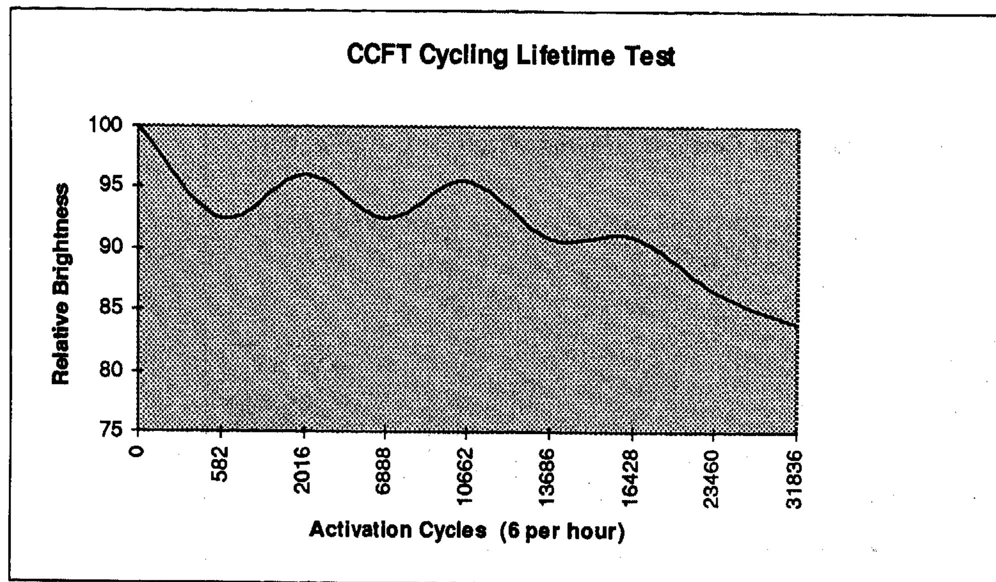
Graph 3. AMLCD Response Time vs. Ambient Temperature



Graph 4. AMLCD Module Contrast Ratio vs. Viewing Angle vs. Temperature



Graph 1. AMLCD Contrast Ratio vs. Temperature (Measured Normal to Display)



Graph 2. AMLCD Module Brightness vs. Temperature (measured Normal to Display)

Graph 5. AMLCD Module Viewing Angle vs. Temperature

Graph 6. CCFT Fluorescent Backlight Life Test (Continuous Operation)

Graph 7. CCFT Fluorescent Backlight Cycle Life Testing (Lamp ON 5 minutes, OFF 5 Minutes [6 cycles\hour])

The results of these supplemental tests indicate the sensitivity of AMLCD technology to the ambient temperature. In the case of the Primary Instrument application, this degraded performance, (i.e, reduced contrast, constricted viewing angle, slow display response, and dimmer display brightness), demands the use of a heater to bring the AMLCD display and the

CCFT backlight system up to at least -20 C as quickly as possible (with present modules).

The Cold Cathode Fluorescent (CCFT) backlight for a particular AMLCD Module was evaluated in a Life Test. A module was powered continuously while another was cycled at the profile of 5 minutes ON, minutes OFF (6 cycles\hour). Both tests were conducted at room temperature (23°C). The display brightness of the two modules was measured periodically. The continuously ON test evaluates the CCFT phosphor while the cycling test evaluates the CCFT electrodes. The results indicated the CCFT backlight is capable of a 10,000 hour life (to half initial brightness) in both a constant and cycling mode at room temperature.

We conducted numerous supplemental EMC tests on these same AMLCD modules. The result of the baseline (as-is out of box) EMC testing showed very high levels of RF noise across the measured spectrum. Continued experimentation revealed that there was, as expected, significant RF noise conducted through the wire harness. Tests also showed significant RF radiation was coming through the module case, and significantly, through the display glass itself. We applied RF suppression techniques to substantially reduce RF noise. However, the module still exhibits relatively high levels of RF noise emission.

Summary

The next generation of AMLCD displays will offer substantial improvements in viewing angle performance, contrast, and display transmissivity. This will help to lower backlight brightness (and temperature rise) and will make the display more sunlight readable.

Improvements on the horizon include the integration of logic and row/column driver

circuitry on the display glass for lower cost and higher reliability.

The present state of AMLCD technology does not appear to be fully ready for automotive primary cluster applications at a reasonable cost (as measured against the standards outlined in this paper). Improvements need to be realized in both optical performance (especially vs. temperature) and environmental ruggedness.

However, AMLCD technology is continuing to evolve and improve. Up to this point, the computer and consumer electronics applications have fueled AMLCD growth and influenced its development. We see a new wave of growth on the horizon for the automotive application of AMLCD technology. As automotive applications increase and higher volumes appear on the horizon, AMLCD R&D will focus more and more on the automotive issues and challenges.

ABSTRACT

The veiling glare effect in automotive vehicles consists of diffuse and specular scattering of sunlight onto and from the windshield. This effect occurs over a wide range of solar elevation angles and increases with increased degree of inclination of the windshield. Thus its effect on visual acuity must be considered in automotive design. The present research on the subject of veiling glare only addresses scattering from a clean windshield and ignores the larger effect of scattering from dust, dirt or haze on the front and back faces of the windshield since the latter is operator dependent (can be removed by cleaning the windshield). In this paper, we present an analysis of autmotive veiling glare that takes into account windshield reflectivity without and with coatings, and the characteristics of dashboard cover materials. The analysis develops a new reflection model for rough surfaces, based on laboratory measurements of reflectivity as a function of wavelength and angle of incidence, and on reflection and/or scattering angle.In the case of windshield reflectivity, single-film, 3-film and graded-index coatings are considered for both s and p polarizations and a range of windshield rake angles, and calculations are compared to laboratory and full scale measurements. In the case of dashboard reflectivity, surface texture and material ligthtness are considered. Specular and diffuse reflection components are analyzed in terms of angle of incidence, color and polarization direction. It is found that texture has a large effect on the reflected light, especially at large angles of incidence and causes a noticeable forward scattering component which includes specular reflection. Experimental measurements and computer-generated models show that this forward scattering effect can be as large as 10-20 degrees. The presence of forward scattering has the result of increasing the range of solar elevation angles that produce veiling glare. Windshield and dashboard reflectivity effects are then combined and analyzed to determine how they impact the veiling glare process.

INTRODUCTION

The stray light, not associated with the incident image, that is seen in the windshield by the driver of a vehicle is called glare. It results from light reflected and/or scattered by the windshield. This light can come from basically two sources: (1) the reflection of sunlight from the dashboard cover material, and (2) the scattering of sunlight from deposits on the windshield of the vehicle. The latter is easily removed by the vehicle operator by simply washing the windshield. The former is often what is referred to as veiling glare. This paper will discuss the results of a comprehensive model developed to simulate the contributions to veiling glare from the windshield with and without anti-reflective coatings and from the texture of dashboard cover materials.

Veiling glare must be controlled in order to assure clear visibility of objects ahead. Attempts to reduce veiling glare have played an important role in automotive design. Because the major component of veiling glare has been reflection by the windshield of light scattered or reflected by the instrument panel cover, its effect has been considered in the design and color selection of instrument panels and dashboard materials for the broad range of windshield rake angles used today.

Although a sandwich of polymer film between two glass panes, the windshield may be treated optically as a single glass panel, because the refractive index of the polymer layer matches that of the surrounding glass. It is well known that the reflection of light from an uncoated glass plate exhibits a strong dependence on wavelength as well as angle of incidence. This is shown in Fig. 1 where the reflection is calculated from both inner and outer surfaces of the windshield for s- and p-polarized incident light. Note that for windshield rake angles (angles of incidence) of 60-65 degrees, the reflectivity coefficient approaches 20%. Of course, that is 20% of the light reflected from the dashboard cover, not the light incident on the windshield from outside. Therefore, the reflectivity

75°	40	30	20	10	0	-10

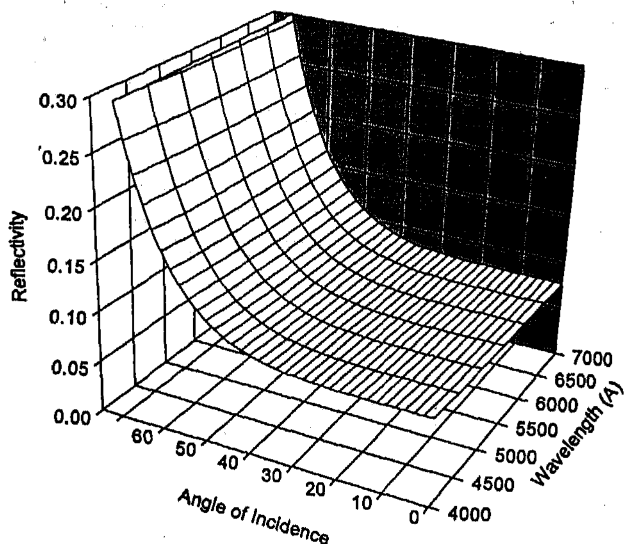

Fig. 1 - Reflectivity from both sides of the windshield, summing s and p components.

of the dashboard cover material is of utmost importance in the evaluation of driver visual performance. As a result, anti-reflection (AR) coatings and/or low reflection - low scattering dashboard materials have been considered in automotive designs that have large windshield rake angles.

AR coatings fall into two classes: interference or graded. The interference coatings consist of a single film or a stack of films designed to reflect light destructively for a given wavelength and angle of incidence. Graded coatings are designed to reduce the reflected light by decreasing the sudden jump in refractive index between air (n=1.0) and the windshield (n=1.5). In general, single-film interference coatings have a narrow reflection minimum as a function of wavelength, and angle of incidence. This can be improved by making multilayer coatings. By contrast, graded-index coatings yield a broader minimum, but the reflectance minimum depends directly on the refractive index at the outer edge of the coating. This number is limited by MgF_2 (1.38) which is about the lowest limit of glass refractive indices.

In most windshield designs, only the inner surface is coated with AR films. Therefore, the inward reflected light from the outer surface of the windshield contributes the greatest portion of the veiling glare, and it determines the minimum reflection achievable.

When considering the geometry of the windshield-dashboard-driver system, it is possible to calculate the solar elevation angles which will maximize veiling glare for a variety of windshield inclination and dashboard angles as shown in Fig. 2. The solar elevation angles are shown in Table 1. In the table, the solar elevation and the dashboard angles are measured from the horizontal while the windshield angle is measured from the vertical. It is clear that solar veiling glare occurs at relatively high elevation angles for windshield angles of 55-65 degrees. As the solar elevation angle decreases to the horizontal, the solar veiling glare becomes inconsequential since the sun will also be directed into the driver's eyes.IN this case, the driver will take action to avoid looking into the sun, also eliminating the veiling glare.

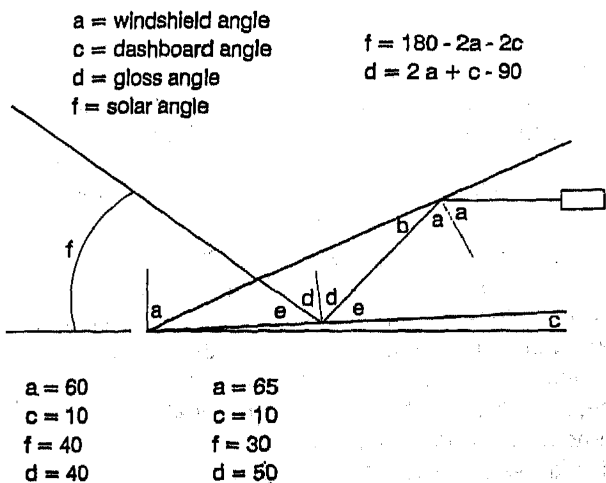

Fig. 2 - Sketch of windshield, dashboard and solar elevation relationships.

Methods for mitigating the amount of veiling glare received by the driver must rely on the use of anti-reflective windshield coatings as discussed above, and on the use of non-reflective dashboard cover materials. In this paper, we discuss a comprehensive model designed to simulate the effect on veiling glare of windshield AR coating materials and of surface roughness in the instrument panel covers.

Main Section

ANTI-REFLECTIVE WINDSHIELD COATINGS - In a previous paper,[1] we calculated the reflection coefficient for windshields without and with anti-reflective coatings on on the inner surface for s and p polarized light. A menu-driven computer program was developed in Excel format to calculate and plot the total reflectivity expected from uncoated windshields and those coated with any combination of up to 10 layers. The studies showed that s- and p- polarized reflected light can be reduced with single-layer, 3-layer and graded-index coatings on the inner surface of the windshield. The graded-index coatings were developed using a proprietary sol-gel fluorination process that reaches a minimum refractive index of 1.41 at the outer surface of the coating. One of the major advantages of graded-index coatings is that they show a much weaker wavelength dependence than the multi-layer coatings, thus the coated material does not exhibit a tinge of color.

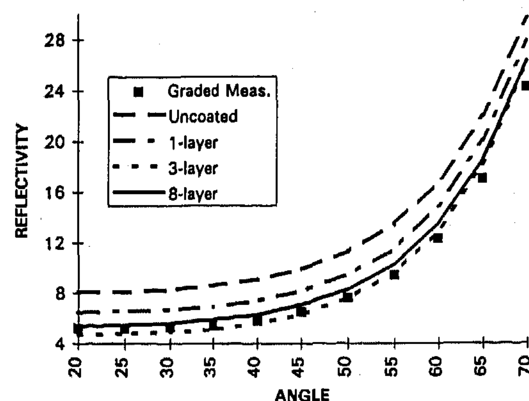

Fig. 3 - Percent reflectivity vs angle for green light compared between uncoated windshields and windshields coated with 1-layer, 3-layer and a graded-index coating (represented by 8 layers).

The results of reflectivity measurements are shown in Fig. 3 for measurements at the wavelength corresponding to the green color (550 nm). Two 3-layer coatings were tested. In the first, we used index and thickness relationships available in commercial AR coatings. These, however, are best used with light at normal incidence. AR behavior can be improved by using index and thickness values more appropriate for angles of incidence between 50 and 70 degrees. The results of using these new coatings are shown in Fig. 3, along with the reflectivity of an optimized 8-layer coating. Note that this formulation gives a lower reflectivity than the graded-index coating only at shallow angles of incidence. However, as stated above, the graded-index coating gives less wavelength dependence and avoids any color in its reflection spectrum.

DASHBOARD MATERIAL ROUGHNESS -In order to develop an understanding of the role f roughness and lightness of dashboard cover material on reflectivity, we conducted exploratory laboratory measurements followed by the development of a new model. The model was then reduced to a menu-driven Excel-based program which can be combined with the windshield and coating calculation program to yield a comprehensive simulation approach to modelling the entire veiling glare system. In the experimental study, we examined several dashboard materials of different color and roughness. The roughnesses were measured with a gloss meter at 60°. Reflectivity measurements from the dashboard materials for light incident at 60-65 degrees showed an unexpected forward shift in the reflected light from the specular angle as shown in Fig. 4 for both s and p components. The shift in reflection angle from specular was observed to be as large as 17 degrees. This forward shift was more pronounced in the p-component of the light for all materials. We find that this shift increases the range of solar elevation or rake angles that maximizes solar veiling glare. Thus it extends the effect through a greater daytime period.

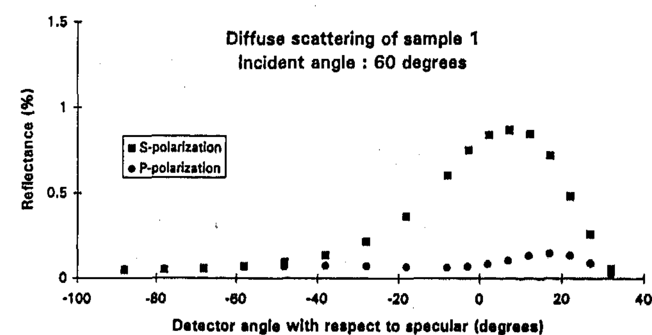

Fig.4 - Reflected light from sample 1 cover material, showing the shift in the reflection peak for s and p-polarized light

An analysis of the source of the forward shift in the reflection peak determined that it was due to the fact that a rough surface exhibits a distribution of reflection angles. We modelled this process by generating Gaussian distributions of reflection angles centered about the windshield rake angle. Calculation of the angular dependence of the reflected light showed that for most reasonable entrance apertures, there will be a forward shift in the reflection angle as shown in Figs. 5a and 5b, for a variety of distributions. Measurements of the roughness of the dashboard cover surface were conducted using a contact profilometer and the resulting angular distribution is shown in Fig. 6. The curve is best fitted by two Gaussian distributions (one very broad and one very narrow). Even though the simulations resulted in

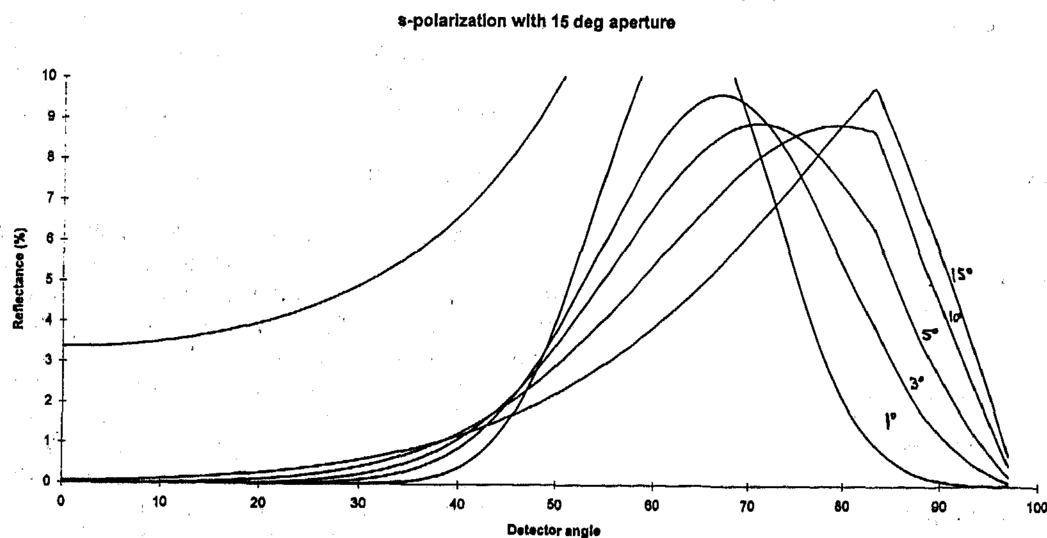

Fig. 5a - Calculations of forward scattering of the s-polarization for a variety of angular distributions corresponding to different roughnesses (angular distribution widths of 1°, 3°, 5°, 10° and 15°).

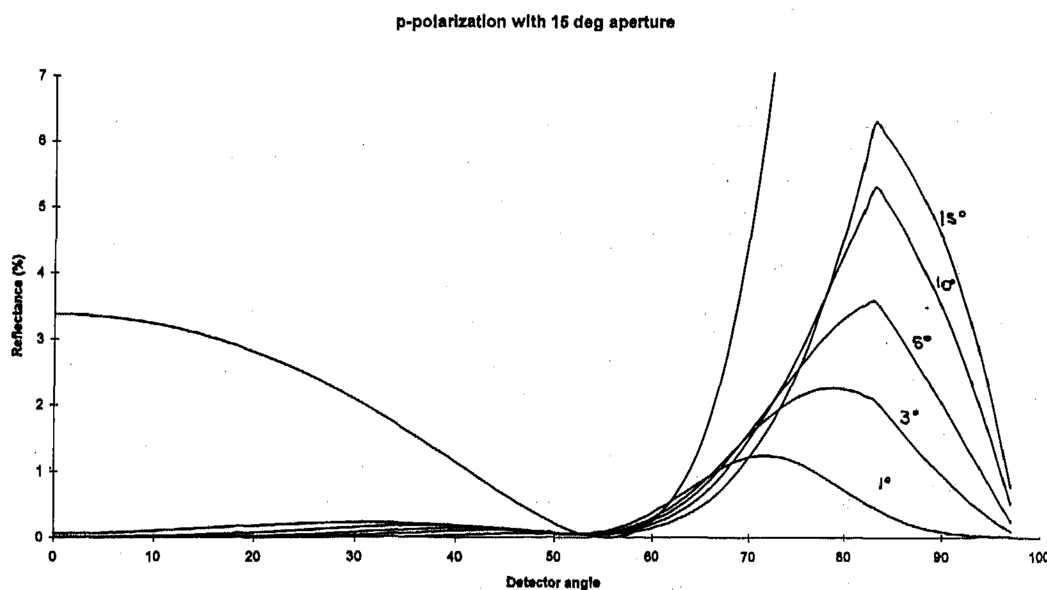

Fig. 5b - Similar plot for the p-polarization.

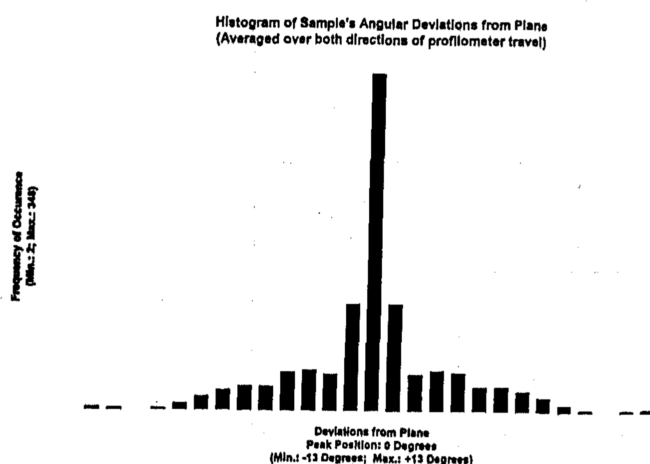

Fig. 6 - Histogram of dashboard roughness.

very close agreement with the measurements of the angular dependence of the reflection coefficients, tests were conducted to investigate the effect of smaller angles of incidence. Clearly, if the forward reflection is due to a combination of a broad distribution of surface angles and the asymmetry in the angular dependence of the reflection coefficient as shown in Fig. 2, the s and p components will behave differently around Brewster's angle of incidence. Measurements were conducted at 50° (5° below Brewster's angle) and at 55° (Brewster's angle). The results showed a backward shift in the reflection from specular at a 50° angle of incidence in only the p-component while the s-component exhibited the expected forward shift in scattering angle. At Brewster's angle, the p-component showed two peaks, one above and one below specular and zero reflection at the specular angle (see Fig. 7). This strictly follows the behavior predicted by our model and shows without doubt that the forward scattering measured

forward scattering measured at 60° and 65° angles of incidence is a direct result of the roughness of the dashboard cover.

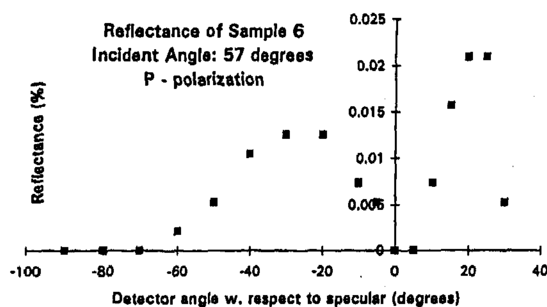

Fig. 7 - Reflectivity of the p-polarization at Brewster's angle.

Dashboard materials tested are listed in Table 2. The term "soft" in the color column indicates a subdued color rather than vibrant. The 60° Gloss column lists the Gloss Meter measurements.

Essentially, the results showed no correlation between the lightness and the 60° gloss measurements, while there was good agreement between the 60° Gloss measurements and the directly measured reflectivity (see Table 3). The specular reflection maxima, as well as the forward scattering angles, are shown in Table 3 for both the s- and p-polarization components.

The table shows larger forward shift values for the p-component than for s due to the steeper increase in reflectivity with angle of the p-component for angles of incidence near 60°. Fitting the forward scattering curves and examination of the profilometer traces showed that the distribution of angles of incidence is relatively narrow (eg. less than 5° at half-max). It should be noted that the forward shift is sufficiently large to significantly increase the range of solar elevation angles which produce direct veiling glare. Thus increases of 10-20 degrees in the solar elevation angles will produce veiling glare long before the sun appears in the line of sight of the driver. Increasing the windshield rake angle to 65° will increase the angular shift of the forward scattering for both the p- and s-components of the reflected light.

8	7°	0.65	17°	0.12	5.62

CONCLUSIONS

We have examined the components of veiling glare associated with the windshield reflectivity and with the dashboard reflectivity. Clearly, the addition of AR coatings to the inner surface of the windshield is desirable to reduce veiling glare. We have examined the properties of the dashboard materials and how they contribute to veiling glare. It is clear that rough materials will reduce the total scattered light, however, they increase the forward scattering of the specular light which increases the range of solar elevation angles that produce veiling glare. In the opposite case, shiny and smooth surfaces increase the amount of scattered light, while they reduce drastically the range of solar elevation angles that produce veiling glare. In materials selection issues, it is still better to reduce the total amount of scattered light, even though it produces veiling glare over a longer period of time during the day.

Finally, this work has led to an understanding of the relationship between surface roughness and reflectivity, and to the development of a comprehensive simulation model that covers uncoated and coated windshields and any dahsboard cover materials of known roughness for any light condition and any windshield rake angle. The simulation program is easy to use and menu-driven. Work is currently under way to calculate directly the corresponding Veiling Glare Index.

Reflection Characteristics of Automobile Interior Materials

Frank P. Nanna
TRICOR Systems, Inc.

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

Automobile interior surface reflections and gloss have presented problems for users and manufacturers alike. Eye-fatiguing glare and windshield reflections can range from minor irritations to major safety concerns. Matching various interior components produced by different organizations can also produce problems.

This paper describes gloss/reflection measurements of samples of materials commonly used by manufacturers. Natural environment and laboratory measurements are performed and their results compared.

The measurement results show that the geometric composition of grain can affect both the amplitude and directionality of the reflection and that current measurement techniques may be inadequate.

BACKGROUND

There are two readily apparent criteria for the surface finish of automobile interiors, *appearance* and *functionality*. Manufacturers attempt to provide a pleasing appearance by utilizing grainy materials to simulate the look of much more expensive leather. They also attempt to match or harmonize all viewable components, including grainy materials produced by different manufacturers, which has created problems. Most often the appearance mismatch is determined by humans and, as such, is subjective.

Functionally, the interior is intended to diminish glare so as to not impair the driver's vision or fatigue his/her eyes. Care must also be taken to avoid geometric configurations that can produce objectionable imaging in the windshield.

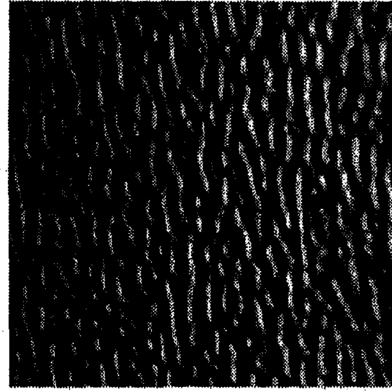
The prediction of glare and windshield imaging is a relatively straightforward optical problem as long as the interior surfaces are smooth. The introduction of a grainy surface changes the problem considerably. The nature of the grain can alter not only the amplitude but also the direction of the reflected illumination.

Some manufacturers use coatings in an attempt to control the reflective/gloss characteristics. The coatings are designed to reduce the gloss and possibility of glare. Many manufacturers utilize gloss measurement devices designed to the American Society for Testing and Materials (ASTM) standard D523 to evaluate the effectiveness of the coatings. A discrepancy between the measurements made by the device and a manufacturer's human evaluation of the gloss led to this paper.

OBJECTIVE

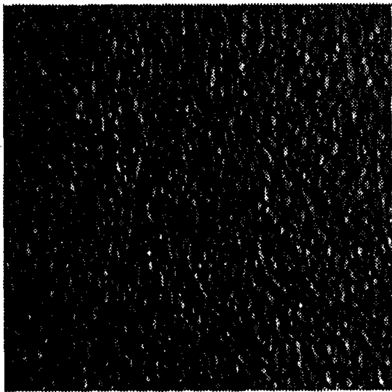
The objective of the tests and analyses were to determine relationships between illumination, product orientation and observer viewing angle. Other studies[1] showed a relationship of illumination source size to perceived gloss. This study looks at the geometric relationship in a natural environment. The tests performed were not meant to be all inclusive but rather to determine gross effects that warrant further examination.

DESCRIPTION OF THE TESTS



Qualitative and quantitative testing was performed both indoors and outdoors. Measurements were made on five different grain samples commonly used in automobile interiors and a non-grained control sample (Figure 1). Each of six black samples were coated at the same time to control variations in reflectance/gloss. The manufacturer of the material supplied the samples along with gloss measurements at 60° and 85° as measured on an ASTM D523 instrument.

Crude, short-range qualitative tests were conducted that confirmed the manufacturer's opinion of the discrepancy between human and device evaluation of the gloss of the samples.



A second psychophysical test was performed with 12 subjects to rank the gloss/brightness of the samples at a distance where the grain could not be perceived. The subjects were viewing the samples perpendicular to a large (1.0 m x 1.25 m) illumination source from a distance of 5.2 m. The height of the subjects' eyes were maintained at a height to provide a 30° elevation look angle. Statistically, the subjects identified the gloss/brightness ranking of the samples consistent with the device measurements. The subjects experienced considerable difficulty in the ranking even though the results appeared consistent. During the course of the test, it was noted that a change in look angle changed the ranking order of the samples. Various pairs of samples reversed their relative gloss/brightness appearance when the observer moved to a different look angle. Sample testing with a photometer confirmed the transition. At that point the decision was made

Sample 6

Figure 1 Grain Samples

to collect qualitative data in the natural environment where the material would be used.

Testing was accomplished outdoors with the samples solar illuminated and in shadow. Solar-illuminated measurements were limited to the sun residing in the forward hemisphere to coincide with the most severe environment encountered by a driver and an instrument panel.

Azimuth and elevation measurements were made in accordance with Figure 2. Solar-illuminated measurements were limited to two solar angles. Our experience in optical stealth and camouflage dictated that data on more solar angles is better accomplished by computer simulation[2,3]. A calibrated barium block standard was used to provide a reference brightness measurement with the varying solar intensity levels.

Tests of the samples were conducted in an indoor environment using the large light source and a video camera-based gloss measurement system. The results of these tests and corresponding outdoor tests are compared to the measurements provided by the ASTM D523 device.

SOURCE OF ERROR

Solar location was determined by time and a computer program for the longitude and latitude of the tests, however, a finite time was required to make the measurements. Some variation of results occurred due to the physical location of the photometer field of regard on the sample.

TEST RESULTS

Test 1 (Figure 3) was conducted at a solar elevation angle of 29°. The photometer was at the angle of reflection of 29° and then moved at 15° intervals in azimuth, maintaining the 29° elevation relationship with the sample.

On axis (0° Az) the samples reacted as would be anticipated. The non-grained sample exhibited the highest brightness. All samples exhibited specularity with readings exceeding the barium which has a total hemispherical reflectance approaching 100%. At 15° azimuth all but one of the grainy samples exceed the brightness of the non-grained sample and varied from approximately 19% to 52% of their on-axis values. The trend continued as the off-axis angle was increased for four of the five samples.

Test 2 (Figure 4) was a repeat of Test 1 except the solar elevation and measurement angle were at 50°. It is immediately seen that the sun's angle with respect to the samples significantly changed the specular content of the reflection. The sample measurements were reduced significantly to 25% of their value at 29° in the on-axis condition, although the solar intensity increased approximately 60%. The pattern of diminished brightness approximated the 29° measurements, except the 45° azimuth angle was reached before the brightness levels of four of the five samples exceeded that of the non-grained sample.

Tests 3 and 4 (Figures 5 and 6) were designed to test the brightness sensitivity of the samples with respect to elevation look angle. The two solar elevation angles tested were 30° and 50°. In both cases, the azimuth angle was held constant on axis (0° Az).

The Test 4 samples changed values as a function of look angle. Only sample 1 and the non-grained sample peaked at the 50° reflection angle. The peaks of the other samples varied along with their values relative to each other and the non-grained control sample. The 50° solar and elevation look angle strongly suggested that the various grains exhibit directional reflectivity. The effect is not as obvious but does appear to be present in the 30° readings.

Test 5 (Figure 7) was conducted with the samples in a shady/overcast condition. Only elevation look angle was changed. The results suggest that the grainy surfaces were more capable of distributing surround light in all directions than the non-grained sample.

Test 6 was conducted employing a (1.0 m x 1.25 m) illumination source. The source was constructed with fluorescent lamps covered by diffusing glass. The samples were placed approximately 30 cm in front of the source and

measured with a photometer. The illuminator panel provided a relatively uniform source at an approximate overall source size of 120° in azimuth and 70° in elevation although the effective size was less. The data shown in Figure 8 is relatively benign.

Test 7 employed a TRICOR Model 801A Surface Analysis System. The device uses a video camera capable of providing 240,000 data points on a sample which is illuminated by an extended (18 cm x 23 cm) illumination source. The device is calibrated to the same black glass plate used to calibrate the ASTM D523 device and is assigned a gloss level of 255. The unit is capable of dividing the levels of gloss into selectable bands based on a percentage of sample points. The data shown in Figure 9 shows the average value of the 20% highest and 100% (average value) of gloss data points. This selectability allows a simulation of observer viewing distance under various lighting conditions. For example, at short range the observer can resolve the grain and gloss projected from that grain, whereas at longer range the individual grain variations are not resolvable due to the resolution limits of the eye.

Utilizing some percentage of the brightest data point in effect shows the potential capability of the surface gloss/reflection. A small illumination source cannot produce the light rays over an angle sufficient to produce a reflection into the camera's field of view due to the normals of a grainy surface.

Figure 10 shows gloss measurements from an ASTM D523 device. The device incorporates a small collimated light source and a photodiode focused on the surface reflection of the source from a surface. Calibration of the unit is accomplished by assigning a value of 100 to a measurement of black gloss standard of a prescribed index of refraction.

The ASTM D523 device was designed to measure the gloss of flat samples and makes no other claim. Its use for measuring curved or textured surfaces is highly suspect due to its physical construction. Figure 11 shows its proper use and the effects of curved and irregular surfaces. The intent is that the collimated light emitted by the source is collected by the relatively small photodiode. When the surfaces are curved or irregular, the reflected ray's directions are changed, reducing the number collected. The figures at the right are intensity maps of the surface of the photodiodes for the different conditions.

MEASUREMENT COMPARISONS

Table 1 shows a comparison of 30° on-axis measurements of gloss and brightness outdoors solar illuminated (Tests 1 and 2) and shady test (Test 5), indoors with the ASTM D523 device, the large illuminator (Test 6) and the 100% and 20% values of the video camera system (Tests 7 and 7a). All values were normalized to the non-grained sample reading for that test to allow a comparison.

The data clearly shows that the grainy sample's brightness/gloss with respect to the non-grained sample directly increases with the effective illumination source size confirming our previous report[1]. It is obvious that a greater number of the surfaces provide reflection to the sensor as the source size is increased. The effect is maximized when the entire hemisphere becomes the source and the grainy surfaces equal or exceed the smooth non-grained surface.

SUMMARY OF TEST RESULTS/CONCLUSIONS

The testing showed that grainy surface reflections/gloss are significantly influenced by the environment, the geometric composition of the grain and the viewing angle of the observer. The data indicates that the geometric composition of the grain affects the directionality of the reflection from the surface.

A lower solar elevation angle (<50°) reflected brightness levels can reach objectionable levels. On-axis levels can exceed 10,000 Foot Lamberts (fL) at low sun angles which is approximately the value of a cloud edge in close proximity to a high noon sun. Brightness levels exceeding 2,000 fL are prevalent even with the sun off-axis at typical driver viewing angles. The 2,000 fL corresponds to the horizon on a bright day or the sun reflecting from the desert.

The data suggests that gloss-reducing coatings may require a more complex analysis to achieve their objectives on grainy surfaces. The impact of the findings on the automobile interior manufacturing industry appears to be the following:

1. Appearance and functionality should not be independent parameters in designing the grain employed in interiors in general and on the top of instrument panels in particular. The directional reflection of various grains can increase susceptibility to glare or windshield imaging.
2. If harmony is defined by grainy surfaces being produced by different manufacturers being geometrically alike and presenting the same brightness, it can be accomplished at the uninstalled level on identically shaped material. Once the geometry of the surface or its spatial orientation is changed, the perceived brightness of the various parts will change with the environmental conditions.
3. The ability to reproduce and match grainy materials manufactured by different entities cannot be accomplished by using an ASTM D523 device. The device was designed to measure flat surfaces and performs well in that capacity. To ensure reproducibility and matching materials, the geometric characteristics of the grain along with the gloss need to be monitored.
4. Optimum functionality of interiors from a glare and imaging aspect would appear to be most easily accomplished by computer simulation. Allowable variations in basic interior geometry in combination with grain directionality could be rapidly assessed under all pertinent environmental conditions and viewer aspect angles.

Considerations on a Feeling of Troublesomeness Regarding Automotive Head-Up Displays During Driving

Kazumoto Morita, Jinichi Mashiko, and Takeo Okada
Traffic Safety & Nuisance Research Institute

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

The authors have carried out two types of tests regarding head-up displays (HUDs) for the purpose of determining the relationship between display position and a feeling of troublesomeness for the driver.

The first test was a basic experiment to evaluate how troublesome the HUDs were to an observer sitting in a chair outdoors. The collected data was used as the basis for carrying out approximation by means of two-dimensional normal distribution.

In the second test, the observer was actually in a car and a mock-up HUD making use of clear film was used to carry out the experiment in investigating how the feeling of troublesomeness changed depending on whether the vehicle was in a stop state or in a moving state. Compared to a stop state, the results in a driving state showed a shift toward the left side for the distribution of a feeling of troublesomeness. The reason is probably because the distribution of the line of vision of the driver moves toward the left when driving in Japan.

INTRODUCTION

One method of transmitting information to the driver when driving a motor vehicle is via head-up displays (HUDs) which display vehicle speed on the windshield. The devices have been mounted on market-sold vehicles since around 1988[1,2]. Up to now, HUDs have been used mainly to indicate vehicle speed. More recently, however, there have been proposals to use HUDs as a display device for navigation systems[3,4]. In the coming days, it is expected that HUDs will be employed for the purpose of displaying a variety of information.

When it comes to the technology of HUDs, the situation is different from that in jet fighters where professional pilots with skills operate the equipment. In automobiles the users are ordinary drivers. That means the equipment must be easy to read and use. Considering how one of the characteristics of the HUDs is that they overlap with the scenery in the front of the vehicle, an important question is the position on the windshield where the HUDs are located.

The display position of a HUD must be determined for a variety of reasons. We might readily assume that, in order for the driver to quickly read and understand the display contents, the ideal HUD position would be directly in front of the driver. Indoor tests carried out by Okabayashi and others have studied accuracy in simultaneously apprehending the information regarding the scenery in front of the car and the displayed information according to the display position[5]. Results show that there is a high accuracy rate for grasping information in a position directly in front of the observer and in a range of vision within several degrees.

Nevertheless, when actually driving a vehicle, if HUDs are directly in front of the driver they overlap with the scenery to the front and are perceived as troublesome by the driver. In considering comprehension of the information, it is naturally desirable that HUDs be located as much as possible in front of the driver. However, considering the feeling of troublesomeness to the driver, it is also important to locate the device at a position that is somewhat removed from a position directly in front of the driver.

For these reasons, the authors carried out two types of experiments to determine the extent to which the driver experienced a feeling of troublesomeness depending on the display position of a HUD. Of the two types of tests, the first was a basic experiment in which the HUD was displayed on plate glass on a desk and the observer sat in a chair in order to evaluate the feeling of troublesomeness. In the other type of test, the observer rode in a compact vehicle and there was evaluation both in a stopped state and in a driving state in order to evaluate the extent of a feeling of troublesomeness.

METHOD OF BASIC EVALUATION TEST

EXPERIMENTAL METHOD - An observation test was carried out at a test course located in Kumagaya City, Saitama Prefecture in Japan. Figure 1 shows the overall test conditions. An observer seated in a chair (right side of figure) observed a HUD image displayed on a flat display glass located on a desk. The person conducting the experiment (left side of figure) changed the display position of the HUD in carrying out the experiment. The observers placed their chins on a chin rest (height: 1.00 meters) to define the position of the head. In addition, a compact car was located at a point about 50 meters in front of the observer and observers were instructed to look in that direction.

As Figure 2 shows, there were 20 different display positions. The point directly in front of the observer was considered the origin point. The direction was exposed as the angle of vision. As for the horizontal direction, there were a total of 5 different positions ranging from 6 degrees to the left to 6 degrees to the right at intervals of 3 degrees. As for the vertical direction, there were a total of 4 different positions ranging from 6 degrees in a downward direction to 3 degrees in an upward direction at intervals of 3 degrees. Regarding the angle in a horizontal direction the right side was plus. Regarding the angle in a vertical direction, the upper side was considered plus. The experiment was designed so that the center of the HUD image was displayed in the display position shown on the coordinates of the horizontal and vertical directions.

Figure 3 shows an example of display conditions (display position located 6 degrees to the left and 6 degrees downward). As Figure 3 shows, the HUD image (created by using a fluorescent display tube) is the number 88. The color of the display image was green (chromaticity coordinates: x=0.242, y=0.436) and the display luminance measured in the direction of observation was 1600 cd/m^2 (all actual measurement values measured in dark room). The distance from the observer's eye to the HUD image was about 1.2 meters. The general size of the HUD image of the market-sold vehicles was used as a reference in making the vertical angle vision of the display image (88) seen by the observer to be 0.7 degrees and the horizontal angle of vision to be 1.2 degrees. The display plate glass was a plate with a reflectivity of 20% after coating the surface with oxidized titanium. This was set at an incline of 31 degrees from the horizontal plane. The transmissivity of the plate glass from the observer's direction was 75%.

In the three-day test carried out in the present experiment, the weather was both fair and cloudy. The horizontal illuminance measured by facing the receptor of the illuminance meter towards the zenith was about 5,000 to 80,000 *lx*. The road surface luminance measured at a position about 50 meters to the front of the observer was in a range between about 200 and 3,700 cd/m^2.

Regarding the order of the experiment, for each display position the HUD image was shown for 10 seconds to the observer. The observer was then asked to give a

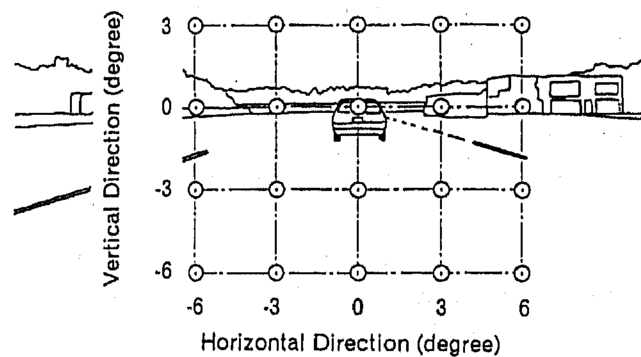

Fig.2 Display positions of the HUD

Fig.1 Basic evaluation test scene
-an observer (right side) and an examiner (left side)-

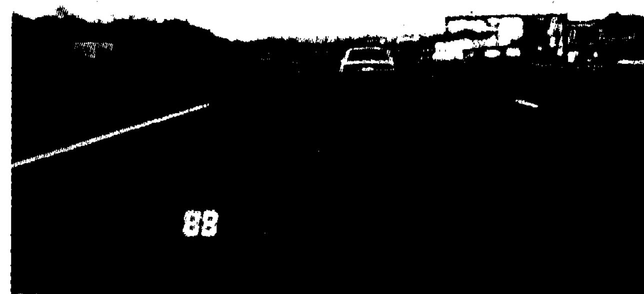

Fig.3 An example of HUD image

subjective evaluation of a feeling of troublesomeness according to the integers from 0 to -4 as shown in Table 1. (It is admitted by the authors that how they feel depends on their own judging scale.) The 20 types of display positions were selected at random and evaluation was carried out two times for the same display position.

There were a total of 15 observers with normal color vision and with an average age of 34.1 years (7 observers in their 20's, 3 observers in their 30's, 4 observers in their 40's, 1 observer in his 50's). That meant there was a total of 30 evaluation data obtained for a single display position.

Tab. 1 Rating Scale for a Feeling of Troublesomeness

Evaluation value	Meaning
0	Not troublesome
-1	Slightly troublesome
-2	Rather troublesome
-3	Very troublesome
-4	Extremely troublesome

EXPERIMENTAL RESULTS - Of the evaluation standards over 5 levels regarding a feeling of troublesomeness, when it came to determining the extent to which a position was troublesome to the observer, various judgments can be made. In this report, we will consider the total of the answers including "rather troublesome," "very troublesome" and "extremely troublesome" in order to examine the feeling of troublesomeness. Speaking conversely, we can say regarding the evaluation results "not troublesome" and "slightly troublesome" that the observers did not have any problem in this respect.

If we obtain the total of the above three types of replies for each display position, we obtain a figure like that in Figure 4. At the origin point, the total for the three replies of "rather troublesome," "very troublesome" and "extremely troublesome" was equal to the total number of 30 cases.

Examining the distribution of this feeling of troublesomeness we see that the feeling was greatest at the origin point and that the feeling decreased as one moved either to the right and left or up and down.

The evaluation results are discrete for the display positions determined for every 3 degrees of the angle of vision. This data is used as the basis in attempting to approach the distribution of a feeling of troublesomeness by means of a two-dimensional joint normal distribution as shown in the following formula (EQ (1))[6]. Here, the horizontal direction is the x axis and the vertical direction is the y axis.

The five parameters included in the above formula are obtained as follows.

$$\left.\begin{aligned} &E[x] = \mu_x \\ &E[y] = \mu_y \\ &E\left[(x-\mu_x)^2\right] = \sigma_x^2 \\ &E\left[(y-\mu_y)^2\right] = \sigma_y^2 \\ &E[(x-\mu_x)(y-\mu_y)] = \sigma_x\sigma_y\rho_{xy} \end{aligned}\right\} \cdots\cdots(2)$$

(E[•] means an operation of deriving the expected value.)

If we use the evaluation results as the basis for calculation, these parameters are as follows:

μ_x=0.03
μ_y=0.32
σ_x=3.56
σ_y=1.89
ρ_{xy}=0.006 .

The average of x and y corresponds basically with the origin point.

Remaining now is the question of whether the two-dimensional normal distribution approximated with EQ (1) is fitting as the actual distribution of evaluation results. Thus, it is possible to verify this problem by carrying out an χ^2-test[7] regarding the level of compatibility. The total of the replies for "rather troublesome," "very troublesome" and "extremely troublesome" becomes the observed frequency fi (i=1 to 20). The total value for the observed frequency fi was 187 cases. In addition, two-dimensional normal distribution is used as the basis for deriving $z(x,y)$ for the 20 display positions by means of EQ (1). The

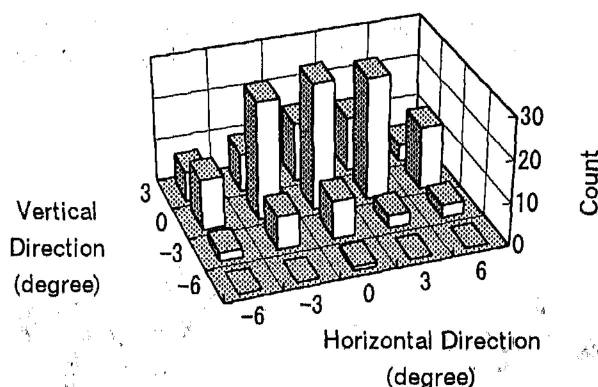

Fig.4 Total of replies including "rather troublesome", "very troublesome" and "extremely troublesome"

$$z(x,y) = \frac{1}{2\pi\sigma_x\sigma_y\sqrt{1-\rho_{xy}^2}}\exp\left[-\frac{\sigma_y^2(x-\mu_x)^2 - 2\sigma_x\sigma_y\rho_{xy}(x-\mu_x)(y-\mu_y) + \sigma_x^2(y-\mu_y)^2}{2\sigma_x^2\sigma_y^2(1-\rho_{xy}^2)}\right]\cdots(1)$$

expected frequency Fi (i=1 to 20) for each position is obtained from this value so that the total is the figure of 187 cases as mentioned above. The observed frequency and expected frequency are used to obtain the value of X^2 by means of the following equation.

$$X^2 = \sum_{i=1}^{k} \frac{(fi - Fi)^2}{Fi} \cdots\cdots (3)$$

The distribution X^2 is χ^2 distribution in terms of approximation. By comparing the two it is possible to check the level of compatibility. If the value for X^2 as shown in EQ (3) is obtained from the present data, X^2=17.47. On the other hand, regarding the level of freedom of χ^2, the constraint conditions in order to obtain the expected frequency are 6 items (the 5 constraint conditions generated to derive the prior five parameters and the single constraint condition generated by the total number of data). The figure of the level of freedom is thus 20-6=14. If the level of significance is 5%, the value is χ^2=23.68. A comparison of the values for X^2 and χ^2 shows that $X^2 < \chi^2$. As a result, we could confirm that it is possible by means of the above two-dimensional normal distribution to approximate the actual distribution of evaluation results.

Figure 5 shows this two-dimensional normal distribution in a range from -10 degrees to 10 degrees in a horizontal direction and from -6 degrees to 6 degrees in a vertical direction. In order to obtain generality, there is expression in terms of the ratio of replies rather than the number of replies regarding the z axis. In other words, the total of the replies for "rather troublesome," "very troublesome" and "extremely troublesome" for each display position is expressed as the ratio after dividing by the total replies for those display positions. In Figure 4, the total of the replies for the above three evaluation values at the origin point was basically equal to the total of 30 cases. Taking this into consideration, we see that the maximum value for axis z in Figure 5 is 1.0. The figure also shows the contour lines at an interval of 0.2 regarding the feeling of troublesomeness. Figure 6 shows the same two-dimensional normal distribution as a plan view. In this case, too, there is display of contour lines at an interval of 0.2 regarding the feeling of troublesomeness. In Figure 5 and Figure 6 the range from 0 to 0.2 for a feeling of troublesomeness is shown by the gray section. In other words, this shows the range in which the total for the three evaluation results of "rather troublesome," "very troublesome" and "extremely troublesome" does not exceed 20% in relation to all replies. Stated otherwise, it shows the range where the total of evaluation results for "not troublesome" and "slightly troublesome" exceeds 80%.

Looking at the results of computing with EQ (2), we see that the correlation coefficient ρ_{xy} of x and y is almost zero. As a result, this is considered separate regarding x and y. In other words, if we obtain the evaluation results independently in a horizontal and vertical direction, it is possible to estimate the two-dimensional normal distribution for the whole. If we use the present evaluation results as the basis, we obtain the following. That is, if we obtain the average and standard deviation from the measurement evaluation results on a horizontal line at the position y=0, the values are as follows: μ_x=0.18, σ_x=3.62. And if we obtain the average and the standard deviation in the same way only from the measurement evaluation results on a vertical line at position x=0, the values are as follows: μ_y=0.17, σ_y=2.13. Considering the scattering of data in the evaluation test, we assume that it is possible to obtain results that are basically the same as the values obtained from 2-dimensional total evaluation as in EQ (2). Given the above, if we obtain the distribution of a feeling of troublesomeness in the representative horizontal and vertical directions in the evaluation test, we can estimate the 2-dimensional distribution and thus achieve efficiency in data gathering during the experiment.

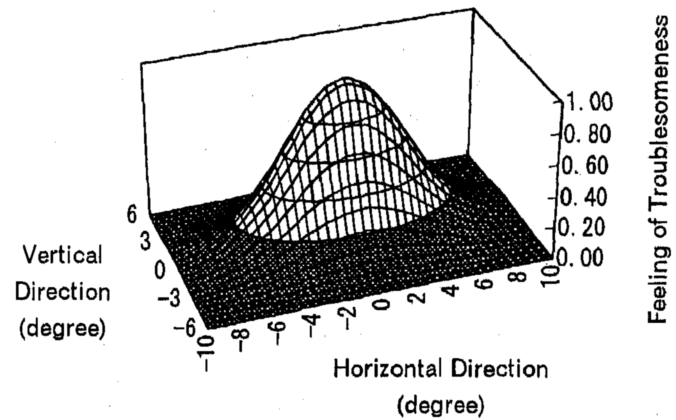

Fig.5 Distribution of a feeling of troublesomeness approximated by two-dimensional normal distribution

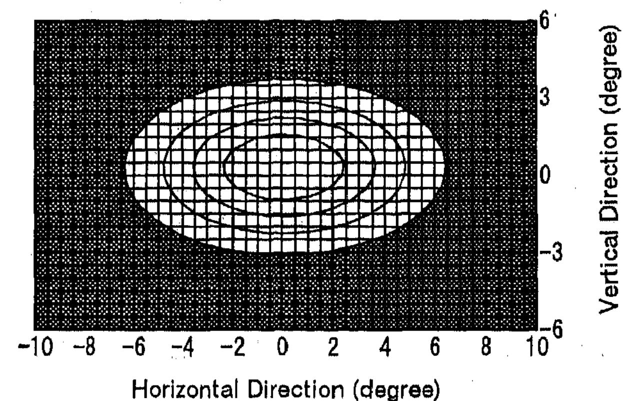

Fig.6 Plan view of two-dimensional normal distribution regarding a feeling of troublesomeness

As for the coordinates of the display positions analyzed above, they correspond to the central position of the HUD image when the display image has a value of 0.7 degrees in the direction of height and 1.2 degrees in a sideways direction. We can expect that, if the size of the display image changes, the results of evaluating a feeling of troublesomeness will also change.

EFFECT OF HEIGHT OF EYEPOINT OF DRIVER

Up to now, the discussion was based on an experiment in which the chin of the observer is supported by a chin rest so that the eye position of the observer is fixed. In actual life, however, people with different body types and driving positions are driving vehicles, which means the eye position changes. Regarding the HUD image, if one ignores the optical distortion of the display device, the position of the image does not change. As a result, depending on the position of the driver's eyes, the angle of the direction in which the image can be seen will change.

Considering how the HUD device is located in the vehicle instrument panel, the cases are more numerous in which HUDs are displayed in a downward direction in relation to the driver. Thus, we will consider the problems when HUDs are displayed in a downward direction vertically. Subsequent statements concerning the angle of vision will be expressed as the depression angle. If the depression angle is large, it means that the angle is large in a minus direction when using the method of expression used up to now for angle of vision.

If the HUD position is established according to the standard eyepoint (this point will be described later), the depression of angle in relation to the HUDs will increase for persons with an eyepoint higher than the standard eyepoint. Conversely, for persons with a lower eyepoint than the standard eyepoint, the depression angle will be smaller (Figure 7).

This being so, regarding a feeling of troublesomeness in the case of observers with a lower eyepoint than the standard eyepoint, the HUD image will become visible upon approaching the origin point directly to the front so that a feeling of troublesomeness will be felt to increase. The apparent change in the HUD position according to the eyepoint height is not only related to the height of the eyepoint but also to the horizontal distance from the eyepoint to the HUD image.

In order to investigate the change in the depression angle according to the eyepoint height, there is use of an "eyellipse"[8] which describes the elliptical shape of the driver's eye range. The conditions of the eyellipse used are as shown below when using the values of a normal compact vehicle as reference. This is a 95th percentile side view when the normal driving and riding seat track travel is 165 mm (Figure 8). The back angle is 25 degrees. The eyellipse setting method is as determined in ISO4513. Under these conditions, in this paper the standard eyepoint position is determined to be the intersection of the datum lines x-x and z-z in the eyellipse side view. In other words, the point located at 0.635 meters in a vertical direction above the seating reference point is the standard eyepoint position.

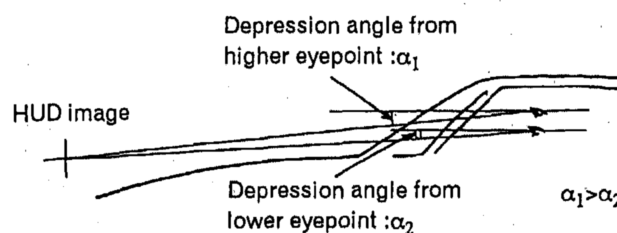

Fig.7 Change in depression angle owing to height of driver's eyepoint

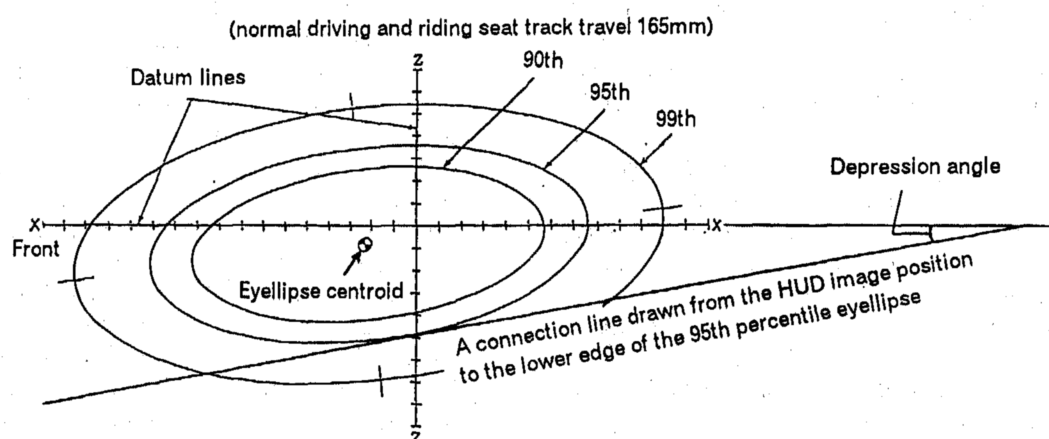

Fig.8 Side view of eyellipse template

The following is a discussion of the HUD image seen from depression angles of 4 degrees, 5 degrees, 6 degrees and 7 degrees from the standard eyepoint. A connection line is drawn from the HUD image position to the lower edge of the eyellipse of the 95th percentile. The horizontal distance from the standard eyepoint to the HUD image is changed from 0.8 meters to 4 meters.

Figure 9 shows the change in the angle (depression angle) of this connecting line from the horizontal line. As this shows, when viewed from a low eyepoint, the HUD image can be seen at the position of the depression angle that is smaller than the depression angle from the standard eyepoint. If the distance from the standard eyepoint to the HUD image is close, the depression angle is especially small. In other words, it is sensed as close to the position directly in front of the driver.

For example, regarding a display in which the depression angle is 5 degrees and the HUD image position is at a distance of 1 meter when seen from the standard eyepoint, if this is examined in terms of an eyellipse of the 95th percentile, it can be seen at a position where the depression angle is 2.1 degrees. To consider matters in terms of an eyellipse of the 95th percentile means that if a plane seen as a straight line in the side view is drawn tangent to the lower edge of the eyellipse, then 95% of the driver eye locations will be above the line and 5% of the driver eye locations will be below the line. That is 5% of the drivers with a lower eyepoint are viewing the HUD image at a depression angle that is even smaller than the depression angle of 2.1 degrees. Thus, considering the feeling of troublesomeness, although there is almost no problem for drivers with a standard eyepoint (Figure 5, Figure 6: The feeling of troublesomeness is 0.02 at a point located at 0 degrees in a horizontal direction and 5 degrees in a downward direction), for drivers with a low eyepoint this will be felt as troublesome. (In Figures 5 and 6, the

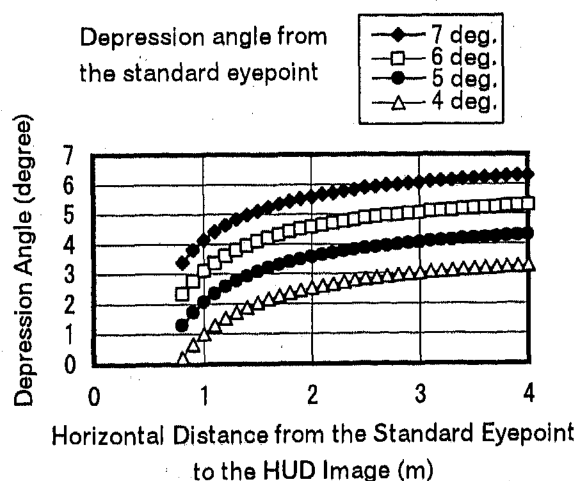

Fig.9 Change in depression angle when viewd from low eyepoint (in terms of the 95th percentile eyellipse)

feeling of troublesomeness is 0.47 at a point located at 0 degrees in a horizontal direction and 2.1 degrees in a downward direction).

As the above shows, even in cases where the eyepoint is low, in order to decrease change in the depression angle in relation to the HUD image, it is better to display the imaginary HUD image at a position far removed from driver and directly to the front. Nevertheless, there have been reports of a feeling of strangeness among drivers if it is displayed too far away[9]. For this reason it is desirable to display the image at an appropriate position. Considering Figure 9, we can consider it desirable to display the HUD image at a position that is about 1.5 meters or more distant from the driver so that marked changes in the angle of depression do not occur.

On the other hand, we can assume that in the case of drivers with a low eyepoint, if there is a structure in which the HUD position can be adjusted to a low position, this can act as one method of reducing changes in the angle of depression.

EVALUATION TESTS CARRIED OUT WHILE DRIVING A VEHICLE

EXPERIMENTAL METHOD - In the basic evaluation test, the observer sat in a chair and observed a HUD on a plate glass. In the present experiment, the observer rode in an actual vehicle (compact car) to evaluate the HUDs. The vehicles used in the test included the observation car in which the observer was riding and a vehicle located at a position about 50 meters in front. The vehicle to the front was used as a target when the observer was looking forward.

Because it was difficult to install an actual HUD at an arbitrary position in the vehicle, a mockup HUD using clear film was attached to the windshield.

The standard eyepoint of the observation vehicle was set as described above. In other words, a point located 0.635 meters above the seating reference point of the driver's seat in a vertical direction was established as the standard eyepoint.

As for the display position, the point directly before the standard eyepoint was made the origin point. In a horizontal direction (on the x axis) this was expressed in terms of the angle of vision from the standard eyepoint in establishing 7 points from -15 degrees to 15 degrees at intervals of 5 degrees. In a vertical direction (on the y axis), there were 5 points ranging from -6 degrees to 6 degrees at intervals of 3 degrees (Figure 10). In addition, as a reference, there was addition of the following four points: (x = -5 degrees, y = -3 degrees), (x = -5 degrees, y = 3 degrees), (x = 5 degrees, y = -3 degrees), (x = 5 degrees, y = 3 degrees). Because the origin points overlap in the horizontal and vertical direction, the total number of display positions was 15 points.

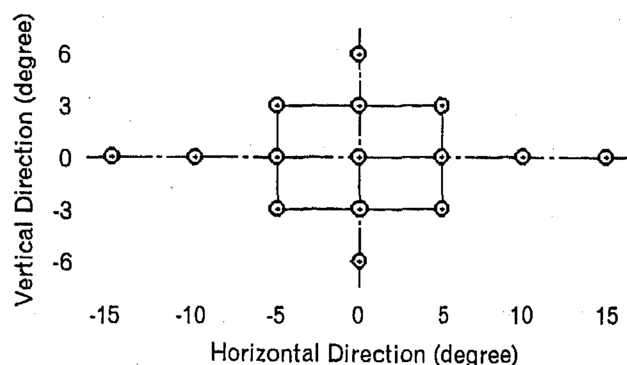

Fig.10 Display positions of the mockup HUD

As was the case already, the HUD image was a green figure 88. Regarding the size of the numbers, at the origin point directly to the front, the size was approximately 0.8 degrees in a vertical direction and approximately 1.3 degrees in a horizontal direction.

In the present experiment, because clear film attached to the windshield was used as a substitute, there were the following differences compared to an experiment with an actual HUD.

(1) Regarding the mockup HUD used this time, it was not a case of bright display as is true for an actual HUD. Instead, the numbers appeared darker than the background. The transmissivity of the green numerals on the clear film was 47%.

(2) By attaching the mockup HUD to the windshield, the distance from the standard eyepoint to the display position is shorter. For example, the distance from the standard eyepoint to the origin point display on the windshield is approximately 0.56 meters. With a normal HUD, the distance to the display position is generally longer.

(3) The windshield is at a slant in relation to the driver and also has a complex curved configuration. As a result, the distance from the standard eyepoint to the display position on the windshield changes in relation to the individual display positions. For this reason, if the size of the numerals on the clear film is the same, the display size seems to change somewhat according to the display position. In the present experiment there was use of two types of mockup HUDs for which the size on the clear film was slightly different. This was done so that the apparent difference in display size according to the display position would not be that pronounced.

There was the following additional problem with the sitting position. Regarding the up-down direction of the observer's eye position, the height of the driver seat was adjusted so that the windshield origin point height would agree with the position of the driver's head in the vehicle located 50 meters to the front. In a horizontal direction, there was adjustment of the sitting position of the observer in a left-right direction so that the position of the origin point would match the position of the driver in the vehicle to the front. (Because the distance from the eyes of the observer to the mockup HUD is short, if the observer focuses on the vehicle to the front, the two images of the mockup HUD in the left and right eyes of the observer will be seen on the right side and left side respectively. Thus, the driving position was adjusted so that the car in front can be seen between the two images.) Nevertheless, regarding the front-back direction, the driving position is left up to the observer so that his eye position does not definitely match the standard eyepoint. Regarding the HUD position, it is not necessarily true that all observers see the HUD image in the display position of the angle of vision that was set.

Because of the above restrictions, the results obtained in this experiment are not used to obtain distribution of a feeling of troublesomeness. Instead, they are mainly used to make a comparison of the feeling of troublesomeness between a stop state and a driving state.

The observers carried out two types of tests two times each: an experiment in which evaluation was made with the car in a stopped state, and an evaluation made when the vehicle was traveling at 60 km/h. The observer observed the HUD image for approximately 10 seconds and then replied concerning results of evaluation of feeling of troublesomeness using the same standards as in Table 1. The display order of the HUD positions was random.

There was a total of 14 observers with normal color vision and with an average age of 27.1 years. That meant there was a total of 28 evaluation data obtained for a single display position. The weather during the test alternated between fair and cloudy.

EXPERIMENTAL RESULTS AND CONSIDERATIONS - As was the case with the basic evaluation experiment, regarding a feeling of troublesomeness, there was an evaluation of the number of replies for "rather troublesome," "very troublesome" and "extremely troublesome."

Figure 11 shows the evaluation results when the vehicle was stopped. Regarding the vertical direction, this is more or less symmetrical with the horizontal line of y=0. As for the horizontal direction, the feeling of troublesomeness was distributed to the left in relation to the vertical line of x=0. Figure 12 shows the results of evaluation during driving. These results are similar to the evaluation results when the vehicle was stopped. However, an examination of details shows a large number of replies on the left side and the lower side.

If this distribution is examined in terms of average and standard deviation, the values when the vehicle is stopped are $\mu_x = -1.9$ and $\sigma_x = 6.4$ in a horizontal direction, and $\mu_y = 0.6$ and $\sigma_y = 2.9$ in a vertical direction. In this case, the values in a horizontal direction are derived only from the evaluation results on the horizontal line y=0; the values in a vertical direction are derived only from the evaluation results on the vertical line x=0. During driving, the values are $\mu_x = -2.6$ and $\sigma_x = 6.7$ in a horizontal

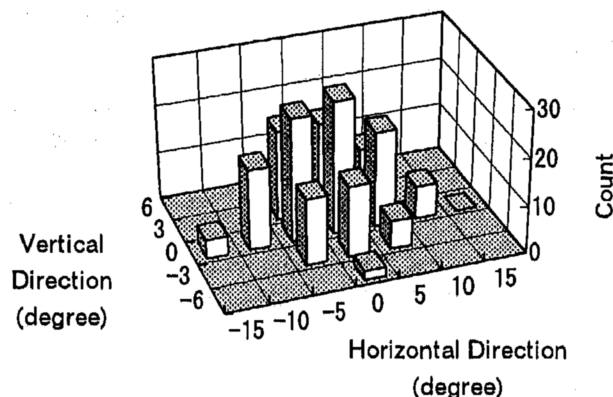

Fig.11 Evaluation results of a feeling of troublesomeness (when the vehicle is stopped)

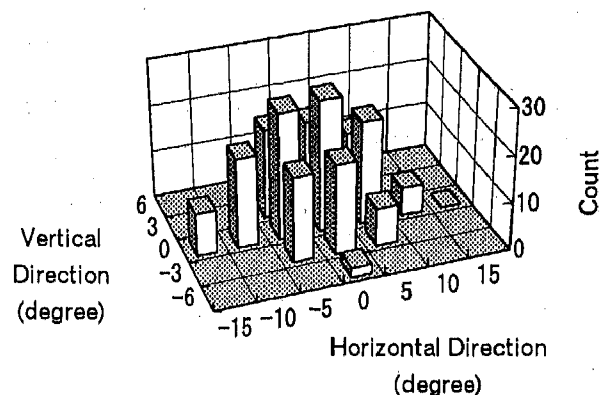

Fig.12 Evaluation results of a feeling of troublesomeness (during driving)

direction, and $\mu_y = 0.4$ and $\sigma_y = 3.0$ in a vertical direction.

Thus, the distribution of a feeling of troublesomeness shifted to the left during actual driving as compared to when the vehicle was stopped. On the other hand, regarding a vertical direction, the distribution during driving shifted slightly downward as compared to when the vehicle was stopped, although this was not a marked difference. As for the spread of distribution, no marked difference was ascertained between when the vehicle was parked and when it was driven.

In past research which studied the distribution of the line of vision of the driver during driving, it was clear that the line of vision of the driver was distributed toward the side of the street (sidewalk side)[10,11]. In other words, in cases like that in Japan where the cars (with steering on the right) are driven on the left side of the road, the line of vision is distributed toward the left side[10]. On the other hand, in cases such as in the USA where cars (with steering on the left) are driven on the right side of the road, the line of vision is distributed toward the right side[11]. Thus, when driving the car as in this case instead of sitting in a parked car, the reason why the distribution of a feeling of troublesomeness shifts to the left side is because the line of vision (attention) of the driver tends to shift to the left by force of habit so that HUDs located in that direction were perceived as troublesome.

On the other hand, regarding a distribution of the line of vision in a vertical direction, Okabayashi et al. have produced the following research results[5]. According to those results, the center of distribution of the line of vision in a vertical direction is roughly at the origin point on highways. On roads that are highly congested, this shifts to a position that is about 1 to 1.5 degrees below the origin point. In the present experiment, the traffic conditions allowed for leeway since the observation vehicle was located 50 meters behind the other vehicle on the test course. That meant the level of congestion was low and that conditions were close to those on a highway. As a result, even when driving, the amount of shifting of the line of vision to the bottom was small compared to when the car was stopped. When driving on roads with a high level of congestion, the distribution of the line of vision shifts downward. As a result, the distribution of a feeling of troublesomeness also is measured as shifting downward.

CONCLUSION

In order to clarify a display position of HUDs in which there is no feeling of troublesomeness for the driver, the authors carried out two types of tests. The first was a basic evaluation test in which plate glass was placed on a desk outside and an HUD was displayed on the plate glass. An observer seated in a chair were then asked to evaluate the feeling of troublesomeness regarding the HUDs. In the second test, an observer actually seated in a vehicle was asked to evaluate the feeling of troublesomeness of the HUDs. In this experiment a mockup HUD made of clear film was used to carry out the test in order to investigate whether there are differences in the feeling of troublesomeness when the vehicle is parked and during driving.

The results of the first basic test are as follows:

(1) The feeling of troublesomeness is highest in the display position located directly to the front of the observer. This decreases as the position moves away from that position either to the left and right or up and down. This distribution of a feeling of troublesomeness can be approximated with 2-dimensional normal distribution.

(2) When the feeling of troublesomeness is expressed in terms of 2-dimensional joint normal distribution, the correlation coefficient of the horizontal direction and vertical direction is almost zero. As a result, the

evaluation results for the horizontal direction and vertical direction are independent. In other words, by obtaining the values in a horizontal direction and vertical direction separately, it is possible to estimate the 2-dimensional normal distribution.

(3) When HUDs are displayed so that they can be seen below by a standard driver, the HUD image can be seen close to the position directly in front for drivers with a low eyepoint. Thus, we can estimate that the feeling of troublesomeness will increase for drivers with a low eyepoint.

The results for the test in which observers sat in actual vehicles are as follows.

(4) Compared to when the vehicle is stopped, the distribution of a feeling of troublesomeness during driving shifts toward the left. The reason is that, generally speaking, the distribution of the line of vision of the driver tends to shift toward the left. The reason why the line of vision shifts toward the left is the case of Japan where the cars (with steering on the right) are driven on the left side of the road. In cases such as the U.S. where cars (with steering on the left) are driven on the right side of the road, the distribution of the line of vision will shift conversely to the right. Thus, we can assume as a result, that the distribution of the feeling of troublesomeness will shift toward the right in the United States.

(5) As for the vertical direction, when it came to the present test where there was sufficient leeway in driving conditions on the test course, there was almost no difference recognized regarding the distribution of a feeling of troublesomeness between a driving and parking state. Past research on roads with a high level of congestion shows clearly that the distribution of the line of vision shifts downward. As a result, when driving on roads with a high level of congestion, we can estimate that the distribution of a feeling of troublesomeness will also shift downward.

In the present research, we revealed that in display positions close to the area immediately in front of the driver, the HUDs are felt as troublesome. However, regarding information of an urgent nature that must immediately be relayed to the driver, we can assume that the emphasis is more on speed of understanding and accuracy of understanding than troublesomeness. This may indicate that it is actually better to locate the HUDs closer to the area directly in front of the driver in the case of transmitting urgent information.

New Optical Distortion Measuring Method Using Digital Image Analysis of Projection-Moire Patterns

A. S. Redner and G. K. Bhat
Strainoptic Technologies Inc.

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

Optical distortion of images observed through windshields is due to the geometry to a small degree, but to a larger extent, due to effects occurring in production. The detection of manufacturing defects is of primary concern for on-line and off-line inspection procedures. Zebra patterns commonly used to detect serious windshield defects only yield qualitative and highly subjective results. This new method uses fine Moiré screens projected through the inspected windshield on a master grating, directly yielding a full-field fringe pattern directly revealing the line-of-sight deviation. PC-based Digital Image Analysis of the Moiré Fringes permits nearly instantaneous quantitative evaluation yielding a two-dimensional map of distortion levels and deviations. Complete derivation of Fringe-order relations to the measured distortion parameters is included in this paper, as well as a description of the software used in Digital Image Analysis.

Introduction

Quality control (QC) in manufacturing of automotive glazing includes an valuation of the optical quality, or "distortion". Certain amount of distortion is always present, since even most perfect curved glass placed at an angle to the line-of-sight will introduce some distortion (1). This geometry related distortion is taken into consideration in product design and is usually negligible.

The quality control is more concerned with detection of manufacturing defects and problems that are traceable to the float-glass tempering, bending, or in case of laminated panes, to the laminating process. Presently, the QC operations are primarily relying on visual inspection. Unfortunately, the approaches used for visual evaluation are subjective and not quantifiable. The new method developed by the author is designed to fill the existing gap, using PC-based vision technology in place of the human eye.

Optical Inspection Parameters:

Image-Displacement, Deviation and Distortion

Figure 1 below identifies the types of optical problems encountered in a transparency. The image DISPLACEMENT occurs when a ray of light crosses glass of uniform thickness placed at an angle. The displacement is very small and in fact, does not affect the vision or the quality of the observed image. The DEVIATION of line-of-sight α moves the image, similarly to the action of an optical wedge. A uniform deviation (or a perfect wedge) seldom occurs in practice, and does not distort the image quality.

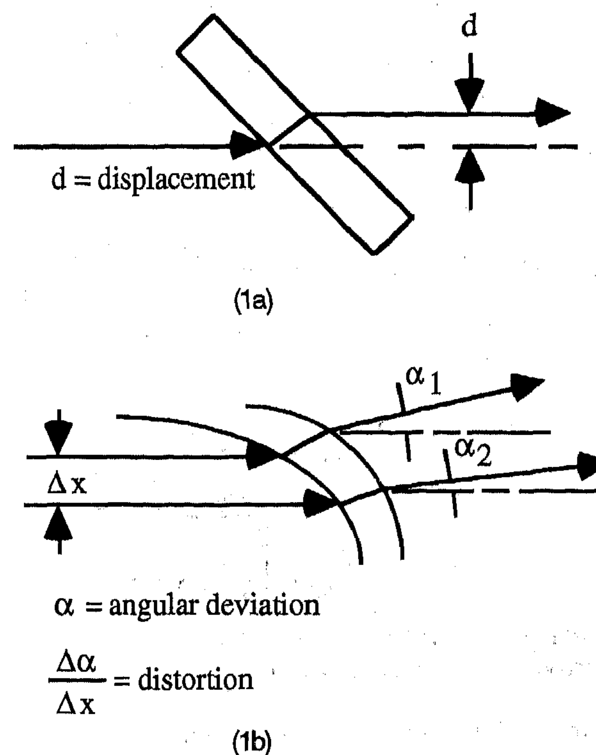

Figure 1: Optical Distortion Parameters

What is mostly of concern, is the DISTORTION defined as gradient of the deviation angle α, or $\Delta\alpha/_{\Delta x}$ (2) (3). The DISTORTION is actually the element that not only deviates the angular position of the observed object, but also deforms its shape and is clearly the most disturbing type of defect.

Presently used Methods

The most widely used method in QC is a "ZEBRA" board consisting of a brightly illuminated white screen containing black lines, (typically 1 inch wide) traced at 45°. The operator observes the "ZEBRA" through the inspected pane and decides the "QUALITY".

Although extremely simple in concept, the method is highly effective in locating gross distortions, and the only instrument used (the human eye) combines the lowest reproducibility with highest cost, that in a 3-shift production environment approaches 0.25M/year, without considering the cost of training and lapses due to operators fatigue or inattention.

The GRID METHOD (3) is more suitable for use in a developmental or design qualification test, since the analysis of the image is extremely time consuming. This method primarily designed for aircraft transparencies uses a large-scale grid-board containing 12.7 to 25.4mm square array of lines, and uses a double exposure. Measuring of deviation and distortion is performed manually, comparing photographs of the grid observed with and without the inspected pane. While the method is effective to reveal the angular deviation, it is very ineffective in attempting to quantify the distortion. It is interesting to note that the ASTM precision statement clearly indicates that " it is not practical or justifiable to specify the precision and bias...because of the operator-sensitive nature in the measurements of the test photos".

The RASTER METHOD described in EDE/324 (2) and ISO 3538C was developed primarily for windshields. It requires an examination of an array of circular dots projected through the examined windshield using a slide projector. (Figure 2)

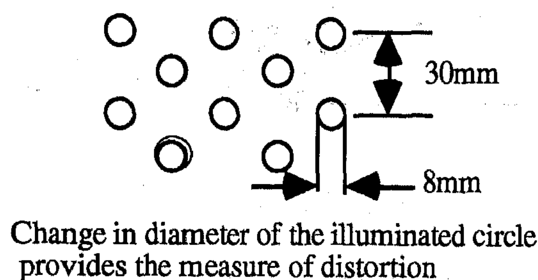

Figure 2: Raster Method of Measuring Distortion

The method is designed for an engineering laboratory, and reveals distortion as a change in image magnification of approximately 8mm diameter circles spaced approximately 30mm vertically and horizontally (2). The information is highly discontinuous and the process of data reduction is strictly dot-by-dot. Such process is inherently slow, even using machine vision. The large spacing between data points makes it inaccurate, since a 22mm defect can be totally missed by this system, making this concept unsuitable for Quality Control.

Visual application of this method (using a template) is yielding a margin of error up to 20% of the limit value of $\Delta\alpha/_{\Delta x}$ assuming that the operator can evaluate a change in the projected image within a fraction of mm.

Considering that the required distortion should not exceed 2' of arc (2), the increase of the 8mm circle at 2m distance becomes 1.16mm implying a distortion of 14.5% of the size, that is an extremely large change of magnification.

Moiré Method for Distortiometry

The optical schematic of the newly developed MOIRÉ DISTORTIOMETRY method is shown schematically in Figure 3.

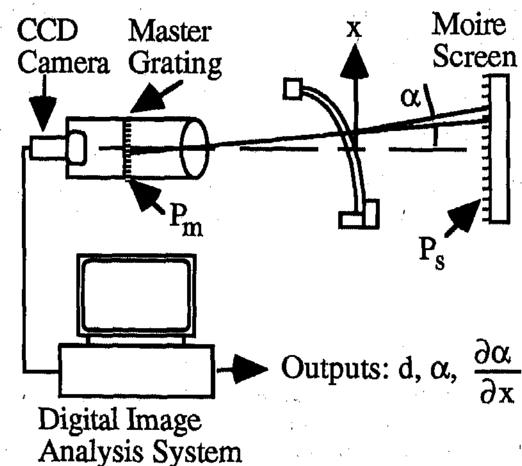

Figure 3: Optical Schematic of Moiré Distortiometry

Here, a MOIRÉ screen is projected on a high-density reference master through the inspected pane, forming MOIRÉ fringes. A Digital Image Analysis system (DIAS) performs the analysis the MOIRÉ pattern, retrieving a full-field information on image displacement, d, angular deviation

$$\alpha = \alpha(x, y)$$

and distortion $D = \partial\alpha/_{\partial x}$ and $\partial\alpha/_{\partial y}$.

The PROJECTION MOIRÉ FRINGES can be formed using an illuminated screen projected on the master, or in some applications, the master is projected on the screen, yielding identical results. In both instances, Moiré fringes reveal the relative displacement of lines, between the screen and the master due to deviations of rays crossing the inspected transparency.

In the derivation below, it is assumed that the magnification of the system is equal to the ratio of the screen and master pitches, $m = P_s/_{P_m}$. In absence of a tested pane, a constant fringe order is then observed throughout. A relative motion of projected lines due to the deviation generates Moiré fringes. The fringe order N is related to the deviation and pitch by:

$$N = L\alpha/_P \qquad (1)$$

The resulting light intensity modulation $I/_{I_0}$ is related to the fringe order N by:

$$I/_{I_0} = \sin^2 \pi N \qquad (2)$$

The displacement d, and the deviation of line-of-sight α is then obtained on a full-field view from the fringe pattern by:

$$d = Np$$

and the deviation becomes :

$$\alpha(x,y) = Np/_{L_1} = \frac{p}{\pi} \; arc \; \sin\sqrt{I/_{I_0}} \qquad (3)$$

The distortion in horizontal and vertical plane is quantified also on a full-field view.

$$\text{Distortion } (x,y) = \frac{\partial\alpha}{\partial x} \; and \; \frac{\partial\alpha}{\partial y} \qquad (4)$$

Since the detection of fringe order N is accomplished using the Digital Image Analysis within 1% of the fringe order N, the minimum detectable deviation angle $\alpha_{\min}$ using a 50 $l/_{in.}$ (2 lines/mm) screen placed at 2 meter from the examined pane, becomes:

$$\alpha_{\min} = \frac{Pmm}{100x2000_{mm}} = \frac{1}{2x100x2000} = 2.5x10^{-6}$$

$$radius\;(0.0086\ \text{min.}\ arc) \qquad (5)$$

The sensitivity of the Moiré method exceeds the sensitivity of the Raster projection method approximately 100 fold.

Software Description

The Moiré pattern revealing the distortion is quantified and detected by introducing "Carrier fringes." Carrier fringes are generated using a combination of optical magnification and master/screen pitch ratio. Figure 4 shows evenly spaced carrier fringes recorded using a CCD camera, in the absence of the pane,

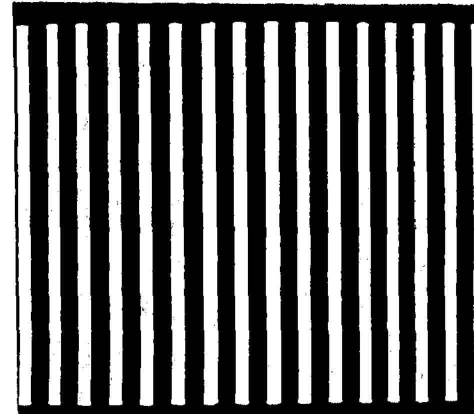

Figure 4: Carrier Fringes Recorded in Absence of the Inspected Transparencies

and Figure 5 shows the carrier fringes (distorted) with the pane in position.

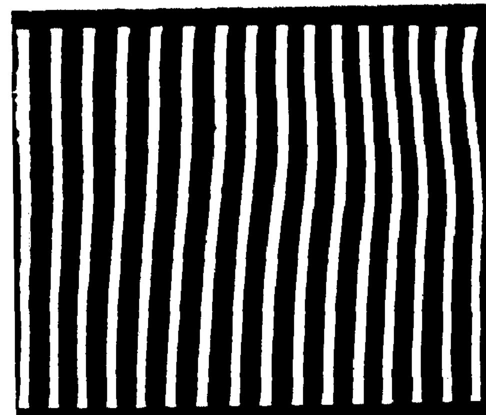

Figure 5: Moiré Fringes Recorded with the Transparency in the Field of View

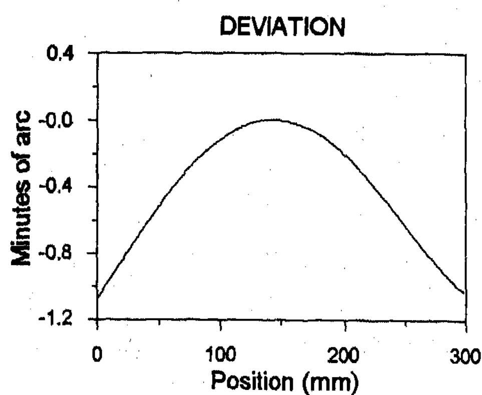
Digital filtering and phase unwrapping techniques are employed to extract the carrier fringe orders. The deviations are obtained by computing the difference between the two carrier fringe orders. The distortion is then computed by differentiating the deviation field.



The software is menu driven and includes Graphical User Interfaces (GUI) for user interaction. The software includes two major options: (1) Quality control and (2) Engineering analysis.

Quality control option is used for on-line inspection of panes. When the operator selects this option, after placing the pane in position, the image of the Moiré fringe pattern is acquired and the computation of the deviation function d(x,y) is performed at all points. This function is used to generate a full-field pseudo-color map, illustrating graphically the distortion. A PASS-FAIL decision is automatically made based on a preselected threshold level. Figure 6, for example, shows full field map of deviation values

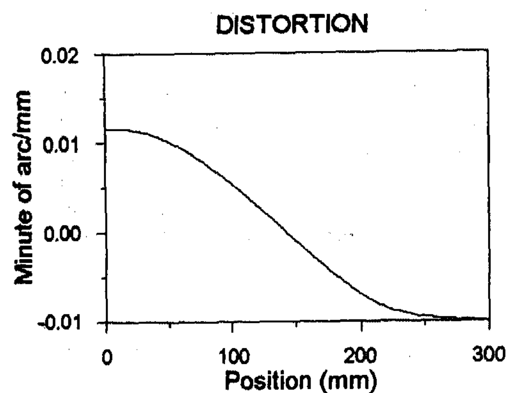


Figure 6: Full-Field Map of Deviation

and Figures 7a and 7b show respectively the deviation and distortion values along a cross section of the analyzed region.

(7a)

(7b)

Figure 7: Deviation and Distortion Along a Selected Cross-Section

Engineering analysis option is used for research and development purposes. The images are captured and analyzed as in quality control. However, no automatic decision is made. The operator has the choice of performing several types of analysis, including:

1) saving and retrieving images.

2) image enhancement by noise reduction and contrast stretching.

3) point analysis to obtain deviation and distortion values at any desired point in the image.

4) line analysis to obtain deviation and distortion values along any desired line in the image.

5) area analysis to obtain deviation and distortion values within any desired region in the image.

6) color coding to visualize different levels of deviation and distortion

7) saving numerical values of deviation and distortion for post processing and display.

<u>Conclusions</u>

A newly developed MOIRÉ DISTORTIOMETRY method was developed and its merits demonstrated. The method permits direct full-field data-acquisition revealing optical distortions due to light passing a windshield or aerospace transparency. The speed of response of the system is compatible with ON-LINE inspection requirements and the sensitivity is a 100 fold improvement over visual concepts.

A Look at the Automotive-Turbine Regenerator System and Proposals to Improve Performance and Reduce Cost

David Gordon Wilson and Andreas Carl Pfahnl
Massachusetts Institute of Technology

ABSTRACT

The adoption of turbine engines for automotive power plants has been hampered by the high cost, high leakage and high wear rate of present designs of ceramic-matrix regenerators. Proposals are made and analyzed here for design directions to achieve substantial improvements in all three areas. These include lower-cost extruded and pressed matrices; and clamping seals coupled with incremental movement of the rotary-regenerator matrix.

INTRODUCTION

The development of the ceramic automotive regenerator is briefly described. Next, a review of its present status discusses the current diverse-natured problems still inhibiting the commercial use of ceramic regenerators. Finally, a series of changes in the method of operation, manufacture, and design that could greatly improve the performance and reduce the cost are introduced and reviewed.

BACKGROUND. The designers of early automotive gas turbines recognized that, whereas aircraft turbine engines had achieved dominance using cycles incorporating high-pressure-ratio compressors and high-temperature air-cooled turbines but without heat exchangers to capture the heat from the turbine exhaust, this approach was not viable for automotive turbines (McDonald,1980[1]). Small compressors cannot produce pressure ratios of over 10:1 without suffering penalizing losses in efficiency because of the very small high-pressure passages required and the consequent relatively large blade-tip clearances. Two other adverse factors are that high-pressure-ratio compressors have very poor part-load efficiencies, and small turbine blades cannot be air-cooled. Accordingly, the principal alternative cycle was rightly considered the better choice: a low compressor pressure ratio (of the order of 4:1) and a high-effectiveness heat exchanger.

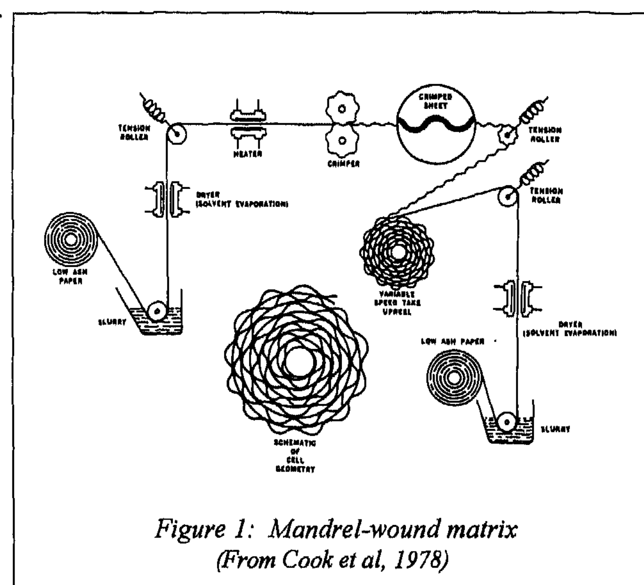

Figure 1: Mandrel-wound matrix (From Cook et al, 1978)

(The effectiveness - the proportion of potential exhaust heat actually recovered - started in the early 1950s at about 75% and has been continually increased) (Wilson, 1995 [2]). Early rotary regenerators were made of stainless-steel. Alternate bands, wavy and plain, were wound around a mandrel and brazed (figure 1). Metal regenerators of this type were used in the celebrated 1963 Chrysler demonstration when fifty turbine-powered automobiles were loaned to over two-hundred members of the public for up to three months each. However, the resulting large quantity of nickel-chrome alloys considerably increased the cost of the engine. The head of the Chrysler program, George Huebner, stated subsequently that the cost of the materials alone in its turbine engine was over eight dollars per horsepower versus $1.50 per hp (1963 dollars) for the total production cost of the then-current spark-ignition engine (op.cit.). Huebner had approached Corning Glass with regard to the possible use of ceramics for regenerator matrices, but it was a British rival, Rover, that put Corning Cercor regenerators to first use in its 1965 entry of a regenerative turbine car in the prestigious Le

Mans 24-hour race. The remarkable performance of the regenerators, as well as of the turbine engine itself, seemed to assure their future application in automobiles.

By this time, Ford had initiated its own effort to develop ceramic regenerators beginning with the lithium-aluminum-silicate (LAS) type in 1965. The most serious problem surfaced after years of extensive highway testing with its Ford "707" truck engine. It was found that sulfur from diesel fuel and sodium from road salt damaged and caused failures of the regenerators (Cook et al, 1978 [3], Day, 1979[4]). Notable challenging mechanical-design problems persisted in the sliding seals and drive system.

Although by 1974 Corning had developed two alternative ceramics, aluminum silicate (AS) and magnesium aluminum silicate (MAS), and although Ford had greatly improved on the mechanical systems and was close to full-production commitment, the project was terminated. The engine was eventually sold to Teledyne.

The ceramic regenerator was not sidelined, however. As turbine-rotor-inlet temperatures in small engines have increased to about 1650 K, boosted partly by the government-sponsored advanced-gas-turbine (AGT) and other programs, some form of ceramic material became mandatory for motor-vehicle regenerators. The coupling of high inlet temperatures to the relatively low cycle pressure ratio gave a turbine-expander exit temperature too high for metal heat exchangers. Development on both ceramic recuperators (tubular and plate-fin) and rotary regenerators continued, which for the latter heat-exchanger type meant improving primarily on the manufacturing methods, ceramic materials, and seals.

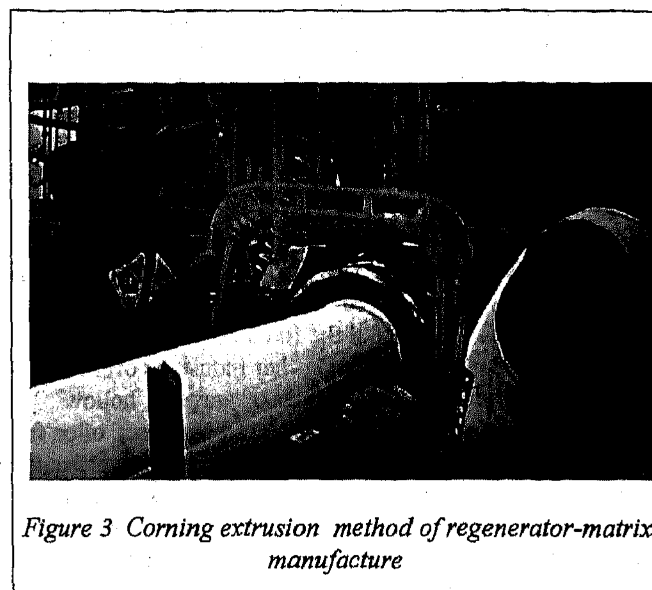

Figure 3 Corning extrusion method of regenerator-matrix manufacture

MANUFACTURING METHODS. Corning manufactured most of the regenerator disks in a manner similar to that described previously for the stainless-steel disks (figure 1), except that in place of metal foil, teabag-type paper soaked in ceramic slurry was used (Day, 1994[5]). The disks then underwent a firing schedule before the surfaces were machined. The final versions typically had a porosity (proportion of open area) of 0.7 and a hydraulic diameter of the passages of about 0.5 mm, a degree of fineness of manufacture that still inspires awe (figure 2).

The wrapping method of regenerator-matrix manufacture was too expensive for large-scale production. It also necessarily involved non-optimum passage shapes, and a flow resistance that could vary spatially (London and Shah, 1973 [6],

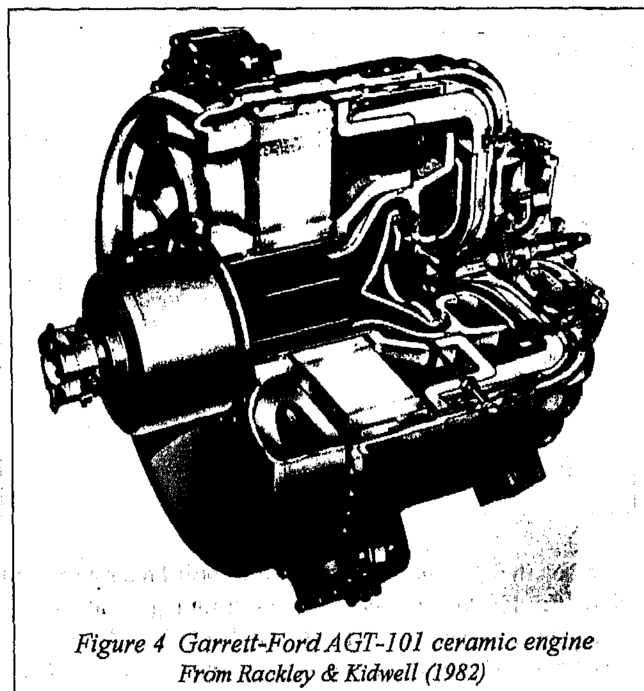

Figure 4 Garrett-Ford AGT-101 ceramic engine
From Rackley & Kidwell (1982)

and 1980 [7]). Corning developed an extrusion method of core manufacture that is potentially far lower in manufacturing cost, and allows more-advantageous square and rectangular passages of uniform size to be produced (Day, 1994, op.cit.) (figure 3). It was used, for instance, in the advanced Garrett-Ford AGT-101 engine (Rackley and Kidwell, 1982[8] (figure 4).

SEAL PERFORMANCE AND WEAR The rotary regenerator was invented by Fredrik Ljungstrom in 1920 (Hansson (1955)[9]) as a variation of the fixed-bed regenerators developed for the metallurgical and other industries over millennia. In these, a container of stones or gravel or hollow ceramic bricks is heated for a period by hot gases, often from a furnace exhaust. Then the combustion or blast air would be switched to pass through the hot solids to pick up heat. The three or four fixed-bed regenerators associated with blast furnaces are called "hot stoves" or "Cowper stoves", and usually two or three are being heated while one is transferring heat to the blast air.

Ljungstrom put the solids in a rotor that passed the inlet and outlet ports continuously. Thus the sliding seals acted in the place of the flow-switching valves. However, they could not seal against a large pressure, and Ljungstrom's rotary regenerators were applied principally as air preheaters for steam-generator combustion air, recovering heat from the near-atmospheric-pressure exhaust stream.

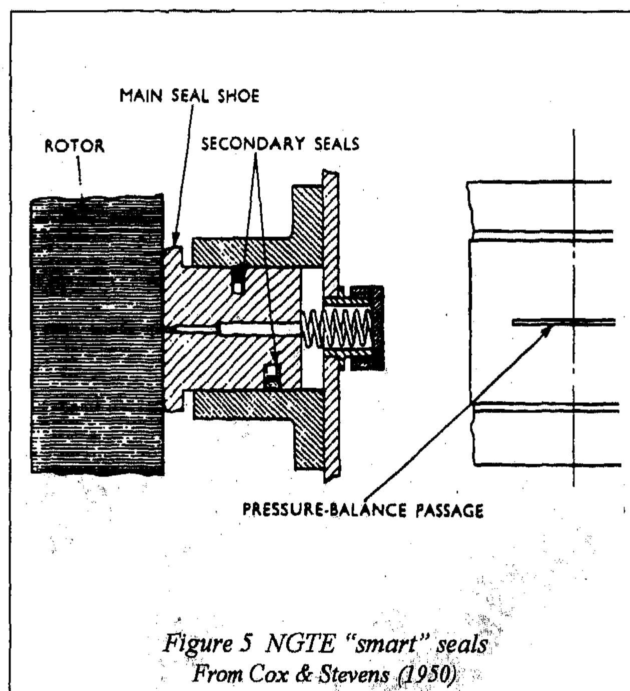

Figure 5 NGTE "smart" seals
From Cox & Stevens (1950)

When the National Gas-Turbine Establishment in Britain took on the development of the Ljungstrom regenerator for turbine engines, a seal was developed that followed the surface of the stainless-steel matrix as it passed under it (Cox and Stevens, (1950)[10]) (figure 5). Most other regenerator seal designs work towards achieving the same goal, of providing a means of pressing a low-wear rubbing seal on the regenerator core while allowing some play for it to follow the surface. The disk tends to warp while operating in the high temperature gradient. Seals supported by bellows [Norbye, 1975[11]] and by leaf springs were developed to allow for the flexibly following the matrix surface (Davis and Jackman, 1996[12]). All these designs have one commonality: they are rubbing face seals. Therefore they wear.

Wear has produced the problems that plagued these designs and those of today: leakage and a relatively short working lifetime. Leakage of the compressed air flow imposes a significant penalty on the cycle thermal efficiency (Pfahnl and Wilson, 1996[13]). Furthermore, the useful life is set by the increasing leakage producing an eventually unacceptable performance penalty (Shimada et al, 1993[14].

PROBLEMS OF PRESENT REGENERATORS

The substantial potential reduction in mass-production costs brought about by extrusion did not immediately make automotive turbine power viable. New seal designs and wear-face materials have so far not turned out to be low-cost, high-performance solutions. Many problems still persist in the ceramic regenerator that prevent low-cost implementation in a small automotive-size turbine. However, the following lists specific problem areas (including those mentioned above) where new ideas, concepts and design methods could significantly contribute to making ceramic regenerators a viable commercial heat exchanger for motor-vehicle use.

MANUFACTURE The extrusion method of matrix manufacture can produce cores to a present maximum diameter of about 300 mm, a limit brought about because of stress limits in the fragile extrusion die nozzle. This size limits the application to low-power engines (below 100 kW) or compromises the design of larger engines.

OPERATION Three problems are the following.

1. The leakage rates under the high-pressure sliding seals of regenerators, at a reported minimum of three percent of the compressor-delivery air, impose a high penalty on the overall engine thermal efficiency (approximately a one-point loss in efficiency for each one-point increase in leakage).

2. The seals and disk faces often wear rapidly, increasing the actual leakages to over 15% (Shimada et al, op cit).

3. The use of monolithic cores that can be only replaced, not repaired, increases the cost of ownership.

DESIGN Three design problems frequently found in current regenerators are these.

1. In most existing regenerator designs, the exhaust-side pressure drop is extremely high, often over ten percent, adding a large penalty on the engine thermal efficiency

2. On the compressed-air side of the matrix the pressure drop is often a small fraction of one percent, a value too low to produce uniform flow through the matrix. The effectiveness of the regenerator suffers seriously (Wilson, 1966[15]).

3. Designs having a low regenerator effectiveness penalize the engine thermal efficiency unnecessarily.

PROPOSED CHANGES

The following sections examine the potential of segmented construction of a rotary regenerators, coupled with discontinuous rotation, and other-than 50-50 hot-cold face-area split to address the previous listed regenerator-development problems.

DISCONTINUOUS ROTATION At MIT a regenerator design intermediate between the continuous-rotation Ljungstrom type and the switched fixed-bed stoves has been under study. An approximation to continuous rotation is a stepper-motor type of movement. The regenerator rotor could move rapidly through an incremental angle, pause for a period, and then move again. If the pause period were considerably longer than the period for rotation, the seals could be brought up hard against the matrix faces and held there to inhibit virtually all seal leakage. Withdrawing the seals for rotation should occur over such a small distance that simply relaxing the applied seal pressure may suffice. Seal wear should be drastically reduced and may become negligible, since wear is a strong function of the applied force. The effective seal-clearance height during rotation would, therefore, be less than that found under normal seals after a period of wear. Various projects have been undertaken to assess the feasibility and design of such a discontinuously-rotating regenerator.

Beck examined the discontinuous-rotation case to determine the penalty that would be incurred over the continuous-rotation case. He found that a penalty could be entirely avoided if the incremental-movement angle and the angle between the two radial high-pressure seals were chosen appropriately (Beck, 1993[16]). For instance, if the incremental movement is 30 degrees and the angle between the radial seals is 120 degrees there would be no effectiveness penalty.

In design studies of methods of achieving accurate incremental movement we have examined forms of Geneva mechanisms, geared stepping motors, and pneumatic actuators. There appears to be a high degree of design freedom. Although aesthetically one would like to produce a controlled acceleration-deceleration profile that would minimize matrix stress and perhaps conserve the sum of kinetic and potential energy, Long showed that an incremental-movement period that occupied only ten percent of the time between rotations would not produce damage-inducing stresses in a typical ceramic matrix (Long, 1992[17]).

Similarly there appears to be considerable design freedom in the choice of mechanisms for withdrawing the high-pressure seals through a chosen distance and for reapplying them (or for simply reducing the seal pressure).

An examination of many of the design aspects of discontinuous-rotation regenerators was made by Pfahnl and Wilson, 1996[18]. No areas of great difficulty were found.

The cost of introducing a discontinuous-movement mechanism into a standard rotating regenerator, at least at the design stage, seems small compared with the obvious benefits. A retrofit would be clearly more costly.

SEGMENTED MATRIX ELEMENTS. If the matrix moves in increments of 30 or 45 degrees, there is no longer a great need to use matrix elements that prevent through-core leakage under the seals, as at present. The matrix could be porous not only axially but peripherally, so long as there were barriers to through-core leakage where the seals clamp to the matrix faces.

This possibility opens up a great deal of design freedom. A matrix could be made of a collection of individual segments, each contained within a thin solid wall (figure 6). The matrix in this surrounding casing could be sintered of such low-cost elements as spheres or twisted square-section rods or tubes of various cross-sections.

Doing so could greatly reduce the manufacturing cost of the matrix. The segments could be mass-produced. Being of considerably smaller size than the total matrix, extrusion could be used on the segments which could then be assembled

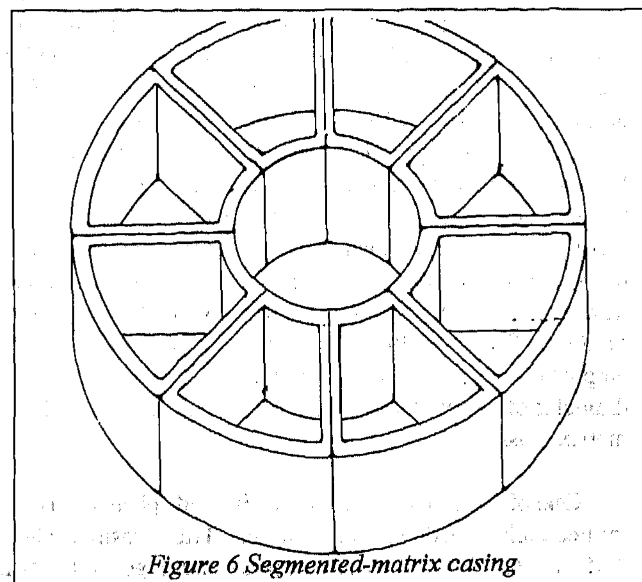

Figure 6 Segmented-matrix casing

into a disk that would be much too large to be extruded. Or just the cylindrical casing "shell" could be formed and filled with the matrix elements mentioned above. A cost of only a few percent of that for extruded elements is anticipated.

A large matrix built up in this manner and held together perhaps by one or two circumferential bands would have two additional advantages over a monolithic disk. The thermal stresses would be much lower. Thermal-expansion coefficients are very low for most ceramic materials, but the ductility is also very low, so that thermal stresses and fatigue become very important design criteria. And if a disk segment became clogged or otherwise damaged, it alone could be withdrawn, perhaps through a casing access panel, and replaced.

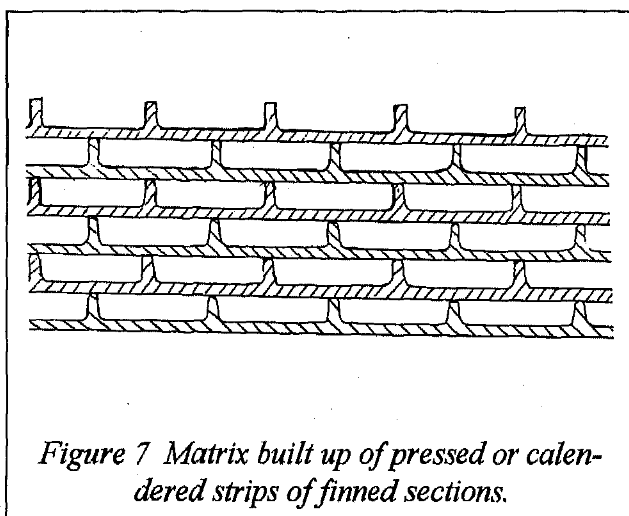

Figure 7 Matrix built up of pressed or calendered strips of finned sections.

RESULTS OF COMPARATIVE DESIGN STUDY.

We examined the performance of alternative regenerators for a 100-kW automotive engine using the basic method of Kays and London[19] with some additions given by Beck and Wilson (1996)[20]. We have incorporated refinements that allow us to specify the hot-side (low-pressure) pressure drop (we normally start at 3% of the local total pressure), and to choose at least the range of the cold-side pressure drop (we aim to get as close to 1% as possible). A further development is to allow the designer to specify the temperature gradient through the matrix. Too high a temperature gradient increases the axial conduction and the thermal stresses. The method chooses a surrogate, the temperature gradient of the hot-side flow. At present we have chosen to limit the thickness (or perhaps the "thinness") to the value giving a hot-flow gradient of no more than 7.5 degrees K/mm. The principal outputs of these calculations are the required hydraulic diameter of the passages, and the face area, rotation rate, and matrix mass.

One of the low-cost matrices, sintered spheres, was immediately revealed as unattractive. The porosity is about 0.35, so that the face area and mass of the regenerator disk(s) would double compared with a matrix of porosity 0.7. Packed but aligned circular tubes would produce a matrix composed of two types of passages, with one hydraulic diameter inside the tubes and another for the "outside" flow between the tubes. These nonuniformities would produce flow and heat-transfer nonuniformities. Open-cell "reticulated" ceramic foam, mentioned by Day (op. cit.) could be an advantageous low-cost matrix, but no heat-transfer or flow-friction data have been produced to the authors' knowledge.

One apparently low-cost method is suggested in figure 7. Finned ceramic sheets that would give rectangular passages of length/width ratio close to four (which appears to be near the optimum shape) could be produced quickly by pressing or calendering and fed under automatic control into the segment casings before sintering. Cook et al (op. cit.) investigated calendering among other alternatives for coiled matrices. A matrix formed in this way would apparently have no thermal or fluid-friction compromises compared with extruded matrices, which at present are the standard against which other approaches should be judged.

CONCLUSIONS AND RECOMMENDATIONS

We have used qualitative arguments (some quantitative analyses are in a companion paper) to conclude that rotating a regenerative-heat-exchanger matrix in increments of, say, 30 or 45 degrees under relaxed sealing pressure and clamping the seals during a succeeding rest period would simultaneously greatly reduce the seal leakage and the seal and rotor wear.

If this method of operation (for which MIT has a patent [21]) is adopted, a segmental form of construction of the regenerator rotor is proposed. Doing so would presumably reduce manufacturing costs, give more design freedom (especially with regard to regenerator- or engine-size limit), reduce thermal stresses, and give the potential of replacing only one segment of a regenerator matrix in the event of local damage.

This approach would also increase the face area and weight of the matrix to a small extent, and would require measures to prevent seal leakage along the necessarily chamfered edges of the segments.

ACKNOWLEDGMENTS

Early work on the concepts discussed in this paper was funded by Lincoln Laboratory. Several generations of undergraduate and graduate students have worked on associated hardware or analytical projects. The authors express their appreciation for all these contributions.

ABSTRACT

Flywheel energy storage systems (FESSs), commonly known as flywheel batteries, are being developed for a number of power averaging applications in the transportation industry. Most FESS designs incorporate rotors made from composite materials for which operating experience is limited and little failure data is available. Given the high energy levels inherent in these devices, a major task for the FESS designer is to provide adequate containment structures to insure safe operation in the event of flywheel failure. This paper discusses ongoing work intended to provide a better understanding of composite flywheel failure mechanisms and development of a methodology for safe containment design.

INTRODUCTION

The University of Texas at Austin Center for Electromechanics (UT-CEM) is currently under contract to develop composite FESSs for power averaging on hybrid electric transit buses and high speed locomotives. In addition, UT-CEM is participating in a Defense Advanced Research Projects Agency (DARPA) sponsored Flywheel Safety Project that seeks to investigate composite flywheel failure mechanisms and to develop systems to mitigate effects of those failures.

This paper discusses FESS principles, applications, and operating parameters. Likely failure scenarios for composite flywheels are shown, the need for containment structures is discussed, and additional information is given regarding the DARPA Flywheel Safety Project. A model to predict containment loads due to composite flywheel failures was developed by Argonne National Laboratory under contract to UT-CEM; the assumptions behind this model are discussed, and some sample calculations are presented. Results from flywheel failure testing are shown, and plans for future tests are discussed. Finally, a discussion of possible approaches to containment design is presented.

FLYWHEEL BATTERY PRINCIPLES

As the world consumption of fossil fuels has increased, so have the concerns about the environmental effects associated with our dependence on this nonrenewable resource. One result of this concern is a growing interest in electric and hybrid electric vehicles. All-electric vehicles typically use a large bank of electrochemical batteries to provide both power and energy storage and are range limited, based on the on board energy storage. Hybrid electric vehicles address the range issue by utilizing a small internal combustion prime power unit to drive an electric generator to meet the average power requirements. To address peak power requirements, an auxiliary energy storage and power conversion device (typically a FESS or a bank of electrochemical batteries) are required. In this type of hybrid system, or when used in conjunction with a bank of batteries in an all-electric vehicle, a FESS is used for power averaging.

Power averaging is accomplished primarily by storing energy generated during regenerative braking then releasing it during acceleration of the vehicle. The generation of braking energy on a vehicle is accomplished through the use of electric traction motors which operate as generators during braking. During the braking period, a motor/generator in the FESS is used to convert the electrical braking energy from the traction motors into mechanical energy in the spinning flywheel. When the vehicle accelerates, the FESS motor/generator converts energy stored in the flywheel back into electrical energy to power the drive wheels, completing the storage and recovery cycle. Because regenerative braking reduces losses, the fuel efficiency of the vehicle can be increased significantly. The peak power required of the prime power unit is reduced as well, which reduces both initial system costs and operating costs.

While both power averaging and regenerative braking have been demonstrated with electrochemical batteries and FESSs [1][2], there are significant benefits to using a FESS. Although electrochemical batteries can have high energy densities, their power densities are typically lower than those for a FESS [3][4]. Furthermore, present electrochemical battery designs require design tradeoffs between power density, energy density and system life. Because FESSs use two distinct components, the flywheel and the motor/generator, to perform the energy storage function and the power conversion function respectively, both of these key parameters can be optimized for

a specific application. Additionally, because a FESS requires little maintenance and can have a service life equivalent to that of a commercial vehicle (compared to the high maintenance requirements for a two to four year life cycle on a conventional electrochemical battery), the life cycle cost for a FESS should be less than that for a comparable electrochemical battery.

UT-CEM and its industrial partners (AVCON Inc. and AlliedSignal Aerospace Equipment Systems) are developing two FESSs for power averaging in hybrid electric drive trains. The first of these is a 2 kWh, 150 kW, 40,000 rpm device for a 13,600 kg transit bus; this device is illustrated in figure 1. In this system, the primary benefits of the FESS are to facilitate the use of a smaller prime power unit, reduce fuel consumption, and reduce emissions. The second system is a 165 kWh, 3 MW, 15,000 rpm system for a high speed locomotive where a load leveling flywheel is required for faster acceleration and reduced emissions. The combination of a flywheel with a hybrid drive train provides the locomotive with the additional benefits of regenerative braking and improved performance without the additional infrastructure expense normally required for all-electric trains [5]. At present, for these two transit applications, where the vehicle is frequently stopping and starting and where fuel costs are a large part of the operating costs, a flywheel battery appears to have a reasonable payback period. Other potential near term uses for flywheel systems are in passenger cars and as uninterruptable power supplies in stationary and mobile applications.

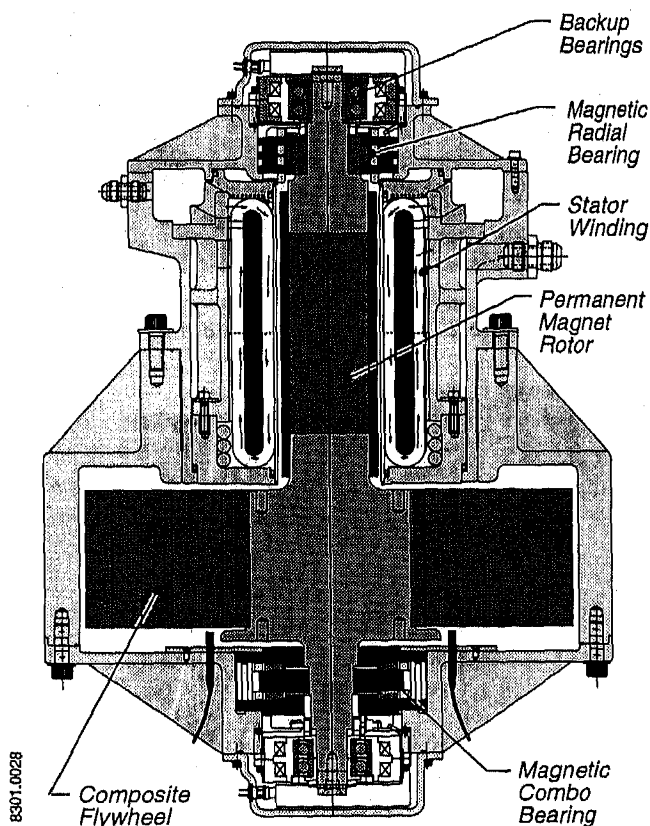

Figure 1. Transit bus flywheel battery

THE NEED FOR CONTAINMENT

A flywheel's energy storage potential is proportional to its mass moment of inertia and the square of the rotational speed. For a specific configuration, speed is limited by the material strength-to-density ratio. In terms of performance, high strength composite materials are currently the preferred flywheel material [6]. Furthermore, while metal wheels may provide a lower cost, albeit heavier, alternative for small stationary applications, composite flywheels will be required to meet the weight requirements for mobile applications. It is also apparent that to maximize energy storage in composite flywheels, they must operate with stresses near their yield strength.

Based on a long history of operating experience, a great deal is known about the failure modes of metallic flywheels and the public has grown accustomed to using them in many everyday applications. This includes their use as power smoothing devices in manual transmission passenger cars, where the flywheel resides in close proximity to both the driver and passenger. This is of no concern to the average driver, and because metallic wheel failure mechanisms are well characterized, there is little reason for concern. Very little data, however, has been published about the failure modes of composite flywheels. What is known is that these failure modes (described later in this paper) are very different from the well characterized behavior of metallic wheels. It is also known that they are both design and material dependent, so accepted design rules have not yet been established. Additionally, catastrophic burst failures during overspeed of certain flywheel designs have been demonstrated during failure testing [7][8][9][10]. Based on the potential for a catastrophic failure and the lack of operating experience with composite flywheels, it is prudent to incorporate containment structures to mitigate the effects of a failure in near-term vehicular FESSs. While this is the approach taken by the U.S. FESS industry, it should be noted that low stress vehicular flywheels have been successfully operated without dedicated containment systems in Germany for many years, with no serious accidents reported.

DARPA FLYWHEEL SAFETY PROJECT

To address the aforementioned concerns, DARPA has funded a Flywheel Safety Project to both determine the effects of typical composite flywheel failures and develop systems to mitigate those failures. The objectives of this project are to develop burst test technology; conduct a combined theoretical and experimental program to gain a fundamental phenomenological understanding of composite flywheel failures; and devise a basic methodology for design of containment structures and systems. The program is fully integrated with Department of Energy efforts in composite flywheel containment and emphasizes technology sharing within the U.S. flywheel battery community. A major outcome of the project will be a final report documenting test results and development of containment design procedures for the U.S. flywheel battery community.

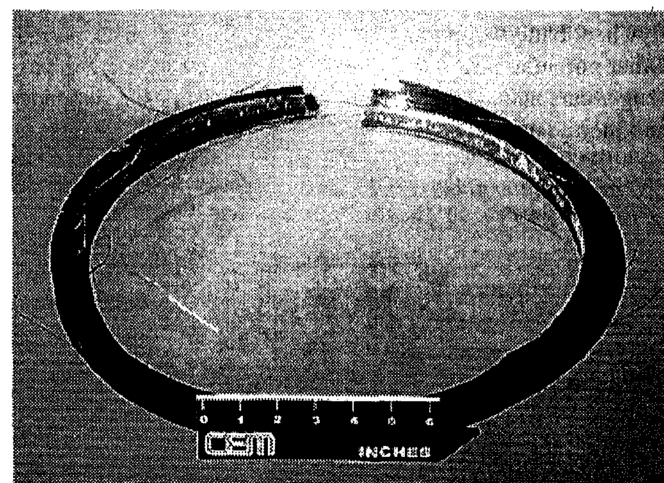
The project couples the major commercial U.S. flywheel spin-test facility, Test Devices, Inc., with a powerful group of competing flywheel battery developers: UT-CEM, Trinity

Flywheels Inc., and U.S. Flywheels Inc. The genesis of this project and the enthusiasm for mutual cooperation stems from the belief that flywheel safety is a problem of such importance and difficulty that it transcends normal competitions. The group membership was developed to pool resources and assemble a combined expertise, representing a suitable variety of flywheel battery design approaches, so that a relatively general approach for design of composite flywheel containment systems could be developed. The commitment to share intermediate test results, interim progress, and final project results stems from altruistic concerns about personnel safety as well as concerns about public perception and the overall health of the flywheel battery market potential. Although the project is relatively new, some results (specifically, results of a detailed literature search) are already available on the internet at the Southern Coalition for Advanced Transportation site, www.advtrans.org.

TECHNICAL BACKGROUND

COMPOSITE FLYWHEEL FAILURE SCENARIOS - Different composite flywheel designs possess a propensity for different types of failures. However, the reader should also be aware that similar designs can experience different failure modes if operating conditions or fabrication techniques are varied. If failure does occur, the more likely scenarios are:

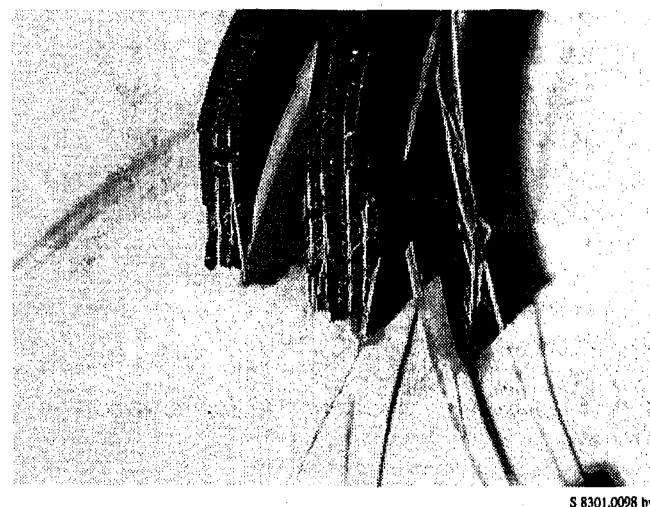
- delamination (i.e., radial separation of layers of composite windings),
- burst, and
- transverse epoxy matrix failure.



These scenarios with causes and effects are listed in table 1. Order of presentation in the table is in the "plane of action" of the event based upon a cylindrical coordinate system.

Table 1. Summary of failure scenarios

Failure Scenario	Cause	Effects of Failure
In the	*Radial (R)*	*Plane*
Delamination: Ring radial separation	• Over speed • Epoxy matrix degradation and/or shifting of imbedded fibers (creep) • Elevated temperature	Maybe benign for some designs: Produces imbalance due to mass shift requiring flywheel shutdown
In the	*Theta (θ)*	*Plane*
Burst: Hoop fiber crack	• Over Speed • Fatigue	Catastrophic with significant energy release
In the	*Axial (Z)*	*Plane*
Matrix crack transverse to hoop fibers	• Induced by high axial tensile stress from Poisson effects	Benign in limited occurrences. May produce imbalance



Mass loaded flywheels, i.e. flywheels with radially increasing specific modulus, generate radial compression with increasing speed. Generally, this design can be more susceptible to burst, especially if loss of the outer ring results in hoop failure of all the inner rings. A burst is a failure of fibers in the hoop direction. Figures 2 and 3 show different views of a graphite composite ring which underwent a burst type failure in static tests. Bursts can be caused by overspeed, fatigue, or fabrication flaws, which either exceed or compromise fiber hoop strength resulting in significant kinetic energy release.

Preloaded flywheel designs, by contrast, exhibit constant or near constant specific modulus. They are characterized by a tendency to delaminate before experiencing a burst, especially when employing lower modulus graphite composites. Delamination is a physical separation of a localized portion of the flywheel due to loss of radial compression, leading to a debond between hoop fiber layers. Causes include high spin loads due to overspeed. Debonds can also be initiated by creep of the epoxy matrix or matrix degradation due to elevated temperature. Polar woven flywheel designs are resistant to delaminations due to the inclusion of radially oriented fibers.

S 8301.0093 bw

Figure 2. Burst of a composite ring

S 8301.0098 bw

Figure 3. End view of the burst of a composite ring

Figures 4 and 5 show views of a delaminated composite ring. Delamination of this ring was caused by a fabrication anomaly. However, the pictured radial separation is representative of a delamination during flywheel operation.

Spin tests conducted at Oak Ridge National Laboratory [11] demonstrated a particular preloaded flywheel design which delaminates during overspeed conditions. This flywheel design failed in a benign mode referred to as a mechanical fuse. At a specific speed, significantly less than burst speed, the delamination event produced a slight mass imbalance which was detected by shaft displacement probes. The flywheel was safely shut down, avoiding a large energy release associated with a flywheel burst.

It should be emphasized that both mass loaded and preloaded flywheels can be designed to delaminate. In addition, not all delaminating flywheel designs possess a benign failure mode. An abrupt, fast acting delamination can result in significant imbalance forces quickly overcoming bearing load capacity. The result is a loss of control of the flywheel leading to flywheel failure.

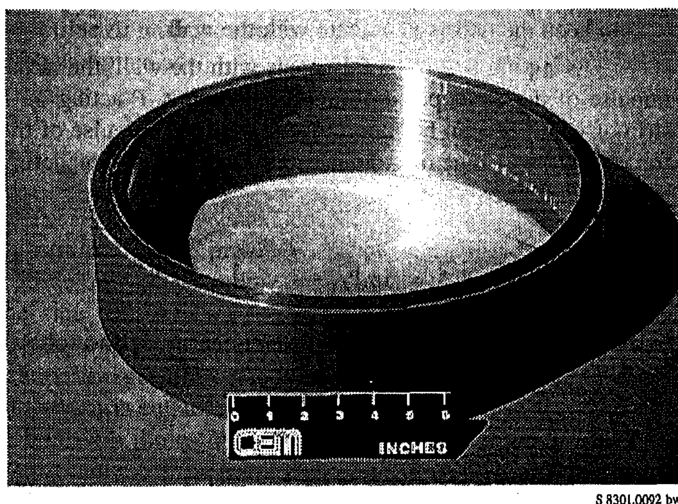


Figure 4. Delaminated composite ring

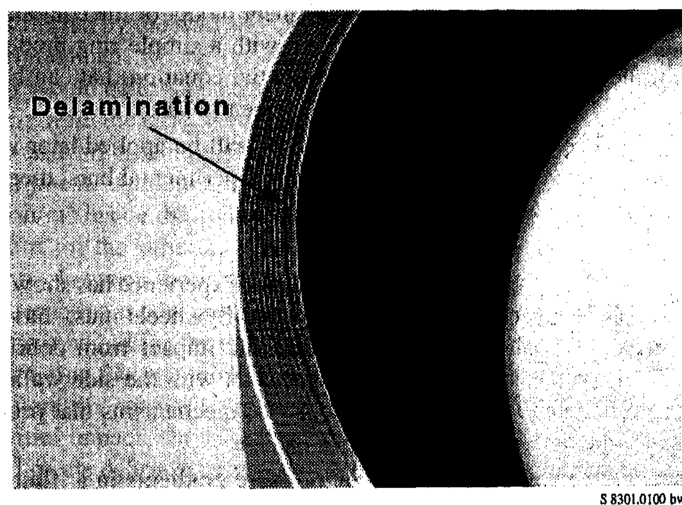

Figure 5. End view of delaminated composite ring

Another noted failure scenario [11] is cracking of the epoxy matrix transverse to hoop fibers. This is usually induced by high axial stresses from Poisson effects due to radial growth. According to the literature, this failure usually produces mild imbalances permitting safe flywheel shutdown.

CONTAINMENT LOADING ESTIMATES - The initial containment loading estimates have focused on the flywheel burst mode of failure, because it is generally agreed that this type of failure would represent the most extreme challenge to the containment. The burst mode of failure is characterized as a sudden failure of the rotor fibers in the hoop direction. For a partial burst, it is assumed that only the most highly-stressed outer rings of the rotor fail. For a complete burst, the entire rotor is assumed to fail instantaneously.

The size and shape of the fragments that are ejected from a flywheel burst are currently being investigated experimentally. If the fragments are large, they can have a sizable component of rotational kinetic energy in addition to their translational kinetic energy. Conservation of momentum can be used to show that the fragment containing the greatest amount of energy is a tri-hub sector that encompasses one third of the rotor. Although such fragments are often assumed for the analysis of the containment of metallic rotors, experience has shown that composite rotors tend to fracture into much smaller pieces.

The seminal work in the analysis of composite flywheel breakup was performed by Coppa [12]. Coppa's model assumes an axially symmetric distribution of finite-sized fragments that impact the containment wall along a tangential trajectory. The momentum transferred to the wall is calculated assuming that the fragments hit the wall and then lose momentum progressively as the fragments crush. In the analysis described below, we have taken a somewhat simpler view that the flywheel burst itself produces sufficiently finely divided fragments such that the debris can be modeled as a continuum during its impact with the containment wall. Experimental results support this assumption.

Radial Wall Loading - The simplified geometry used for the debris loading calculations is shown in figure 6. The inner radius of the rotor is "a" and the outer radius is "b". For complete burst of the flywheel, "a" corresponds to the radius of the arbor, whereas for a partial burst, "a" corresponds to the inner radius of the outer ring. The inner radius of the containment is "c" and its thickness is "h". At time t=0, the rotor, spinning with an angular velocity ω, is assumed to instantaneously break into a large number of fragments of characteristic size Δm. Each fragment is assumed to travel an unimpeded trajectory "s" until it hits the containment wall.

The containment loading for finely divided debris can be determined by modeling the particles as a continuum rather than as discrete fragments. That is, the particles that originally occupied the rotor annulus between r and $r + \Delta r$ are assumed to impact the containment wall between time t and $t + \Delta t$, where t=0 is the time that the rotor disintegrates. The time t at which the particles from radius r reach the wall is related to the radius and the path length s by $s = r\omega t$. Because the particles

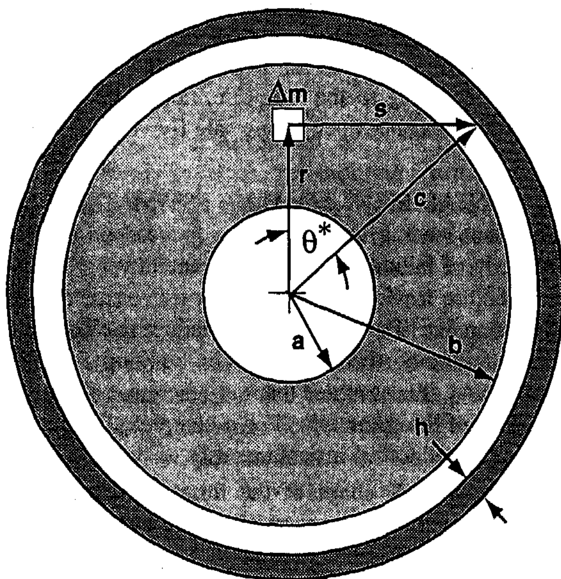

Figure 6. Load calculation geometry

traverse a tangential trajectory, the path length is related to the containment radius c and the original particle radius by the relationship

$$s^2 = c^2 - r^2 = r^2\omega^2 t^2 \qquad (1)$$

The first particles to arrive at the wall come from the outside radius r = b. The last particles to arrive at the wall come from the inside radius of the rotor r = a. The time span over which the impact event occurs ranges from t_0 to t_f, where, from equation (1)

$$t_0 = \frac{\sqrt{c^2 - b^2}}{b\omega} \quad \text{and} \quad t_f = \frac{\sqrt{c^2 - a^2}}{a\omega} \qquad (2)$$

The time increment Δt over which the fragments from the flywheel annulus between r and r + Δr arrive at the wall can be found by taking the differential of equation (1). In differentiating this equation, allowance is made for the fact that the containment radius is increasing during the impact period by a radial displacement w(t). At any time t the containment radius is given by $c(t) = c_0 + w(t)$, where c_0 is the original radius at t = 0. Although w/c_0 is expected to be small, dw/dt can be significant compared to the impact velocity of the fragments. Differentiation of equation (1) gives

$$\frac{\Delta r}{\Delta t} = -\frac{ct\omega^2}{\left[1+\omega^2 t^2\right]^{3/2}} + \frac{dw/dt}{\left[1+\omega^2 t^2\right]^{1/2}} \qquad (3)$$

The mass of the material Δm that came from the radius between r and r + Δr is given by Δm = ρLrΔθΔr, where ρ is the flywheel density and L is the flywheel length. Substituting this result into equation (3) yields the quantity of mass that impacts the wall during time Δt.

The flywheel fragments impact the containment wall at an oblique angle θ* (fig. 6) which depends on the radius from which they originated. The component of velocity normal to the wall is just $v_{n1} = r\omega \sin\theta^*$, or, from the geometry of figure 6,

$$v_{n1} = \frac{c\omega^2 t}{\left[1+\omega^2 t^2\right]} \qquad (4)$$

It is assumed here that the tangential component of the fragment momentum is conserved during impact and the coefficient of restitution for the normal component is equal to zero. The normal velocity v_{n2} of the particles after impact is, therefore, equal to the wall velocity dw/dt. This implies that the debris follows the radial motion of the wall during impact, and is not reflected back toward the axis of the flywheel, potentially doubling the load. The assumption of plastic impact can be justified by the observation that the impact is likely to result in further fragmentation of the debris, and the centrifugal force from the rotational component of the fragment velocity will tend to keep the debris in contact with the wall.

During impact of the fragments with the wall, the radial impulse of the force per unit area, or pressure, P acting on a strip of width Δθ can be found by equating the impulse of the force with the change of momentum of the particles impacting that strip. That is,

$$-Pc\Delta\theta L\Delta t = \Delta m\left[v_{n2} - v_{n1}\right] \qquad (5)$$

Substituting equations (3) and (4) into equation (5) and solving for the pressure gives

$$P = \frac{\rho c^2\omega^4 t^2}{\left[1+\omega^2 t^2\right]^3}\left[1 - \frac{dw}{dt}\frac{\left(1+\omega^2 t^2\right)}{c\omega^2 t}\right]^2 \qquad (6)$$

for $t_0 \le t \le t_f$. The impact loading function given by equation (6) can be used to drive a finite element model of the containment response, or can be combined with a simple ring model of the containment to yield a differential equation that can be solved directly for the radial displacement w(t).

The containment loading model will be applied later in this paper to predict the loading on an experimental burst measurement device (fig. 12 and table 3).

Axial Loading on the End Plates - Experience has shown that a viable containment for composite flywheels must have adequate axial strength to withstand the impact from debris that is deflected axially following impact with the side walls. Unfortunately, little is known about the mechanisms that produce the deflection. Possibilities include

1) the development of axial pressure gradients in a fluid-like bed of debris that builds up on the containment wall,

2) scattering of fragments at the wall from the impact of incoming fragments, or

3) fracture of fragments along oblique planes as they hit the wall, creating a wedge that drives the two pieces toward either end of the containment.

Whatever the cause, equal axial momentum must be directed toward each end plate. An upper bound on this momentum can be found by assuming that the kinetic energy lost during impact with the wall is converted to axial motion of the fragments. Although the conversion efficiency has been assumed here to be 100%, a more realistic value could be determined experimentally, thus avoiding the need to model the complex process of debris deflection. It is further assumed that the debris does not accumulate at the wall, but splits into two streams with the same axial velocity. Since the radial component of the fragment velocity v_{n1} is known from equation (4), and the radial velocity of the fragments and the wall following impact is dw/dt, conservation of energy dictates that the axial velocity v_z of the fragments following impact is $v_z = v_{n1} - dw/dt$. If debris does not accumulate at the wall, it impacts the end plates with the same mass flow rate as it arrives at the wall. This rate is given by equation (3) and the relationship between Δm and Δr. Equating the change in momentum of this mass over time Δt with the axial impulse gives the axial force F(t) on each end plate as

$$F(t) = \frac{1}{2}\frac{dm}{dt} v_z \tag{7}$$

Substitution of the previous results for dm/dt and v_z produces a force on each end plate that is just 1/2 the force exerted on the side wall by P(t). Although the assumptions made here appear to be extreme, it is noted that the model typically yields kinetic energies imparted to the end plates and the axial motion of the debris equal to 3 to 5% of the rotor energy, which is consistent with the estimate from at least one rotor test that produced failure of the lid of the containment vessel [13].

Torque- The calculations given above for the normal loading on the containment wall and the end plates assumed that debris does not accumulate at the wall, but rather is deflected by the wall and the end plates toward the center of the containment where, presumably, much of the remaining energy would be dissipated by collisions between the fragments. If this were the case, the swirling motion of the debris would not exert a significant centrifugal or torsional loading on the containment. Although this picture may be reasonable if the free volume inside the containment is large, it would not be reasonable for the other extreme. Here a debris bed would likely form between the intact portion of the rotor and the wall. An alternative model has therefore been developed to estimate the upper bound for the torsional loading on the containment, recognizing that the model is not consistent with that used to calculate the normal force on the wall and the end plates during initial impact. In calculating the maximum torsional loading, all of the debris is assumed to accumulate next to the wall as it swirls inside of the containment.

Figure 6 can also be used to model the debris bed geometry. Here, each fragment is stopped at the inner radius of the debris bed, instead of reaching the wall. Again, the flywheel is assumed to break up instantaneously. The fragments from the outside of the flywheel impact the wall at the same time t_0 given previously in equation (2). These particles now remain against the wall. Particles from flywheel radius r impact the inner radius $r_2(t)$ of the debris bed at a later time. The inner radius of the debris bed can be found from the conservation of mass and the porosity of the bed γ. Furthermore, the time t at which the particles impact the inner radius is related to their tangential velocity at the time of breakup. The geometric relationships indicated in figure 6 are also valid here if the radius c is replaced by r_2. In a manner similar to the derivation given previously, these relationships can be used to calculate the rate at which mass is added to the debris bed and the radial and tangential components of the velocity of the fragments as they join the bed. The change in angular momentum of the debris at the wall consists of two components. One is due to the addition of new debris from the disintegrating flywheel, and one is due to the slowing down of the debris from the torsional forces at the wall. Assuming that the layers of the debris bed are locked together by the random packing of the fragments, the common angular velocity of the fragments ω_d and the torque T_p on the containment wall can be calculated by equating the torsional impulse with the change in angular momentum.

The pressure exerted on the containment wall from the centrifugal force of the swirling debris can be calculated by considering the equation of motion of a differential element of the debris. The radial component balances the centrifugal force and the differential pressure on the radial faces of the element. However, unlike an intact flywheel rotor, the debris cannot support a tensile load in the hoop direction. The equation of motion therefore reduces to

$$\frac{d}{dr}(r\sigma_r) = -\rho(1-\gamma)r^2\omega_d^2 \tag{8}$$

Equation (8) can be integrated from the inner radius of the debris bed r_2 to the outer radius c. The pressure at the inside radius is small because the normal velocity of the particles impacting the bed is small. Integration of equation (8) then gives the pressure at the wall N_p as

$$N_p(t) = \rho(1-\gamma)\omega_d^2 \frac{\left(c^3 - r_2^3\right)}{3c} \tag{9}$$

The torque on the containment ring T_p is just

$$T_p(t) = 2\pi c^2 L\mu N_p(t) \tag{10}$$

where μ is the coefficient of friction between the fragments and the wall. In general μ has to be determined experimentally. However, if torque is limited by the interlaminar shear strength of the composite fragments (100 to 120 MPa), the effective coefficient of friction could not exceed about 0.3. This is in reasonable agreement with the value of μ (0.36)

needed to match the model results with the torque and spin-down times measured by Steele and Babely [14] during failure of a 0.695 MJ composite rotor.

The torque predicted by equation (10) can be significant and in some applications may be excessive (see predicted torque for a partial rotor burst presented in table 3). For vehicle applications, for example, it is likely that some torque mitigation features must be incorporated into the containment. A discussion of containment concepts which can reduce torque loads is presented later in this paper.

TESTING AND CONTAINMENT DESIGNS

TEST RESULTS - To aid in the design of candidate containment devices, a number of tests will be performed. These include spinning composite flywheels to failure to understand and identify failure modes. Flywheels will also be spun to failure in heavily instrumented burst measurement structures to measure loads. Measuring and understanding flywheel failure loads is key to successful containment designs. Finally, flywheels will be spun to failure in real containment structures to proof test these designs.

Recently, UT-CEM successfully burst a multi-ring, preloaded composite flywheel. This flywheel design was an altered operational design. The operational design, which delaminates before bursting, was altered by substituting weakened graphite material in the fabrication of the outer ring.

Main objectives of the spin test were to demonstrate a controlled composite flywheel burst and then to attempt "soft capture" of the flywheel fragments using a Kevlar catch ring. As designed, only the outer flywheel ring failed at burst. An overview of test results are presented in table 2.

The test flywheel stored 5.8 MJ of energy at burst speed and released 1.1 MJ during the burst event. The flywheel prior to testing is shown in figure 7 and is shown again in figure 8 after testing. Other than failure of the outer composite ring as intended, little damage occurred. Damage was limited to surface wear as shown in figure 9.

Table 2. Overview of test results

•	Outer flywheel ring successfully burst at 35,200 rpm (830 m/s) within the predicted burst speed range of 33,400 rpm to 37,600 rpm
•	Outer ring burst did not cause the remaining flywheel rings to fail
•	57% of the failed ring material was recovered following the test
•	Significant mass of flywheel fragments (80% of the recovered material) was captured by the Kevlar catch ring
•	During multiple low speed runs with dwells and the final run to burst, the flywheel maintained excellent mass balance
•	After outer ring burst at 35,200 rpm and separation from the spindle, the remaining flywheel fell to the bottom of the pit and "spun down". Afterward, inspection of the flywheel showed no damage other than surface wear

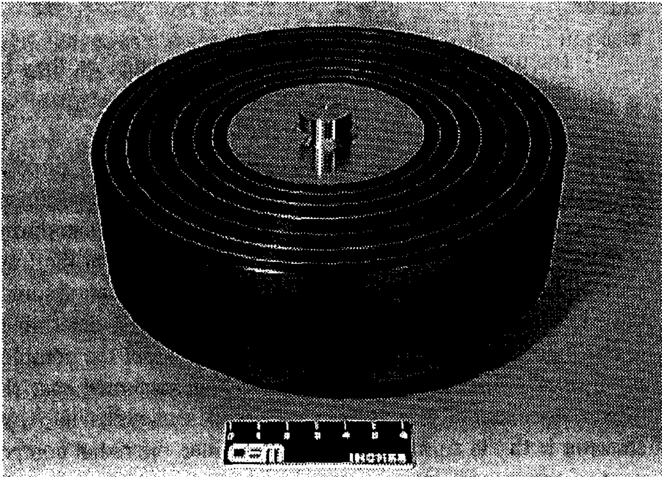

Figure 7. Composite flywheel prior to burst

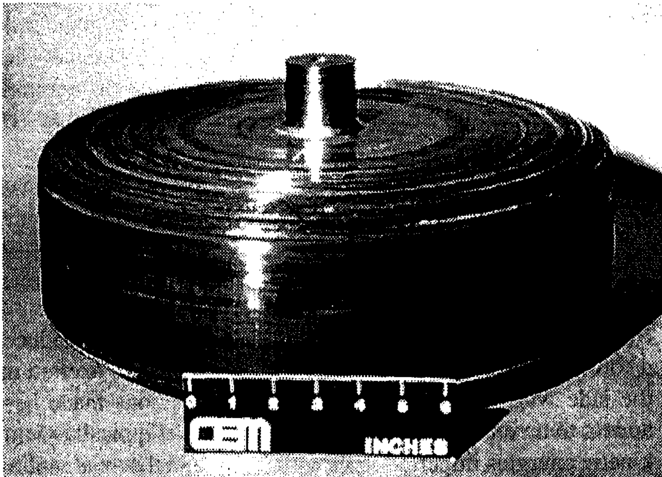

Figure 8. Composite flywheel after burst

Figure 9. Surface detail of composite flywheel after burst

Other flywheel developers have attempted to induce flywheel bursts with mixed results. This test delivered a remarkably clean burst event. Advantages of achieving a successful burst are twofold.

First, bursting a composite flywheel ring clearly establishes both induced and allowable load limits of the composite laminate structure. This correlates analytical tools for designing safe flywheels.

Second, a flywheel design that can be tailored to deliver specific burst energy levels to candidate containment designs presents a valuable tool to assist the DARPA Flywheel Safety Project. Attempts to catch burst fragments are relevant since evaluation of their shape and size may lead to additional insight for improved containment designs.

Flywheel fragments recovered from the Kevlar catch ring varied in size with a high percentage (30%) of significant size. An example of some of the larger flywheel fragments recovered from the catch ring is shown in figure 10.

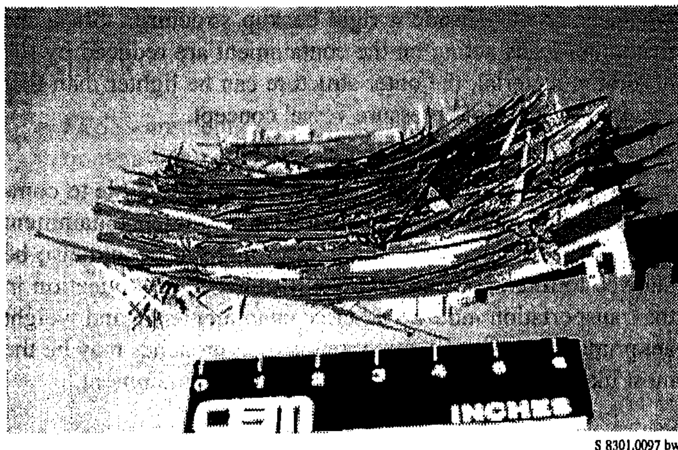

Figure 10. Captured composite flywheel fragments

UPCOMING TESTS - Upcoming tests include additional flywheel bursts early this year. The bursts will occur inside an instrumented steel burst measurement device with the objective of measuring radial, axial, and torque loads.

While the tests described above will use rings designed to burst at overspeed, another test will use a preloaded flywheel designed to delaminate. The purpose of this test is to explore this failure mechanism and its consequences.

Using the loading estimate model previously described, the burst measurement device is being designed to survive burst testing without permanent deformation, allowing it to be reused for repeated tests; an illustration of the device appears in figure 11. Loading calculations for this device appear in table 3, and a curve for the predicted radial impact loading is shown in figure 12.

The burst measurement device will be instrumented so that loads predicted by the loading estimate model can be verified by experiment. In addition, the device is designed so that energy-absorbing materials can be inserted inside the vessel, allowing testing of some of the concepts presented later in this paper.

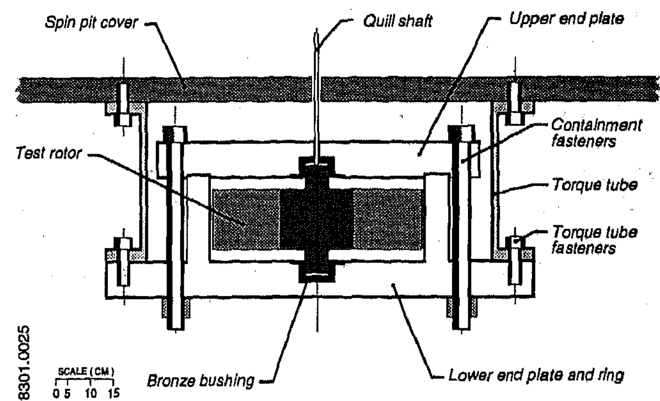

Figure 11. Burst measurement device

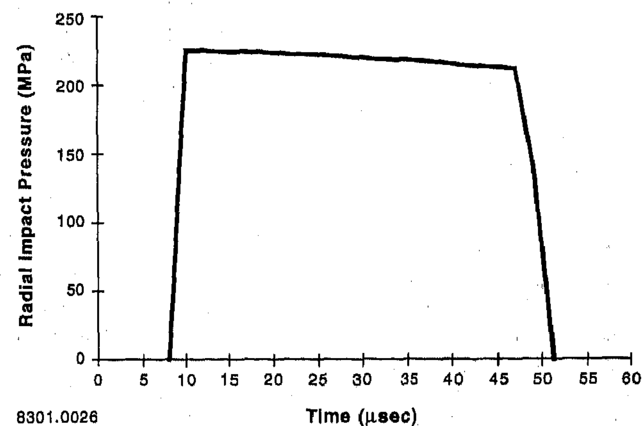

Figure 12. Predicted radial impact loading

DESIGN CONCEPTS FOR CONTAINMENT - Because of the lack of operating experience and test data with composite flywheels, design of adequate containment presents a formidable challenge to the designer. There is a substantial body of experience dealing with metallic flywheel failures, but as discussed earlier, it is unclear how much of that experience can be applied to composite flywheels. In spite of this fact, a number of containment strategies are emerging as potential approaches to the problem. Each has its own set of advantages and disadvantages and each must undergo intensive testing to prove its suitability as a viable containment strategy. In the following discussion, it is assumed that the containment structure must contain a true flywheel burst, which is thought to present the highest forces and energy levels to the containment structure. In all the design concepts discussed below, the containment will be considered successful and effective if fragments from a burst flywheel are completely contained within the containment structure.

Rigid Pressure Vessel - In this approach, a heavy-walled pressure vessel envelops the flywheel, as illustrated conceptually in figure 13. This is a very direct approach to the problem:

the vessel has sufficient strength to contain burst forces without the use of any dedicated energy absorbing materials, although it is acceptable for the vessel itself to sustain permanent deformation during the burst event. In fact, it is probably desirable for the vessel to deform plastically, absorbing a substantial portion of the flywheel energy in the process. Advantages to this approach include simplicity of design and the possibility of substantial safety margins. Disadvantages include difficulties in limiting torque loads on the mounting system and high containment system weight.

Table 3. Burst measurement device load conditions

Load conditions for a flywheel outer ring burst at 35,000 rpm inside burst measurement device

Rotor Information:		
Outer Ring Outer Diameter	0.445 m	17.5 in.
Outer Ring Inner Diameter	0.414 m	16.3 in.
Length	0.127 m	5 in.
Speed at Burst	35,000 rpm	35,000 rpm
Mass	4.46 kg	9.84 lb
Tip Speed	815 m/s	2660 ft/s
Stored Kinetic Energy in Outer Ring	1.38 MJ	1.02×10^6 ft-lb
Measurement Device Shroud Ring Information:		
Radial Thickness	0.051 m	2 in.
Inner Diameter	0.521 m	20.5 in.
Material	4340 Steel	4340 Steel
Predicted Measurement Device Loads:		
Radial Impact Load Duration	42 µs	42 µs
Max. Radial Impact Pressure	225 MPa	32,600 psi
Max. End Force	2.33×10^7 N	5.24×10^6 lb
Approx. Max. Hoop Stress in Shroud Ring	883 MPa	128,000 psi
Shroud Ring Max. Radial. Displacement.	1.12 mm	0.044 in.
Shroud Ring Max. Strain	0.4%	0.4%
Shroud Ring Max. Torque	1.00×10^6 N-m	7.39×10^5 ft-lb

Rotating Liner - The strategy incorporated in this design approach reduces the torque that must be transmitted from the flywheel battery to its mounting system (fig. 14). A rotatable liner inside the containment vessel is impacted by the swirling debris from a rotor burst, absorbing debris rotational energy. The overall effect of the liner rotation is that tangential loading forces acting on the containment are spread over a longer period, thus reducing the maximum torque loads on the containment vessel. In addition, a liner braking mechanism is provided to impart a braking torque to the rotating ring, limiting its maximum angular velocity and dissipating rotational energy. The primary advantage to this approach is that the torque capacity required in the FESS mounting system is reduced. This is achieved at the cost of increased containment system complexity.

Energy Absorbing Liner - This approach includes an energy-absorbing material within the containment, designed to absorb a substantial portion of the debris kinetic energy (fig. 15). As presently conceived, the energy-absorbing material would be located inside a rigid backup structure. Since the maximum loads acting on the containment are reduced by the absorbing material, the outer structure can be lighter than that required for the rigid pressure vessel concept.

Combination of Approaches - It is also possible to combine the approaches listed above into a single containment device. For example, an energy-absorbing liner could also be allowed to rotate, reducing torque loading. For application in the transportation industry where containment size and weight are primary concerns, a combination of approaches may be the most likely solution to providing adequate containment.

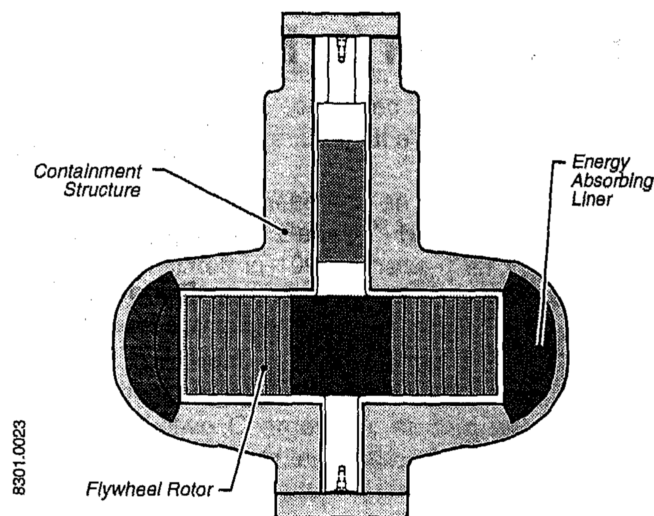

Figure 15. Containment with energy-absorbing liner

SUMMARY

- FESSs are being developed for power averaging applications in the transportation industry.
- A potential for flywheel bursts exists with FESSs that incorporate composite flywheels.
- Failure mechanisms of composite flywheels historically have been poorly understood due to lack of operating experience and experimental data. Test programs are underway which are improving the understanding of these systems.
- Failure modes of composite flywheels are design and material dependent; some designs may prove to fail in a benign manner.
- In the near-term, FESSs using highly stressed composite flywheels should incorporate containment as protection against flywheel bursts.
- A DARPA-sponsored containment development program brings together prominent flywheel developers in an effort to identify a methodology for safe composite flywheel and containment design.
- A theoretical model has been developed to predict containment loads during burst conditions; a testing program has begun to confirm the theoretical predictions.
- In the long-term, operating experience may show that composite flywheels can be designed to fail in a benign manner, so that containment is unnecessary. Alternatively, a better understanding of flywheel failure behavior may lead to lightweight containment designs that take advantage of energy-absorbing features.

ACKNOWLEDGMENTS

The authors wish to thank Robert Rosenfeld of DARPA and Alan J. Sailer of Houston Metro for their support of this work. In addition, we wish to thank Lori Moore, Daniel Gleesing, and Roy Pena of UT-CEM for their assistance in the publication of this paper.

ABSTRACT

Results of the Charger Test Project conducted by Arizona Public Service (APS) indicated the importance of the charger/charge algorithm/battery interface with respect to battery capacity. It also indicated that EVs rapidly charged demonstrated longer cycle life in field testing without reduction in capacity. Additional testing conducted by APS has shown that cycle life of the batteries is strongly related to the charging scheme utilized. Application of results of laboratory charging to the charge scheme utilized in this testing has been hampered by extremely long test periods in field tests designed to cycle batteries to the end of life. Development of a predictive method of cycle life extrapolation based upon microscopic analysis promises to reduce the time required for battery cycle life testing.

INTRODUCTION

Three phases of testing will be addressed. Phase I testing was performed on EVs in the field to evaluate the performance of Hawker Genesis® batteries with a variety of chargers. Based on the results of the Phase I testing, Phase II testing was initiated to examine battery performance in the field at various rapid charge rates. Phase III addresses microscopic analysis of batteries that have been cycled at different rates to determine if the end of useful life can be predicted.

PHASE I - *EV AMERICA* FIELD TESTING

The first round of *EV America* Performance Testing concluded in November 1994. Among the numerous bench mark performance data collected was EV range at constant speed 72.4 km/h (SAE 227A), constant speed 96.5 km/h (SAE 227A), and per fuel efficiency drive cycle (SAE J1634). Over 225 EVs were purchased in the Phase I Program (Solectria E-10 pickups and Force sedans, and US Electricar [USE] ES10 pickups and sedans) by utilities and government agencies across the United States. The *EV America* Phase I range test results for the USE ES10 and the Solectria E-10 pickups are provided in Table 1. All of these vehicles utilized Hawker Genesis® 38 amphour VRLA AGM batteries, model G190W.

Table 1. *EV America* Performance Testing, Phase I Range Testing

EV Manuf	km at 72.4 km/h	km at 96.5 km/h	km at SAE J1634
USE ES10	113.8	76.1	110.7
E-10	117.1	63.6	93.2

In use, the Phase I EVs reported a significant loss in range with low battery cycles. Proving ground range testing (SAE 227A @ 72.4 km/h) in Phoenix confirmed an approximate 50% range reduction in a USE ES10, and a 37% range reduction in a Solectria E-10.

An evaluation by Hawker Energy Products (HEPi) concluded that an undercharge condition existed in the batteries. The USE ES10 was originally equipped with a 2 kW integral charger which charged a 52 battery module, useable 21 kilowatt hour pack. For this vehicle,

HEPi concluded that a minimum 12 kW charging rate was required to properly charge the battery pack. The Solectria E-10 was originally equipped with a 2 kW charger which charged a 36 battery module, useable 16 kilowatt hour pack. HEPi concluded, for the E-10, that an 8 kW charging rate was required at a minimum.

Based on the need for an acceptable charge protocol for the Hawker Genesis® batteries, a field test program was initiated in 1995 (Phase I) for the purpose of evaluating the performance of Hawker Genesis® batteries with a variety of chargers. The following chargers were evaluated; 150 kW Norvik Minit Charger, 2 kW Solectria Charger, 3 kW Solectria Charger, and 6.6 kW Delco Inductive Charger. Six electric pickup trucks were selected for the field test. None of the Phase I EVs were equipped with a battery management system to monitor modules during charge and discharge. Thermal management of the EV packs was limited to a few small muffin fans in half of the vehicles, while the other half had no devices. This test program began in May 1995 and terminated in January 1996. The EVs were driven on the streets and freeways in Phoenix where summer daytime temperatures can reach 49° C.

Table 2 describes the chargers for the Phase I vehicles. Fast charging demonstrated its value early in the test, by restoring the capacity of a battery pack which was believed to have been irreversibly damaged through long term undercharging. The Norvik Minit Charger was used to fast charge two of the EVs at an arbitrarily chosen rate of 3C, i.e. three times the one hour discharge rating of the Hawker battery. EVs charged by the Norvik charger had to undergo a periodic equalization charge. EV138 was equalized periodically with the Norvik charger. Other vehicles were equalized by using on or off board low rate overnight chargers.

Norvik charging used 2.45 volts per cell for the Genesis® battery and equalization was based upon 2.65 volts per cell. EV137 was equalized with the Delco inductive charger. The Delco charger conducted the main charge routine with a 2.45 volts per cell basis and the equalization routine was based upon 2.56 volts per cell. The Solectria chargers used a 2.45 volts per cell and cell equalization was accomplished with extensive overcharging at this voltage.

Table 2. Phase I Field Test EV Chargers and Charge Cycles

EV	Fast Charge Rate	Overnight Ind Rate	Overnight Cond Rate	Equalization Charge
133	N/A	N/A	3kW	Cond
134	N/A	N/A	2kW	Cond
135	2C	N/A	2kW	Cond
137	3C	6.6kW	N/A	Ind
138	3C	N/A	N/A	Fast
139	N/A	6.6kW	N/A	Ind

Ind-inductive, Cond-conductive

Table 3 provides a summary of battery pack performance in the EVs and the cause of battery module failure. Although the batteries were the same in each EV, the consequences of chargers and charge algorithms is dramatically demonstrated in cycle life. In considering the battery performance in this test it was evident that the Hawker Genesis® VRLA AGM battery could be easily damaged by low power charging, and the battery performed better as the charge power increased. It was also surprising that the summer heat in Phoenix did not impact battery performance in high rate charging. One pack was destroyed by a fire, apparently caused by loose battery interconnections. This event reinforced the importance of good battery pack assembly procedures.

Table 3. Phase I Battery Pack End of Life Cycles, Over the Road km, and Module Failure

EV	Charge Cycles	Pack km	Cause of Module Failure
133	197	12,067	grid corrosion, 12 modules
134	52	1,931	thermal run away, 12 modules
135	113	5,749	thermal run away, 36 modules
137	360	26,549	grid corrosion, 8 modules
138	140	6,838	pack fire due to loose connection, 52 modules
139	120	6,240	grid corrosion, 17 modules

From the results of the Phase I field test and autopsy of modules from the EVs, it was concluded that the Norvik 3C charging provided the best vehicle performance and longest battery cycle life. The abrupt failure of 17 modules in EV139 (Delco inductive charger), caused by grid corrosion, was hypothesized to be the result of equalization or overcharging at the elevated voltage portion of the implemented algorithm. (Reference A) Coincidentally, the same number of equalization cycles (120) on EV137, charged by the Norvik charger and equalized by the Delco charger, resulted in a similar failure mechanism in 6 modules. The Solectria 2 kW charger produced battery failure due to thermal run away

early in battery life. The Solectria 3 kW charger produced failure via grid corrosion.

PHASE II - FIELD TESTING

For years, laboratory testing has been performed to determine the effects of charging methods on battery performance in EV applications. Parameters such as battery capacity, life, and grid corrosion have been examined. Results of laboratory testing, to date, have indicated that the charging scheme utilized has a direct effect on battery performance. However, testing within laboratories, even when simulated drive cycles are used for discharge, does not accurately represent the environmental rigors of fleet use. Fleet vehicles do not operate under a controlled set of conditions. Traffic conditions, ambient temperature, and operator usage are just a few of the variant conditions with which the battery must contend.

Significant cycle life extension has been achieved using high charging rates in laboratory testing. Chang and Valeriote *et al* (References B-H) have demonstrated that sealed valve regulated lead acid (VRLA) batteries can be rapidly charged with higher energy efficiency than traditional charging without detrimental effect to the battery and with significantly extended cycle life. VRLA batteries in laboratory testing were given five to ten rapid partial charge cycles and fully recovered their capacity in an extended charge.

Therefore, based on the Phase I and laboratory test results, a new program (Phase II), was commissioned. Phase II focused on: 1) partial charging at 3C, 5C, and 9C rates; 2) determination of whether periodic fast charging would reverse the damage from traditional low rate recharge; 3) evaluation of the cycle impact caused by reduction in the frequency of pack equalization; 4) evaluation of laboratory test results to improve field results; and 5) evaluation of the performance of NiCad and Nickel Metal Hydride batteries in the field environment.

Table 4 describes the field test fleet used in the Phase II program. EVs 114, 130, 136, 137, and 333 were given multiple fast charges per day and operated by a dedicated driver. This method of accelerated aging of the EV compressed the testing time. All accelerated aging vehicles were operated and maintained in accordance with test procedures. The test procedures describe the drive route, the depth of discharge strategy, and the recharge strategy for each EV in the program.

The remaining EVs were driven on arbitrary routes. In fleet testing, the EVs were driven by Arizona Public Service (APS) employees performing a certain work mission. EVs 131 and 134 were driven by meter readers. At the end of the work shift, EVs 131 and 134 were charged by the Delco charger. Twice per month these EVs were given one 3C charge on the Norvik charger.

The EVs used in Phase II Field Testing did not use battery management or battery module monitoring equipment. The thermal management equipment utilized varied between vehicles. The two EVs charged at the 9C rates (114 and 333) were equipped with module cooling systems. Specifically, EV333 was equipped with high air velocity, manually initiated, module cooling. EV114 was equipped with a phase change material provided by Shape. EVs 124, 130, 131, 133, 134, and 135 used small muffin fans, activated by battery temperature, to ventilate ambient air across the pack.

EV116 (Nickel Cadmium), used in the APS Property Construction Department, received almost 100% fast charges, with a minimal number of equalizations. The Nickel Metal Hydride vehicle (EV124) was charged by a Solectria 3 kW charger and given frequent opportunity charges in its fleet mission.

All of the EVs in Phase II were tested during the Phoenix summer, where day time ambient temperatures can be as high as 49°C. On six to eight week intervals, vehicles were given a 96.5 km/h range test (SAE 227A) to evaluate battery capacity.

Table 4. Phase II Field Test Vehicles

EV	EV Model	Modules in Pack	Battery Manuf	Fast Charge Rate	Equalization Charger
114	S10	42	Hawker	9C	Martin M
333	S10	26	Hawker	9C	Norvik
137	S10	52	Hawker	5C	Delco
136	S10	24	GNB	3C	Norvik
136	S10	24	Optima	5C	Martin M
130	S10	36	Hawker	3C	Solectria
131	S10	36	Hawker	3C	Delco
133	S10	36	Hawker	3C	Solectria
134	S10	36	Hawker	3C	Delco
135	S10	36	Hawker	3C	Solectria
124	Geo	15	GMO	N/A	Solectria
116	TEVan	30	Saft	3C	Norvik

The accelerated aging group required extensive use of fast charging. Fast charging occurred at the 3C, 5C, and 9C rates. Daily fast charge cycles varied from one to five. Battery equalizations were varied from every third to every tenth cycle, depending upon the specific EV. Therefore, the majority of EV charging and operation was with partial charge cycles including the overnight

charging. Equalization charge cycles were minimized because of the module failures due to grid corrosion identified in Phase I.

Figure 1 depicts typical rapid charges delivered at the 3C, 6C, and 9C charge rates by the Norvik charger, Model 150kW, manufactured by Norvik Technologies Inc., Mississauga, Ontario, Canada. This charger monitors the resistance free voltage by interrupting about five times per second and then adjusting the applied voltage to match the charge acceptance ability of the battery. An identifier is installed on each EV which permits the charger to uniquely identify its battery type and maximum charge rate. The Norvik charger has an equalization feature which is manually initiated. With the Hawker Genesis® battery in Phase II, charging is accomplished at 2.45 volts per cell. In addition, the battery is temperature compensated and the equalization stage is based upon 2.50 volts per cell.

Figure 1. Norvik Charger Profile

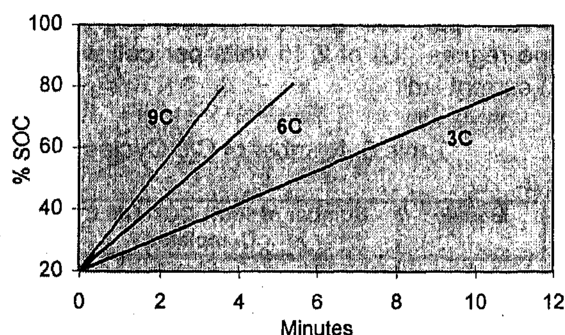

Table 5 provides the results of battery charger performance during the Phase II testing through December 1, 1996.

EVs 333 and 114 were primarily charged at the 9C rate. EV333 was equalized every sixth cycle by the Norvik charger. EV114 was charged overnight by the Martin Marietta 10 kW charger and equalized every fifth charge cycle by the Martin Marietta. Equalization voltage on the Martin Marietta charger was 2.50 volts per cell for the Hawker Genesis® batteries. During the overnight cycle on EV114, the Shape phase change material used for pack thermal stability, was frozen using a standard window air-conditioning unit to circulate air through the battery pack. Although a relatively large number of battery modules were lost by these high rate charges, the results are very promising due to the large number of modules which survived without the benefit of individual module charge control. Typical 9C charge rate module failures were observed to have a hot high rate venting of a module cell, which was detected by the Norvik charger and the charge was terminated.

Table 5. Battery Charger Performance Results Through December 1, 1996

EV	Days of Operation	Pack km	Pack Cycles	End of Life	Module Failures
114	78	2,851	108	no	2
333	165	7,413	200	no	9
137	247	16,064	251	yes	1
136/ GNB	279	6,318	97	yes	0
136/ Optima	175	4,277	137	no	4
130	367	18,008	399	no	1
131	414	6,024	140	no	0
133	610	18,270	427	yes	9
134	368	14,431	344	no	12
135	321	9,855	UNK	no	0
124	473	19,538	379	no	2
116	1,120	19,207	367	no	0

EVs 137 and 136 were charged at the 5C rate. EV137, which utilized Hawker Genesis® batteries, was charged overnight by the Delco inductive charger and equalized at 2.56 volts per cell on every third Delco charge. EV136, using Optima batteries, was equalized every sixth cycle by the Norvik charger. EV137 operated extremely well, incurring over 160.9 km (two partial 5C charges daily) in daily operation. At just under 16,090 km with no battery maintenance whatsoever, one module failed. At this point the test on EV137 was terminated. Problems with battery module interconnections in EV136 caused arcing and battery damage.

EV130 had very successful performance. The vehicle was predominately charged at the 3C rate. Overnight charges were accomplished with the Solectria 3 kW charger. EV130 showed no significant deterioration in range up to the time of its first module failure (17,915 km). The test protocol for EV130 was based on the protocol used for EV137 in Phase I. EV137, during Phase I, operated very successfully at the 3C charge rate using Delco overnight charges. While using this charge scheme, EV137 achieved about 26,549 km. In both cases, these EVs operated extremely well without battery management systems. If these systems were added to these EVs, their performance should improve. With this charge configuration, EV130 accumulated a total of 399 charge cycles and 18,008 km before incurring its first module failure. All of the fast charge cycles delivered achieved 80% State of Charge (SOC) in approximately 15 minutes.

EV131 and EV134 were driven daily in meter reading duty cycles (about 32 to 40 km per day) in Phase

II. EV134 was part of the Phase I testing where, using the Solectria 2 kW charger, 12 battery modules were lost due to thermal run away. These 12 modules were replaced and the pack charged using numerous fast charge cycles at the 3C rate. The vehicle was then moved into the Phase II program. Both EV131 and EV134, at the end of the work day, were charged with the Delco charger with equalizations occurring every fifth cycle. These EVs were fast charged once every other weekend with the Norvik charger at the 3C rate. Over the test period their range continued to deteriorate, until in the early part of November 1996 their range had dropped to about 37 km at constant speed 96.5 km/h. EV133 also continued from Phase I into Phase II field testing. In Phase I, EV133 accumulated about 12,550 km on its pack while being charged by the Solectria 3 kW charger, at which point the range had fallen to about 40 km. At this time the charging scheme for this EV was changed to being charged solely by the Norvik charger at the 3C rate. The range of the vehicle improved significantly and was then returned to fleet duty in construction where it continued to operate until abrupt pack failure at 18,270 km.

Phase II testing also included the evaluation of a Nickel Metal Hydride (NMH) battery and the Saft Nickel Cadmium (NiCad) battery provided with the Chrysler *TEVan*. The NMH is a prototype battery and is evaluated as being very promising. The NiCad battery has proven to be very durable. It has undergone a long period of partial fast charging at about the 3C rate. It has been in operation for three years. Fast charging dramatically reduced the amount of watering required by the battery. It has had extremely good reliability in the thirty months preceding December 1, 1996. There have been no battery modules replaced on this EV.

Preliminary results of the Phase II testing indicate that EVs charged at 3C and 5C charge rates perform extremely well, specifically EVs 130, 133, and 137. These EVs, with no battery management systems installed, achieved over 15,000 km on their battery packs without experiencing end of life of the batteries. In addition, charging at the 9C rate appears possible. However, further testing at the 9C charge rate is required using a battery management system.

Testing in Phase I and Phase II has extended battery life beyond the point which is reasonable to fully test in the field. The time and expense of operating vehicles in excess of 16,000 km dictates that a method be developed to predict remaining battery life such that testing to end of life is no longer necessary to evaluate the effectiveness of a particular charge protocol. In order to determine a means to predict remaining battery life, batteries with varying charge/discharge cycles were subjected to destructive analysis in Phase III of the test program.

PHASE III - ANALYSIS OF CYCLED BATTERIES

When a VRLA battery is cycled, i.e. repeatedly discharged then recharged, a host of largely irreversible processes occur internally. These processes impact the: a) morphology and crystallography of both the positive and negative active materials; b) corrosion and growth of the positive grid material; and c) electrolyte concentration and saturation level as both water loss and consumption of oxygen in the grid corrosion process occurs. Eventually, one or a combination of the above will result in unacceptable battery performance, i.e. end of useful life.

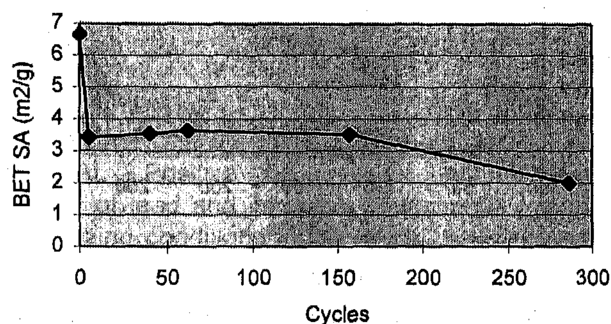
In order to correlate internal aging of the battery with use, a group of Hawker Genesis® G190W batteries were subjected to a number of cycles, as seen in Table 6, and subsequently analyzed. The batteries were cycled at the C/5 rate of discharge to an end point voltage of 1.67 volts per cell and recharged using a constant voltage regime (IU) of 2.45 volts per cell with a 0.4 C/5 (15A) current limit.

Table 6. Number of C/5 Cycles

Module	Number of 100% DOD C/5 Cycles Completed
A	0
B	5
C	40
D	62
E	157
F	286

Positive and negative plates from the above cycled modules were removed, washed so as to remove electrolyte, then dried and stored under inert conditions in order to prevent further changes prior to analysis. Active material samples were then carefully extracted from along the plate diagonal.

The analysis techniques employed for this study were BET Surface Area (BET SA), Particle Size Analysis, X-ray Diffraction (XRD) and Scanning Electron Microscopy (SEM).



CYCLE LIFE CHANGES TO THE MORPHOLOGY AND CRYSTALLOGRAPHY OF THE POSITIVE ACTIVE MATERIAL - Table 7 summarizes the results for the positive active material (PAM).

Table 7. Morphological and Crystallographic Changes of the PAM During Life Cycling

Module	C/5 cycles	BET surface area (m^2/g)	Median pore diam (nm)	XRD % α-PbO_2	XRD % β-PbO_2	XRD % $PbSO_4$
A	0	6.66	24.9	12	81	7
B	5	3.42	35.8	8	88	4
C	40	3.55	28.8	2	96	1
D	62	3.64	49.1	1	97	2
E	157	3.52	4.9	0	100	0
F	286	2.00	4.2	1	99	0

As shown in Table 7, the first measured quantitative change to the PAM, throughout its cycle life, is the conversion from an initially high surface area crystalline material, immediately following formation, to a progressively lower surface area coralloid structure, as seen in Figure 2. (Reference I)

Figure 2. PAM BET SA vs Cycles

This transition may clearly be seen in the following SEM pictures, Figures 3 through 5.

Figure 3. Bulk PAM from Module A, 0 Cycles, x2500

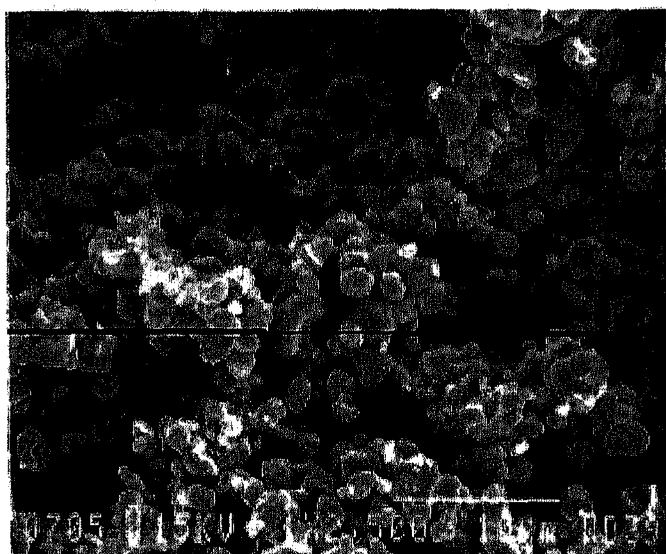


Figure 4. Bulk PAM from Module D, 62 Cycles, x2500

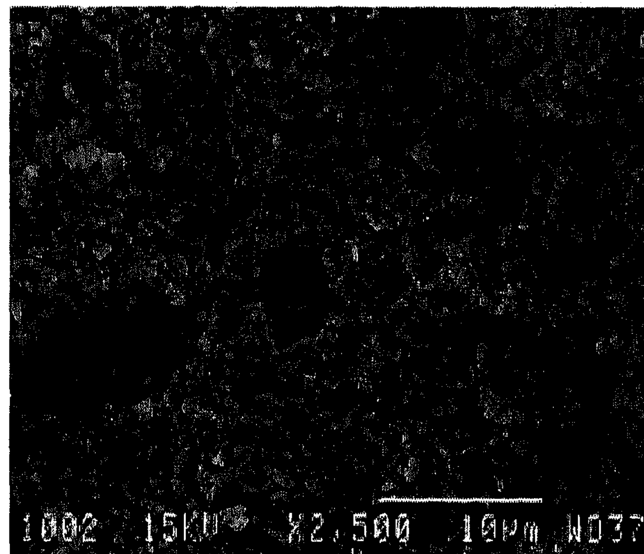

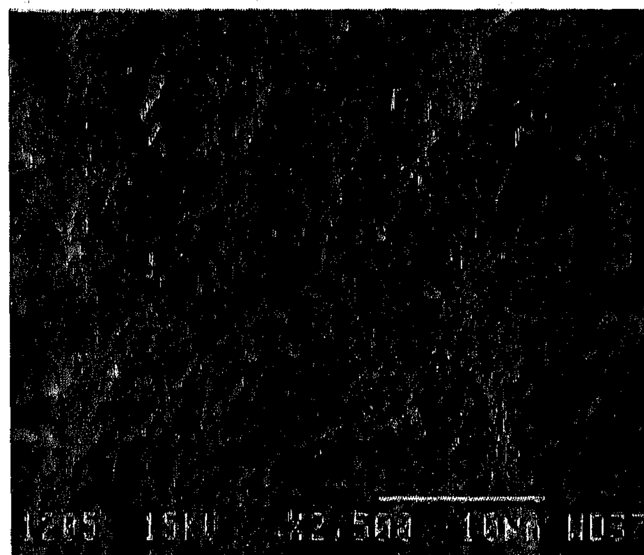

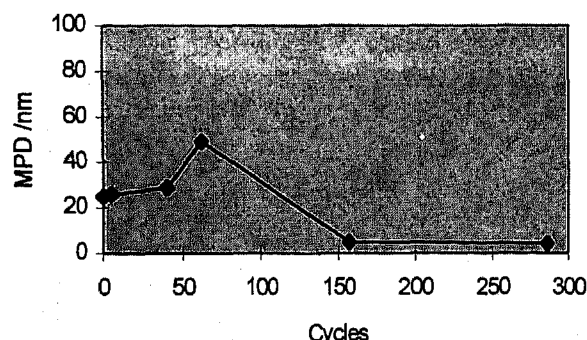

Figure 5. Bulk PAM from Module F, 286 Cycles, x2500

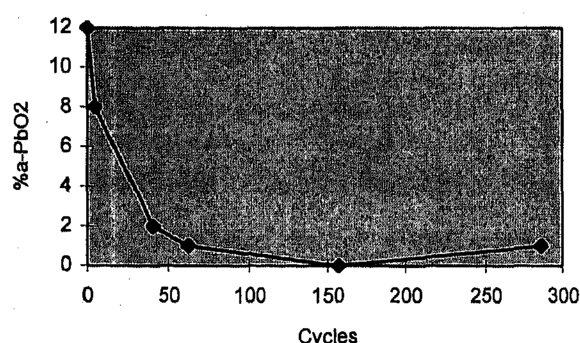
Healthy PAM is typically considered to possess a surface area (SA) of between 3-4 m^2/g. Toward end of life the contraction of the active mass results in a reduced SA approaching 2 m^2/g.

The second measured transition is the reduction in the median pore diameter (MPD) of the PAM, as shown in Figure 6.

Figure 6. PAM Median Pore Diameter



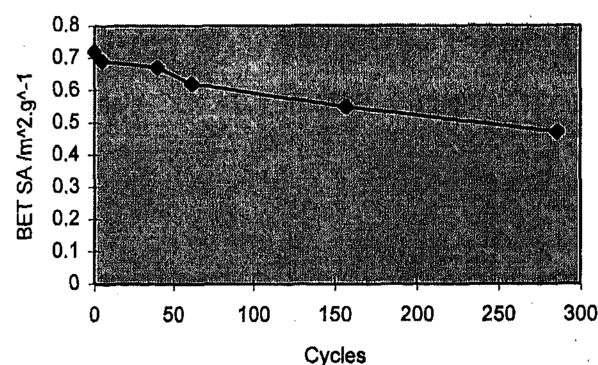
The median pore diameter referred to here is for PAM removed from the grid and gently broken-up, not left in-situ on the grid. It is thought that the in-situ PAM will have both very large pores left in the pellet, as the active mass consolidates, and small pores within the coralloid structure itself.

The MPD is a measurement of the degree of contraction of the PAM. In the above experiment Module E (157 cycles) exhibits a similar MPD to Module F (end-of-life) but still has 50% cycle life remaining. This anomalous behavior may be attributable to the high pack compression associated with the Genesis® technology. It is now recognized that high pack compression alleviates many of the shortfalls associated with cycling the positive plate by physically constraining the PAM. (Reference J)

The third measured quantitative change within the PAM is the transition of the α-PbO_2 component into β-PbO_2. This is shown in Figure 7.

Figure 7. Crystallography of PAM vs Cycles

This transition is generally a function of the battery design, specifically the degree of PAM utilization. For the Genesis® technology, this transition occurs early in life and, consequently, has no correlation with remaining useful cycle life.



CYCLE LIFE CHANGES TO THE MORPHOLOGY AND CRYSTALLOGRAPHY OF THE NEGATIVE ACTIVE MATERIAL - Table 8 summarizes the results for the negative active material (NAM).

Table 8. Morphological and Crystallographic Changes of the NAM During Life Cycling

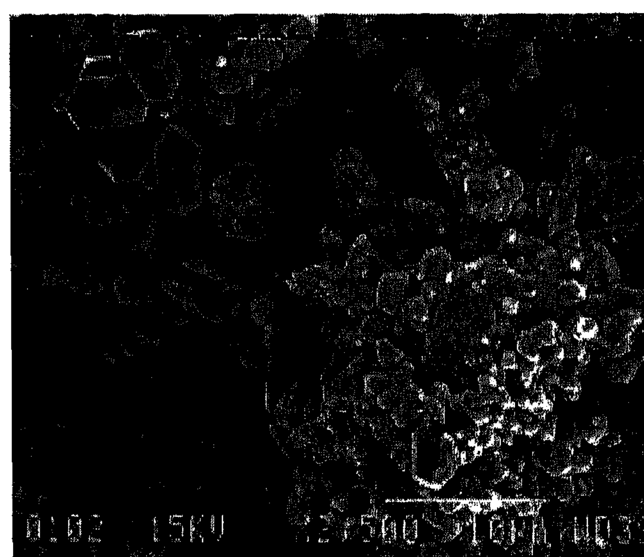
Module	**C/5 cycles**	**BET surface area (m^2/g)**	**MPD (nm)**	**XRD % Pb**	**XRD % PbO**	**XRD % $PbSO_4$**
A	0	0.72	4.8	99	0	1
B	5	0.69	4.7	99	1	0
C	40	0.67	4.5	99	0	1
D	62	0.62	4.2	99	0	1
E	157	0.55	4.5	96	3	0
F	286	0.47	4.9	97	2	1

The only measured change found to the NAM during cycling is a gradual reduction in surface area, possibly as a result of the negative expanders losing activity. This reduction is shown in Figure 8.

Figure 8. NAM BET SA vs Cycles

SEM analysis of the negative plates, at the beginning of life and after 286 cycles, reveals little visual change, as seen in Figures 9 and 10.

Figure 9. Bulk NAM from Module A, 0 Cycles, x2500



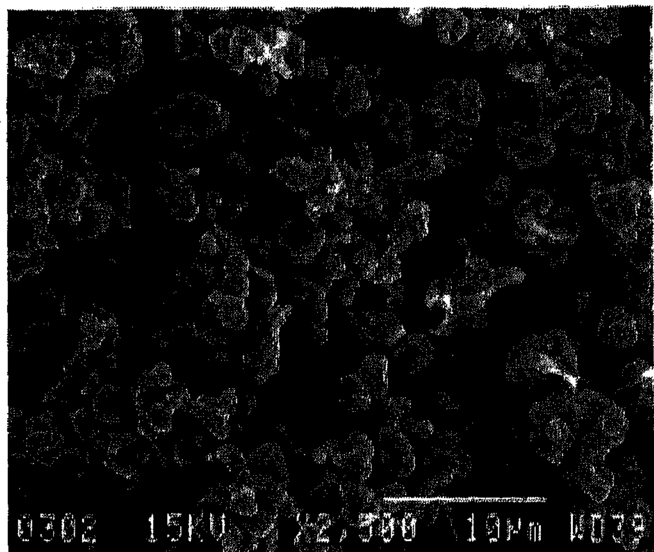


Figure 10.Bulk NAM from Module F, 286 Cycles,x2500

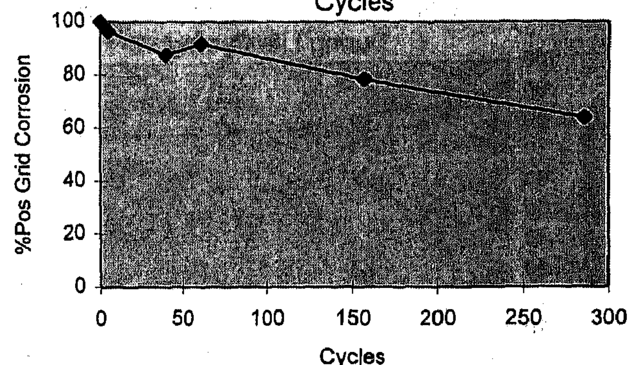


Although the negative electrode was never found to be capacity limiting, even at the end of life, there does appear to be a good correlation with BET SA and cycle number. Recent work indicates that the decline in negative surface area is alleviated by rapid recharging. (Reference I)

CORROSION OF THE POSITIVE GRID MATERIAL - Positive grid corrosion occurs due to the instability of lead and its alloys at the anodic potentials and oxidizing conditions found at the positive electrode. Corrosion is kinetically inhibited by the growth of a passivating layer of PbO_2 on the grid surface. However, corrosion will eventually limit the capacity of the positive electrode by a combination of growth, caused by volumetric changes of the corrosion product at the grid surface and at the grain boundaries, and reduction of electronic continuity throughout the grid. Furthermore, it aggravates the situation by consuming much-needed water from the electrolyte, which in an acid starved system can be a major contributor to end of useful life.

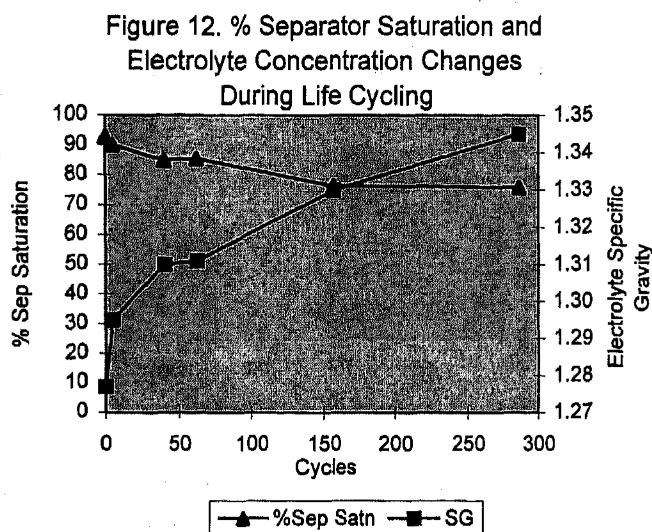
Positive grid corrosion was estimated by mechanically removing the PAM, chemically stripping any residual PAM and corrosion product from the grid, and then finally weighing the residual lead grid. The difference in weight for the sample grid and the grid from Module A (0 cycles) yielded the amount of lead oxidized during cycle life. The results are shown in Figure 11.

Figure 11. %Positive Grid Corrosion vs Cycles

For the Genesis® technology, under these cycling conditions, there is a very strong correlation between % grid corrosion and remaining cycle life.

ELECTROLYTE CHANGES - Water loss is an inevitable consequence of cycling batteries. Water is electrochemically removed from the system by: a) charging inefficiencies resulting in electrolytic decomposition; and b) corrosion of the positive grid consuming oxygen from the electrolyte, according to:

$$Pb + 2H_2O \longrightarrow PbO_2 + 4H^+ + 4e^-$$



The result is a progressive increase in electrolyte concentration and a reduction in saturation level.

These changes were evaluated by: a) measuring the total module weight loss over cycle life, b) removing and weighing the wet glass mat separator from one cell of each of the modules, and c) extracting the acid from the separator and measuring its concentration. These results are summarized in Table 9.

Table 9. Electrolyte Changes During Life Cycling

	C/5 cycles	Module wt loss (g)	% wet sep wt comp to Module A	Electrolyte conc (% H_2SO_4)	Electrolyte SG @ 15°C (kg/dm^{-3})	Calc sep % satn
A	0	0	100	37.2	1.277	92.9
B	5	5.7	95	39.2	1.295	90.2
C	40	12.2	87	40.9	1.310	85.0
D	62	15.8	87	40.9	1.311	85.5
E	157	67.9	82	43.1	1.330	76.5
F	286	88.4	70	44.8	1.345	75.9

Figure 12 shows the variation in % separator saturation and electrolyte concentration with cycle life.

For Genesis® technology, a strong correlation between water consumption exists (measured as % separator saturation), and subsequently, electrolyte concentration and cycle life.

The results of the Phase III testing indicate that positive active material morphology or crystallography does not yield a good correlation to remaining cycle life. It is now recognized that high separator compression alleviates some of the problems associated with cycling the positive active mass. Therefore, high compression systems may continue to exhibit good cycling capability long after the PAM has transformed into a structure traditionally considered to be life limiting. In addition, positive grid corrosion and separator saturation (a measure of grid corrosion and dry out) exhibit a strong correlation to cycle life.

Therefore, based upon work completed to date, grid corrosion and/or separator saturation can be used to evaluate remaining life in Hawker Genesis® batteries. Additionally, measures to reduce grid corrosion/dry out will improve battery cycle life. This includes charge algorithms, particularly the amount of time the battery spends at high charging voltages.

CONCLUSIONS

Battery performance, in Phase I testing, indicates that Hawker Genesis® batteries can be damaged by low power charging. Both Phase I and Phase II testing results suggest that the utilization of a 3C fast charge rate, in vehicles not using battery management systems, provides good vehicle performance and extended battery life. In addition, charging of the Hawker Genesis® batteries at the 9C rate is possible, but a battery management system is required to reduce module failures. In Phase III, it was shown that grid corrosion and separator dry out may be used to predict remaining life in VRLA Hawker Genesis® batteries.

Through Phases I and II of the APS Charger Test Project substantial progress has been made in extending the life of VRLA batteries in fleet service and dramatically reducing the time required for charging. Additional work is required in Phase II testing to determine optimum charge protocols. However, the method of remaining battery life estimation pursued in Phase III is necessary to allow test work to be completed in a reasonable time period.

Future work will include continued Phase III evaluation of batteries cycled in Phase II to solidify the method of remaining life determination. Testing should then commence on batteries, charged between a 3C and 6C charge rate, using battery management systems to validate the preliminary results of Phase II. Testing should also continue using a 9C fast charge rate on batteries with battery management systems. In addition to this testing, other VRLA batteries should be tested to determine if similar cycle life predictive methods can be used.

ACKNOWLEDGMENTS

The authors would like to thank Sean O'Keefe and Scott Lichte, HEPi, for all sample preparation and testing.

DEFINITIONS, ACRONYMS, ABBREVIATIONS

AGM - Absorbed Glass Mat

ALABC - Advanced Lead Acid Battery Consortium

APS - Arizona Public Service

Battery management system - A system designed to manage the charge of each individual module.

C charge rate - The C rate of charging is defined to be the rated energy of a battery delivered over a one hour period. Fast charge rates are linear multiples of that one hour rating.

Comp - compared

Conc - concentration

Cond - conductive

Equalization Charge - Charging of the battery to 100% SOC.

Ind - inductive

Manuf - manufacturer

MPD - Median Pore Diameter

NAM - Negative Active Material

NiCad - Nickel Cadmium

NMH - Nickel Metal Hydride

PAM - Positive Active Material

Partial Charge - Charging of the battery to less than 100% SOC.

SA - surface area

Satn - saturation

SEM - Scanning Electron Microscopy

Sep - separator

SG - specific gravity

SOC - state of charge of the battery

UNK - unknown

VRLA - Valve Regulated Lead Acid

Wt - weight

XRD - X-ray diffraction

Switchable Holograms for Automotive Applications

Bob L. Epling, Donna M. Brandelik, Lalgudi V. Natarajan, Richard L. Sutherland, Vincent P. Tondiglia, and Timothy J. Bunning
Science Applications International Corp.

ABSTRACT

This paper will discuss the relatively new technology of polymer dispersed liquid crystal (PDLC) based switchable holograms and its potential for application in the automotive industry. We have developed a novel photopolymer dispersed liquid crystal based material system, which allows fast, single-step recording of holograms with electrically controllable diffraction efficiency. The various characteristics of the holograms will be described as well as special considerations for various potential device configurations. Material characteristics to be described include transmission efficiency, diffraction efficiency, switching dynamic range, switching speed, recording sensitivity, temperature effects, voltage requirements, and system stability. Device applications to be considered include holographic optical elements, fiber switching, and displays.

INTRODUCTION

Diffractive and holographic optical elements (HOEs) offer the ability to manipulate light in ways not available to conventional reflective or refractive optics. Holography is being applied to an ever increasing range of applications which include displays, holographic interferometry, precision measurements, optical information processing, HOEs, optical switching, polarization control, narrowband notch filters, optical interconnects and couplers, lithography, and data storage.

We have been developing a holographic material system which allows for the single-step recording of

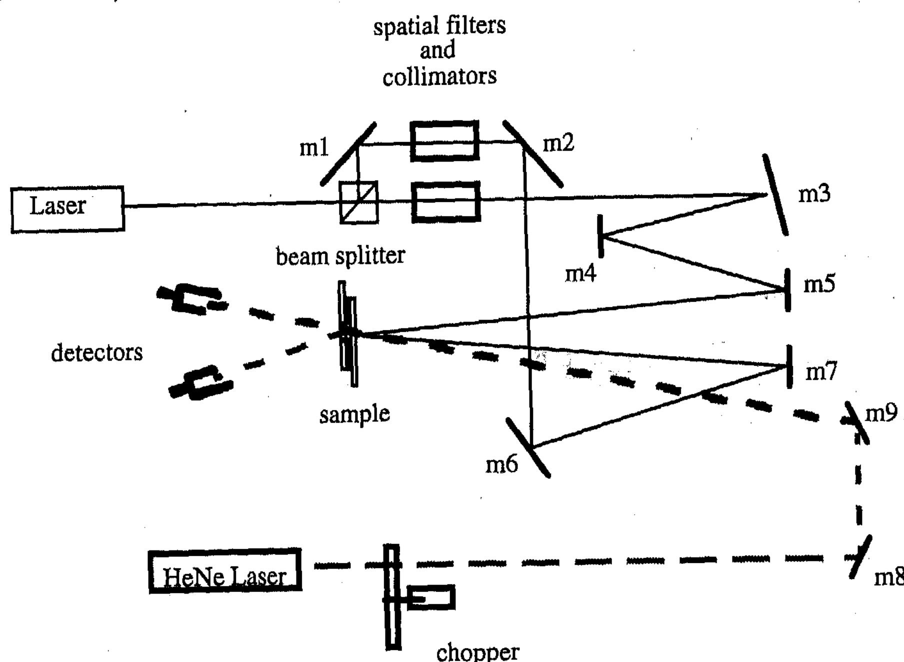

Figure 1 Experimental setup used to write PDLC gratings.

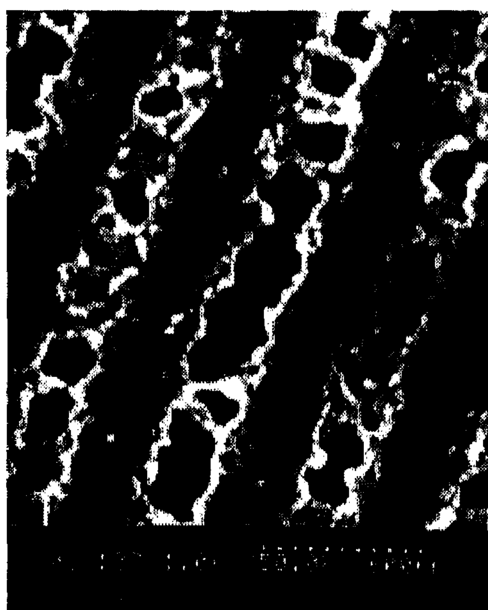
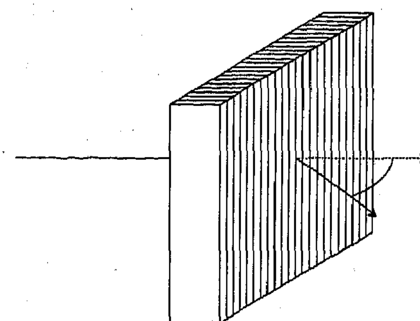
electrically controllable holograms.

Recording - Unlike most holographic recording processes, our PDLC based system allows for a single-step process. The syrup is placed between two indium tin oxide (ITO) coated slides which are separated with 15 - 100 μm spacers. Simple transmission gratings are recorded using the experimental configuration illustrated in Figure 1. In this configuration, two laser beams are crossed at the recording plane. In the regions of constructive interference, the light polymerizes the monomer. A diffusion of the liquid crystal to the regions of destructive interference occurs forming planes (fringes) of microdroplets. An SEM image of these microdroplet fringe plane is illustrated in Figure 2.





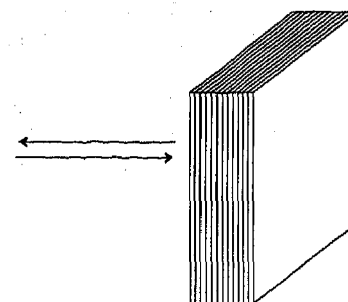


Figure 2 SEM surface view of PDLC grating.

Depending on the recording geometry, transmission gratings or reflection grating can be formed. In the case of transmission gratings, the fringe planes form perpendicular to the recording plane as illustrated in Figure 3. In reflection gratings, the fringe planes form parallel to the recording plane.

Material System - The material system is composed of a acrylate based photopolymer containing a nematic liquid crystal dispersion and has been described previously.[1,2,3,4] As the syrup is exposed, the holograms are photochemically induced by the writing beams in the regions of constructive interference. Polymerization results in a change in the chemical potential of the system and decreases the miscibility of the liquid crystal in the host. The liquid crystal phase separates from the host forming microdroplets of pure liquid crystal. The droplets can range 10 nm to 10 μm and form along the destructive interference fringe planes.

Transmission Grating

Reflection Grating

Figure 3 Fringe plane orientation for transmission and reflection gratings.

MAIN SECTION

SYSTEM PERFORMANCE - Using our PDLC material system, a broad range of performance is achieved. Many tradeoffs can be performed in the material system to optimize a particular performance parameter. The performance characteristics discussed in this paper have been characterized at 633 nm and room temperature, unless otherwise noted. This wavelength is acceptable for the SAE Red J578 (tail lights).[5]

Diffraction Efficiency - The diffraction efficiency for the switchable holograms is defined as the percentage of light diffracted into the Bragg angle relative to the incident beam. Diffraction efficiencies of 99% with narrow angular selectivity (1°) have been achieved. A goal of 40 dB is felt to be achievable. This would correspond to switching between 98% and 0.01% diffraction efficiency.

Dynamic Range - A dynamic range of >35 dB is currently achievable using the current materials and processing techniques. This corresponds to switching between 80% and 0.02% diffraction efficiency. Extending the dynamic range to 40 dB is a primary focus of our current research.

Switching Speed - The switching response times of the holograms have been measured and agree with simple models. Switching "ON" times were found to be approximately 25 μs where the "OFF" times were approximately 44 μs. It may be possible to further reduce the "ON-OFF" times by using a spiked voltage driving scheme.

Recording Wavelengths/Sensitivity - Switchable holograms can currently be recorded using wavelengths in the 400 - 800 nm range. We are currently exploring alternate photoinitiators to extend this sensitivity to the 900nm, 1.3 μm, and 1.55 μm range. Laser intensities of 1 - 3 mW/cm^2 are typically used to record the grating with exposure times of 20 seconds to 2 minutes being typical.

Driving Voltages - The holograms are typically driven using a 2 kHz square wave of approximately 5 V/μm. This corresponds to approximately 80 V_{p-p} for a 15 μm thick hologram. Figure 4 illustrates the diffraction efficiency as a function of driving voltage.

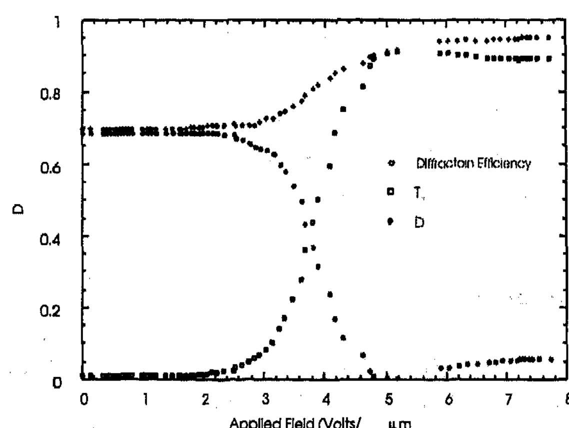

Figure 4 Electrical switching of a transmission grating.

Temperature Range - The currently used liquid crystal (E7) has a nematic range of -10 to 60.5 °C. A broad range liquid crystals are available and broader ranges of operation can be achieved e.g. NP 1291 TNC has a nematic range of -10 to 107°C.[6] As temperatures approach the upper end of the nematic range, the ordinary index of refraction increases while the extraordinary index decreases. For temperatures above the nematic range, the liquid crystal become isotropic and cannot be switched to a clear state. This temperature dependence can have a significant impact on the performance of the hologram. Figure 5 demonstrates the decrease in diffraction efficiency with increasing temperatures. The largest impact of temperature will ,however, be on the switching dynamic range. The decrease in switching dynamic range with temperature will be presented.

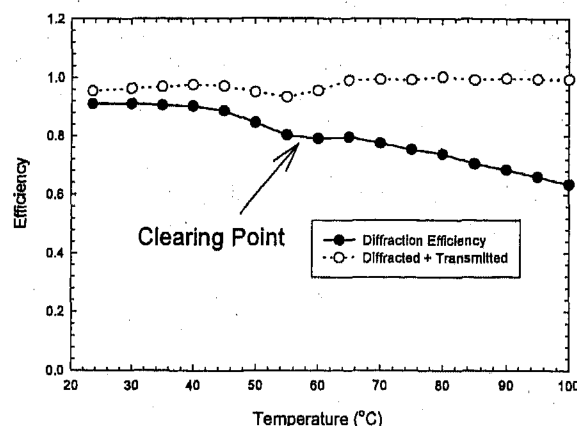

Figure 5 Diffraction efficiency of a PDLC hologram as a function of temperature for E7 liquid crystal.

DEVICE CONFIGURATIONS

Holographic Optical Elements - Switchable holographic lenses or general holographic optical elements can be produced using our material system. Figure 6 illustrates a holographic lens in the "ON" and "OFF" states as well as the chromatic dispersion anticipated with a diffractive lens. These lenses have been produced and can also be stacked to produce a switchable focus lens.[7] A significant advantage of our material system, is that the holograms are recorded in-situ in a single-step process. This feature can alleviate alignment errors of the HOEs.

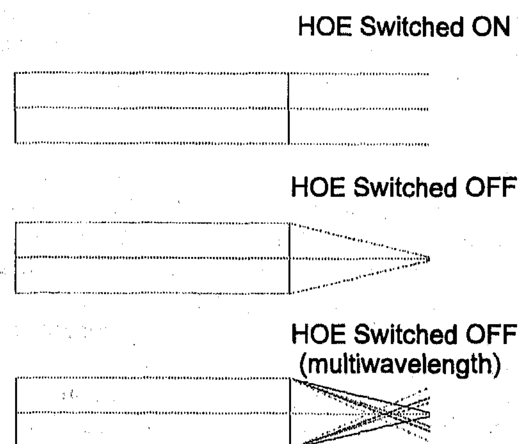

Figure 6 Illustration of switchable holographic lens.

Fiber Optic Switching - Our material system has been used by Foster-Miller to produce a 2x2 single-mode 1.3 μm fiber optic switch. The switch was capable of 25 dB switching.

Holographic Reflection Filter/Displays - Switchable reflection holograms can be formed using our PDLC material. Figure 7 illustrates the voltage modulation of a narrowband reflection filter. Switchable reflection hologram technology is less mature and current work is focused on improving the switching dynamic range. Switchable reflection grating have been explored for application in high contrast reflective color displays.[8] In this application, three switchable filters (RGB) are stacked to achieve a full color display.

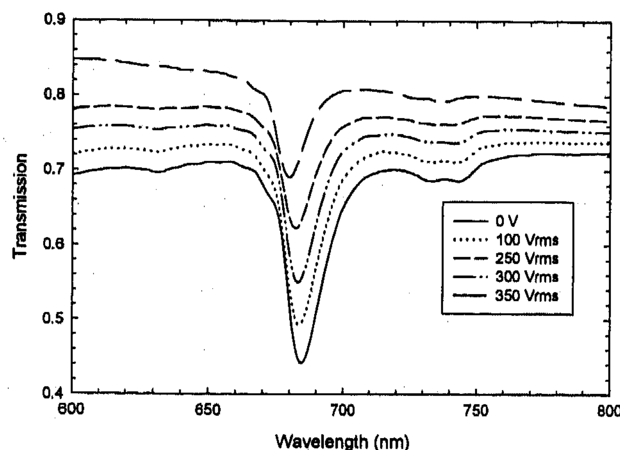

Figure 7 Voltage modulated reflection grating.

CONCLUSIONS

In this paper, we have discussed the current status of polymer dispersed liquid crystal based switchable hologram technology. Various material performance characteristics were summarized however it should be noted that the materials system can be modified to optimize the performance the various parameters. Various device configurations were also presented to illustrate the broad utility of this material system.

ABSTRACT

The development of efficient, multi-output High Intensity Discharge (HID) light sources is important for driving fiber systems in automotive applications, in particular for headlamps. Such systems must collect a large fraction of the light from the HID source while efficiently coupling the light into large core light pipes.

An earlier paper [1] showed how multifocus optical systems can efficiently split the light evenly between separate output ports. Multifocus systems were shown to be more efficient than a mixing rod approach, especially for the case of two ports. In the case of dual output systems, many more cases need to be considered. To facilitate the investigation, a state-of-the-art optical analysis/design program was employed to demonstrate the tradeoffs between six different dual focus geometries. A novel dual ellipse approach is presented.

BACKGROUND

The technology required for automotive headlamp distributed lighting systems is approaching commercial viability. The instant start metal halide light sources [2, 3] required for automotive headlamps are now commercially available [4], and have been used to illustrate that single source headlamp systems are viable [5, 6]. Low cost fibers which can handle the automotive underhood environment are currently under development and fibers for less thermally demanding environments are readily available today. For headlamp systems, as well as other distributed lighting systems, a typical geometry is to use half the light for the driver's side headlamp and the other half for the passenger's side headlamp.

From a system perspective, an automotive fiber system needs to efficiently deliver the light to the output optics on either side of the automobile while minimizing the size of the fibers that are used to transport the light. This means that it is desirable to collect as much light as possible, focus the light into as small an area as possible, and maximize the transmission of the light through the fibers. High collection efficiency allows lower wattage bulbs to be used which minimizes the lamp package size, ballast cost, and thermal impact. Tight focusing of the light distribution means that the size of the fibers can be minimized. Small fibers are desirable to make the routing of the fibers easier and to lower fiber costs. Unfortunately, as the light is focused into a smaller area, the angular distribution gets wider. A wider angular distribution of light, in general, results in poorer transmission through the fiber. Minimizing the size of the light pipe and the extent of the angular distribution is the key to minimizing the size of the output optics.

OVERVIEW

This paper considers some of the tradeoffs in methods used to split the light evenly between two round fibers. To perform this splitting efficiently while focusing the light into a small area and minimizing the angular extent of the light, sources with high luminance and high efficacy are required. Fluorescent lamps provide high efficacy but possess low luminance. Xenon lamps provide high luminance but at only relatively poor efficacy. Metal Halide lamps with short-length arc gaps provide the desired balance between high luminance and high efficacy.

Modeling the light emanating from a discharge sources is complicated by the fact that what the source looks like from different view angles is determined by details such as the electrode geometry, the choice of fill

chemicals, the amount of fill chemicals, the wall temperature, the bulb wall shape, the burning orientation of the lamp, and the power applied to the lamp. Because of all these variables, and there are more, each discharge source will be unique when the luminance Vs view angle is evaluated. Since the intent of this paper is to compare different collector schemes and not perform an exhaustive comparison of the optical modeling of different types of discharge sources, a simple spherical volume source model is considered. This source averages the luminance of the core and the mantel regions of the plasma. The source radiates isotropically from within the sphere and is transparent to its own radiation. Much more complicated models can be developed, but they are outside the scope of this paper.

OPTICAL GEOMETRIES

Six dual focus collector geometries and one single focus geometry are considered using the same light source model. The light source emitting region is a 2.5 mm sphere that is centered inside of a quartz bulb wall that is modeled using an 8 mm outer diameter sphere with 1 mm thick walls. The legs of the lamp are 3.5 mm diameter cylinders that are nominally 20 mm long and are unioned with the spherical bulb wall. The ends of the lamp legs are made absorptive to remove light which might totally internally reflect (TIR) down the length of the legs. The diameter of the absorptive electrodes is 1 mm, and the gap between the two electrodes is 2.5 mm.

Figure 1 shows the seven different collection geometries that were modeled using LightTools®. The names and the details that will be used throughout the rest of the paper are described in the following paragraphs. A reflector reflectivity of 95% and coated glass surfaces with 95% transmission for two surfaces are used.

FIGURE 1A. STANDARD ELLIPSE - The lamp is placed at the first focus of an elliptical reflector with a glass cover plate attached near the rim of the reflector. The angle from the first focus to the rim of the reflector is 35 degrees. The distance from the first focus to the apex of the reflector is 10 mm. This single port collection system is used to provide a basis for comparison to the various dual focus systems.

FIGURE 1B. SPLIT ELLIPSE - The Standard Ellipse of Figure 1A is split in two, with the two halves rotated slightly at the first focal point about an axis 90° out of the paper. The second focus of each half is located 6 mm from the center line. A cover glass is added.

FIGURE 1C. V-MIRROR - The Standard Ellipse is used; however, in this configuration the light is split prior to the second focal point using two mirrors. The angle between the two mirrors is adjusted so that the centroid of the light distribution that is reflected off of the V-mirror is 90 degrees from the axis of the lamp. No cover glass is included in this system so that all geometries considered have the same average surface losses; however, thermal considerations would probably require the inclusion of a cover glass in a practical implementation.

FIGURE 1D. PARABOLA WITH LENSES - The lamp is placed at the focal point of a 10 mm focal length parabola. The angle from the first focus to the rim of the reflector is 35 degrees. The collimated light is then split with two off-center aspheric lenses. The center of each lens is adjusted so that the centroid of the focused light distribution is parallel to the axis of the lamp.

FIGURE 1E. BACK TO BACK ELLIPSES - Two of the 'Standard Ellipses' are cut along the plane that passes through the first focus of the reflector and joined back to back.

FIGURE 1F. DUAL ELLIPSES WITH TAPERED RODS - Two ellipses are truncated along the plane that passes through the first focus of the reflector. The opposite sections of the reflectors that are used in Figure 1E are selected. The reflector shape is also changed to make the reflectors more spherical. The hole near the apex of each of the two reflectors is large enough to ensure that the light which propagates from the first focus to the rim of the reflectors is not blocked during its propagation from the rim to the second focus. The angles with this system are reduced through the use of a tapered rod. The diameter of the output end of the rod is 1.3 times larger than the input diameter. The tapered rod that is pictured in Figure 1F has an input radius of 2.3mm and a length of 30mm.

FIGURE 1G. DUAL ELLIPSES WITH LENSES - The system shown in Figure 1F is used, except that the holes in the reflector are replaced with negative lenses. The negative lenses reduce the angular distribution of the light, performing the same function as the tapered rods.

ILLUMINATION MODELING

Given the geometries described in the previous section, a Monte Carlo ray trace approach was used to evaluate the spatial and angular distribution of the light for each case. The starting positions of equally weighted individual rays are randomly chosen within the 2.5mm sphere and then the direction of eacht ray is randomly chosen using an isotropic distribution. The ray is traced through the system, accurately modeling all refractive and reflective effects. The bundles of rays that are focused at each of the two output ports are analyzed to determine the location of their least-means-squared focus.

The illuminance distribution at the plane in space where the least-means-squared focus occurs is then

computed by averaging the rays in a grid of square collection bins. Smoothed raster plots of this binned data are created. The flux within circular apertures of monotonically increasing size are computed using the raw ray data, not the binned data. This flux versus aperture data is called an illuminance encircled energy distribution curve.

The angular distributions of the rays that pass through a 12 mm port are then used to compute the intensity distributions of the collected light. Because the single port distribution is not split into two, a 18 mm port was used to compute the intensity distribution for the 'Single Ellipse' system.

The intensity distributions are computed by averaging the rays in a polar grid of equal width elevation angles. Each annulus of elevation angle is then divided into bins of equal azimuth width. The bins look like arcs within a pie wedge. The flux within circular apertures of monotonically increasing elevation angles is summed using the raw ray data. This flux versus angle data is called an intensity encircled energy distribution curve.

ILLUMINATION MODELING RESULTS

The illuminance (lumen/mm^2) distributions near the input face of the lightpipes for each of the dual port systems are shown in Figure 2. For the 'Dual Ellipses with Tapered Rods' case the lightpipe input face is the large end of the tapered rod (Fig. 2E). Because all systems possess symmetry, only one of the two output ports is shown. The greyscale levels are chosen such that the peak illuminance in each plot is dark and the area of zero illuminance is white. The size of the fiber required to collect all the light for each of the systems can be qualitatively evaluated by looking at the size of the illuminance distributions. The 'Dual Ellipses with Tapered Rods' and the 'Dual Ellipses with Lenses' show the smallest spatial distributions.

The focusing can be quantified by examining the illuminance encircled flux distribution curves shown in Figure 3. The ordinate represents the diameter of fibers placed at the least-means-squared focus. The abscissa represents the flux collected at the fiber input face divided by the flux that passes out of the lamp. Perfect collection with no transmission losses would be a value of 0.5, since the light is divided between two ports. Because of reflectivity and transmission losses, the maximum is 0.5*0.95*0.95 = 0.45. The port size for the 'Dual Ellipses with Tapered Rods' is the size of the output end of the taper, which is 1.3 times the input size; however, the size of the input end is used to determine how much flux is collected. The illuminance encircled flux distribution results show that the 'Dual Ellipses with Tapered Rods' and 'Dual Ellipses with Lenses' systems possess the best collection efficiency of all the systems modeled. The primary reason is that these two geometries possess reflectors which nearly surround the lamp.

The illuminance distributions for the 'Standard Ellipse' and both ports of the 'Dual Ellipses with Lenses' are shown in Figure 4. Figure 5 shows the illuminance encircled energy plots for the 'Standard Ellipse' and both of ports from the 'Dual Ellipses with Lenses' case--where the outputs from both ports have been combined ideally into an 'effective' single round fiber. The diameter corresponds to the area of the combination of the two ports that are used. For example, if the relative flux for one of the 'Dual Ellipses with Lenses' ports is 0.35 at a diameter of 6.33 mm, then the combination is 0.70 relative flux at $6.33\sqrt{2}$ =8.95 mm.

The intensity distributions (candela vs. angle) for the light collected within a 12 mm aperture for each of the dual port systems are shown in Figure 6. The intensity distribution for the 'Single Ellipse' case is shown in Figure 7. Essentially, the raster plots represent the light distribution as it would appear to an observer looking at the internal surface of a large sphere. The light source is located at the center of the sphere and the observer is far from the sphere. Because the angles are relatively small for all these cases, the dual port intensity distributions are similar to what would be observed if the light that would be captured by a 12 mm diameter fiber were allowed to illuminate a wall on the far side of a room. The 'Split Ellipse', 'V-Mirror', and 'Parabola with Lenses' all show a somewhat half-circular shape because of the splitting geometries. The other cases all show a dip in the center of the distributions. The dip occurs because of the hole near the apex of the reflectors and/or because of bulb blockage. In the 'Dual Ellipses with Tapered Rods' and 'Dual Ellipses with Lenses' cases, some blockage because of the legs of the lamps occurs. This leg blockage depends upon the relative size of the reflectors and the lamp.

As light propagates within a large core optical fiber, the energy within a small annular range of angles will be mixed within that annulus. The intensity distribution becomes rotationally symmetric. Some mixing between small and large angles occurs, but that is determined by effects such as bends in the light pipe and scattering. For straight light pipes with negligible scattering effects, annular structure will be lost at the output end of a light pipe, but the average radial structure will be retained. As shown in Figure 8, by the time light from the focus of the 'Dual Ellipse with Lenses' has traveled through 60 mm of fiber, the intensity distribution is nearly identical to that of the 'Dual Ellipse with Tapered Rods' case.

The intensity encircled energy plots as a function of angle are shown in Figure 9. Since the collection efficiency information is contained in Figure 3, these curves were all normalized by their value at large angles. The curves show that all designs provide greater than 90% of the light within a 33 degree half angle (66 degree cone). These angular distributions are low enough to have good transmission through 0.55 numerical aperture (NA) fibers. The critical angle is arcsin(NA), which is 33.4° for a 0.55 NA fiber.

A very simple model of a short length of high transmission fiber is that it propagates light that is at angles lower than the fiber critical angle (Transmission = 1) and leaks light at angles higher than the critical angle (Transmission = 0). This is shown schematically in Figure 10. This model is an over simplification. Bends in the fiber, propagation of skew rays, and the tightness of the cladding will all cause the effective transmission curve as a function of angle to be less than unity at angles below the critical angle and greater than 0 at some angles above the critical angle. Even so, the binary transmission model provides reasonable performance estimates.

A direct result of the binary fiber transmission model is that the fraction of flux transmitted from one end of the fiber to the other end is the same as the fraction of flux within the critical angle of the fiber. Thus, Figure 9 can be used to determine what fraction of the flux coupled into the fiber propagates from the input end to the output end.

COMPARISON USING ANGLE TO AREA CORRECTION TO PROVIDE EQUIVALENT ANGULAR DISTRIBUTIONS

A nonimaging angle to area converter, shown schematically in Figure 11, can be used to increase/decrease the size of the focused light by decreasing/increasing the angular distribution. This is the technique used in the 'Dual Ellipse with Tapered Rods' case and represents a simple means to match the illuminator NA with the fiber NA. This type of angle-to-area conversion is described by **[7]**.

$$D_1 \mathrm{Sin}(\theta_1) = D_2 \mathrm{Sin}(\theta_2), \qquad \text{EQ. 1}$$

where D_1 and θ_1 are the aperture size and angle at the input to the nonimaging converter; D_2 and θ_2 are the aperture size and angle at the output of the nonimaging converter. An ideal lens-based magnification system is also governed by Equation 1, where D_1/D_2 is the magnification ratio. For example, assume that a system transmits 90% of the light within 20 degrees using a 15 mm fiber. If 90% of the light could be transmitted within 30 degrees, then the equivalent fiber size is 15*sin(20)/sin(30) = 10 mm.

One way to compare the potential performance of fiber optic illuminators that have different angular distributions is to select a percentage of the collected flux and use a nonimaging optical element to adjust the angle within which that flux is contained. Assuming the binary fiber transmission model, the fiber transmission is then independent of the details of the shape of the angular distribution. Of course, if the angular distribution is magnified then the spatial distribution must be demagnified using Equation 1. This scaled spatial distribution plot can then be used to compare the relative amount of flux collected by the fiber. Since the transmission through the fiber is the same for all cases, the scaled spatial distribution plots provide a relative comparison of how much light is delivered to the other end of the fiber.

This scaling approach is used to adjust all the curves shown in Figures 3 and 9 so that 90% of the light is collected within a 30 degree half angle. The scaled illuminance encircled energy results and scaled intensity encircled energy results are shown in Figures 12 and 13, respectively. The graphs show that the 'Dual Ellipses with Tapered Rods' and 'Dual Ellipses with Lenses' cases provide the highest amount of flux in the smallest fibers.

RECOMMENDATIONS FOR FURTHER WORK

If delivery of only a small fraction of the flux were needed for a particular application, then the scaling might be performed using a smaller percentage of the angular distribution. Since we are interested in high efficiency systems, those cases are considered outside the scope of this paper; however, the scaling concept introduced in this section could be used to compare such systems.

It would be valuable to extend the results presented here to include a more detailed fiber transmission model. The angle-to-area scaling approach could then be used to optimize the transmitted light as a function of all relevant fiber and illuminator variables.

CONCLUSIONS

Since the headlamps of automobiles are required to be on either side of the automobile, the natural configuration is one whereby the focusing geometry provides one port on the right and one port on the left. The fiber can be bent to provide this same type of geometry, but the space for the bend tends to require a larger total package size. The 'Ellipse with V-Mirror', 'Dual Ellipses with Tapered Rods', and the 'Dual Ellipses with Lenses' configurations all provide this desired geometry. The 'Dual Ellipses with Lenses' configuration maximizes the light collection into small fibers and also minimizes the required package space.

The analysis of dual focus systems is a complex problem. Computer modeling has been shown to be an effective tool to aid the design of this type of complex optical system. Especially important is the combination of pictures which show important ideas and graphs which quantify the tradeoffs.

Intelligent Audio Amplifier

Jan-Paul F. Huyser
Philips Semiconductors Nijmegen

Darby Hadley
Ford Audio Systems

ABSTRACT

An intelligent amplifier has been developed which delivers output power to either a two or four speaker audio system. The amplifier determines the number of speakers present during the start-up sequence and configures itself either as two BTL amplifiers or four single ended amplifiers. The system does not require any wiring modifications to operate in either mode and will reconfigure itself on each start-up cycle allowing system modifications, such as adding speakers, without additional wiring or hardware modifications.

Difficulties arise when determining the presence of speakers in an automotive environment. Extraneous noise sources such as door slams, hatch slams and engine cranking can cause erroneous measurements thus inappropriate configurations. The presented circuit was determined to be immune to these noise sources and is based upon:

1. Integration of measurements over a fixed period of time

2. Applying a large voltage to overcome noise sources without creating audible disturbances

3. Fixed switch on behavior

INTRODUCTION

A situation typically unique to OEM manufacturers is the requirement to offer a variety of audio systems on a particular vehicle. The problem that arises is complexity not only in the audio hardware but also in the vehicle wiring. A typical audio system line-up may range from a basic 2-channel am/fm radio to a 6 speaker CD system. In an effort to reduce radio complexity in the low to mid-range system and still offer an easy upgrade path, it is desirable to offer one wiring solution for a four speaker system, but have the radio work as either a 2 or 4-channel unit.

In a typical radio, the head unit would contain 4 amplifier channels. If the vehicle were only manufactured with two speakers, 2 of the amplifier channels would be wasted. Other solutions exist where the front and rear amplifiers are out of phase and in a two speaker system, the speaker could be connected between the front and rear channels to create a bridge amplifier delivering four times the power to the front individual speaker. The problem has been that this would either require a unique vehicle wiring harness or a modification to the head unit. Also, if the customer would ever want to add a second set of speakers, again the wiring would either have to change or the head unit would have to be modified.

The question then became, "wouldn't it be nice to offer one set of vehicle wiring and allow the radio to configure itself based on the number of speakers present in the vehicle".

This paper describes an audio system that detects the number of speakers present during a start-up cycle and either configures the radio to deliver 2 channels of 21 watts/channel or 4 channels at 6 watts/channel. The system will reconfigure itself on each power cycle to allow for modifications to the system, such as adding additional speakers at a later time.

The detection method is paramount to the successful operation of the system. Upon early investigations it was determined that there exists a large number of noise sources in the automotive environment that could have an impact on the load detection method thus the system had to be proven reliable under a variety of interference situations.

DESIGN CONCEPT

An auto-detect 2/4 channel amplifier can switch automatically from 4xSingle Ended (SE) to 2xBridge Tied Load (BTL) operation without changing wiring. During the start-up cycle of the amplifier (switching from 'off' to 'on') the presence of the rear speakers are measured. If one of the rear speakers is present, the amplifier is switched automatically to a 4xSE configuration with an output power of 6W per channel. A stereo BTL configuration is selected when **no** rear speakers are detected, allowing

output power of 21W per channel to be delivered to the front speakers (Supply voltage of 14.4V @ THD=10% and R_L=4 Ohm).

Problems associated with load detection in an automotive environment:

1. The speaker suffers from microphone effects. During door (hatch) slams the speakers generate large voltage swings which can disturb the load detection. To avoid incorrect load detection, a large voltage swing will be generated during the load detection.
2. Long wiring to rear speakers suffer from induced noises from other vehicle electrical sources while the engine is running.
3. At engine cranking the sudden supply voltage drop can disturb the load detection.

Extra design criteria are:

1. No plops allowed during load detection.
2. No additional external components

AMPLIFIER PRINCIPLE

Consider an amplifier with 'a common buffer', a 'front' amplifier and a 'rear' amplifier. The presence of a load between the common buffer and the rear amplifier is detected during the 'start-up sequence ' which determines the mode of operation.

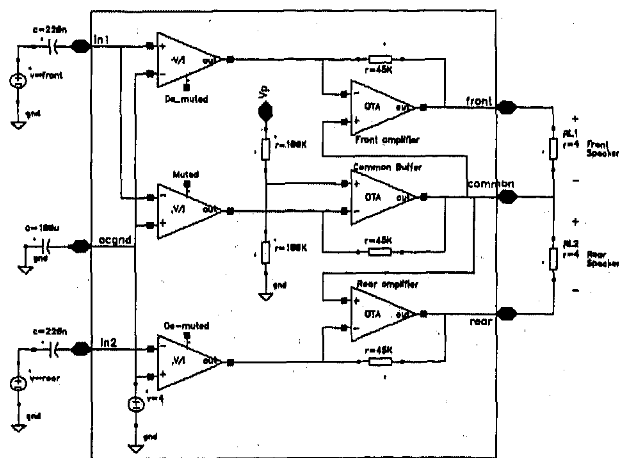

Figure 1 Amplifier in 2xSE configuration with common buffer

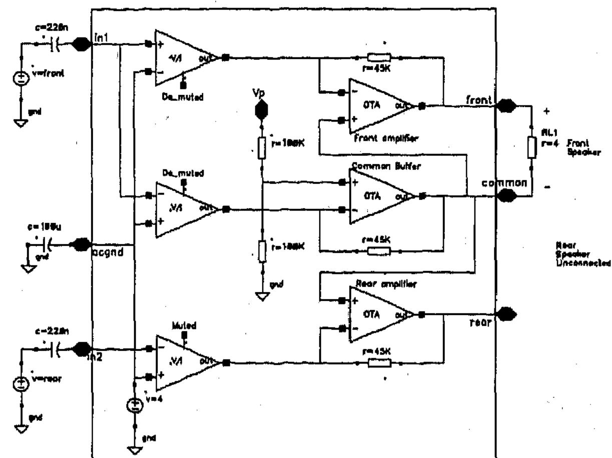

Figure 2 Amplifier in BTL configuration with common buffer output

The amplifier can be controlled in three states:

- Standby	amplifiers switched off (low standby current.
- Mute	common buffer dc biased
- On	input stages and front/rear amplifiers un-muted

In Figure 1, the SE application is given. The amplifier is switched to SE operation (after detection of the rear speaker) by muting the input signal of the common buffer. To avoid dc currents through the load the common buffer forces the output voltages of the 'front' amplifier and 'rear' amplifier at half supply voltage (Vp/2). The system is configured in such a way that the 'rear' amplifier compensates the voltage swing of the 'front' amplifier. When the 'front' and 'rear' input signals are equal and in phase, the output signals of both amplifiers have an 180^0 phase shift (which is compensated at the connector block of the radio). No current will flow into the common buffer and because of this configuration dissipation is minimized.

In the absence of a 'rear' load (Figure 2) the BTL mode is selected after the start-up sequence. During this mode of operation the 'rear' amplifier is disabled (high ohmic) and the common buffer is unmuted. Now the common buffer will complete the bridge of the BTL amplifier (the front amplifier now operates in BTL mode).

BASIC LOAD DETECTION

The load detection principle is explained in three steps:

1. Basic load detection principle by using Figure 3.
2. The load detection principle implemented in an BTL amplifier circuit (see Figure 4)
3. Reduction of external timing/integration components.

At first the 'common' buffer is switched 'on' and due to the fact that Va is rising gradually from 0V to Vp/2, the output (Vb -Figure 3) of this buffer will also rise gradually. The rear amplifier is disabled (high ohmic) during the start-up sequence in the conditions 'standby' and 'mute' and during load detection.
The output of the rear amplifier is forced low by the load detection circuit using the pnp transistor (Q1). When the output of the common buffer has reached the final output voltage level of Vp/2, the output of the rear amplifier is gradually released by the load detection circuit (Vd-Figure 3 increases from 0V to Vp) Due to the load (or an internal pre-load) the output of the 'rear' amplifier now gradually increases from 0V to the output level of the common buffer (Vp/2). From this point onwards, the base-emitter junction of the pnp transistor Q1 is forced reverse. When Vd reaches the voltage Vp, the load detection is finished. Thus a voltage swing of Vp/2 is generated which is applied over the 'rear' load (see Figure 3, voltage Vb-Vc in timing diagram).
During the load detection transistor Q1 will only conduct current when a load is present. This current is measured and integrated over time by the control-block. When the integrated value of this current exceeds a fixed level, a an output signal is generated which indicates a load is present. This output signal is stored in a memory cell which is used to put the amplifiers in SE or BTL mode. Now the amplifiers are enabled.

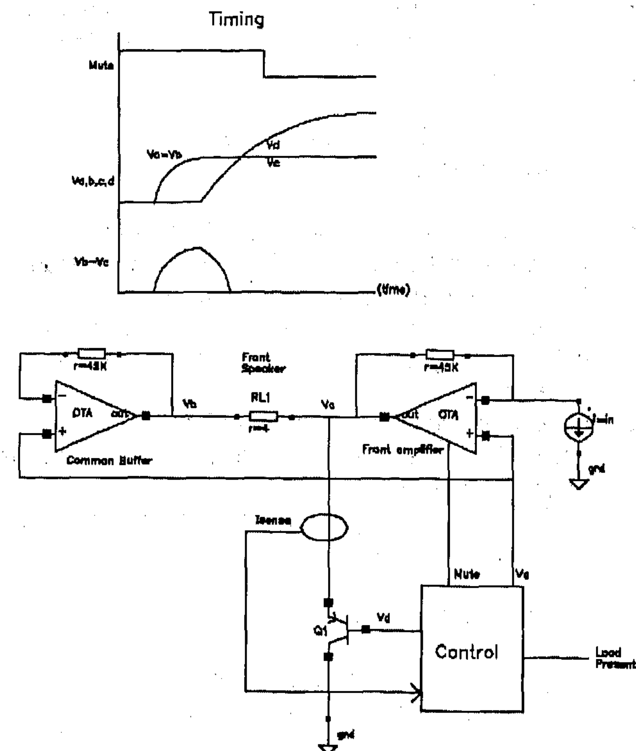

Figure 3 Simple load detection circuit

LOAD DETECTION IMPLEMENTATION

Implementation of the control block is given in the application circuit of Figure 4. The intelligent amplifier can be controlled by the mute/standby interface. When a voltage of :

$$V_{E2}+V_{E3} < V_{msb_on} < V_{E2}+V_{E3}+V_{E4}$$
$$V_{msb_on} = 4V \text{ (= mute level)}$$

is applied to the 'msb_on' pin of Figure 4, the voltage on capacitor C4 gradually starts to rise from 0V to V_{msb_on}. At the moment the voltage V_{C4} exceeds the value V_{E2}, comparator 1 will switch on the supply voltage of resistors R1 and R2. Now, because of the presence of C1, the voltage Va will rise slowly from 0V to Vp/2. The timing C4xR4 should be larger than C1xR1/2. The buffer which is connected as a voltage follower stage, will generate an output voltage equal to Va. The output of the 'rear' amplifier is disabled (high ohmic) by comparator 3 (Comp3) but will be forced low by means of Q3, Q4 and Vd (=0V).
Comparator 2 will switch when V_{C4} exceeds $V_{E2}+V_{E3}$. Now the voltage Vd (=V_{C3}) will rise from 0V to Vp, causing the voltage Vc to rise also. When a load is connected, a current will flow through both Q3 and Q4. Capacitor C2 is being charged when the current of Q4 exceeds the threshold level of I_{ref}. Capacitor C2 will integrate the load current during the load detection. When the voltage Vd exceeds the half supply voltage (Vp/2), the state of C2 (charged/uncharged) will be

stored into a memory cell. The contents of this memory cell indicates if a load is present. Furthermore, because a large voltage swing of Vp/2 is applied to the speaker, a large load current will flow, minimizing the potential of false measurements. Due to the large voltage and the period of integration, the interference generated by the microphone effects of the speakers will have little impact on the detection mechanism. To avoid 'pops', the signal applied to the speaker:

1. must be smooth with no sudden changes.
2. voltage change dV/dt must be small ->t_{detect}>0.4sec.

By applying 9V to the V_{msb_on} pin the voltage on capacitor C4 (V_{C4}) will rise again from it's previous value (4V) to the voltage applied on pin V_{msb_on} (9V). When the voltage V_{C4} exceeds V_{E2}+V_{E3}+V_{E4}, the output of comparator 3 (Comp3) will change state. Now the 'rear' amplifier is disabled.

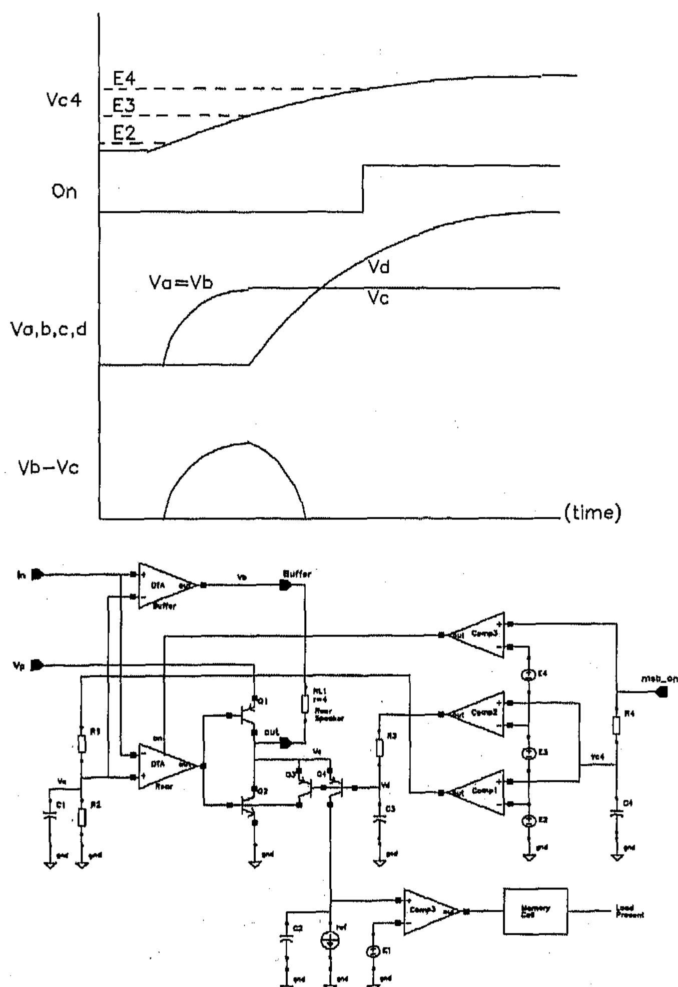

Figure 4 Load detection Implementation

NTERFERENCE FROM THE VEHICLE

Measurements were taken in a typical audio ıystem with a variety of speakers and locations to determine the contribution of various sources. Figure 5 shows that voltage induced by the microphone effect from a typical speaker during sudden cabin pressure changes caused by door slams. As can be seen, the large voltage swing and amount of induced energy onto the speaker terminals can not be ignored.

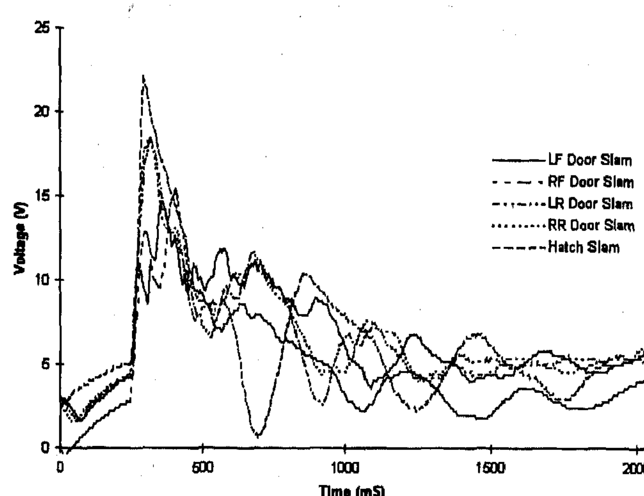

FIGURE 5 - Speaker Voltage from Door Slam

Figure 6 shows interaction of the detection signal with the door slam interference. The integration time for the detection circuit had to be long enough to prevent interference from the microphone effect of a door slam.

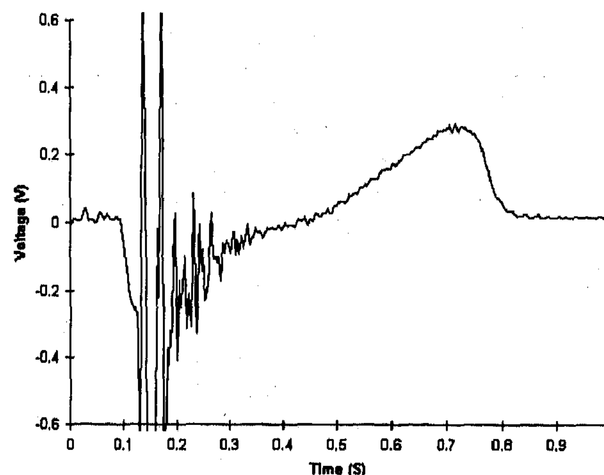

FIGURE 6 Differential Speaker Voltage of Door Slam Interference During Load Detection

REDUCTION IN TIMING COMPONENTS

As can be seen from Figure 4, many timing and integration components are needed. By combining circuits, the extra timing and integration components can be eliminated. In the intelligent amplifier, a signal-ground capacitor and a capacitor on the mute-standby pin are used as the timing capacitor and the integration capacitor. Because of this reuse, no extra components are needed.

The application circuit of the complete intelligent amplifier is given in Figure 7. and in Figure 8, the switch-'off' (=standby) and switch 'on' curves are given.

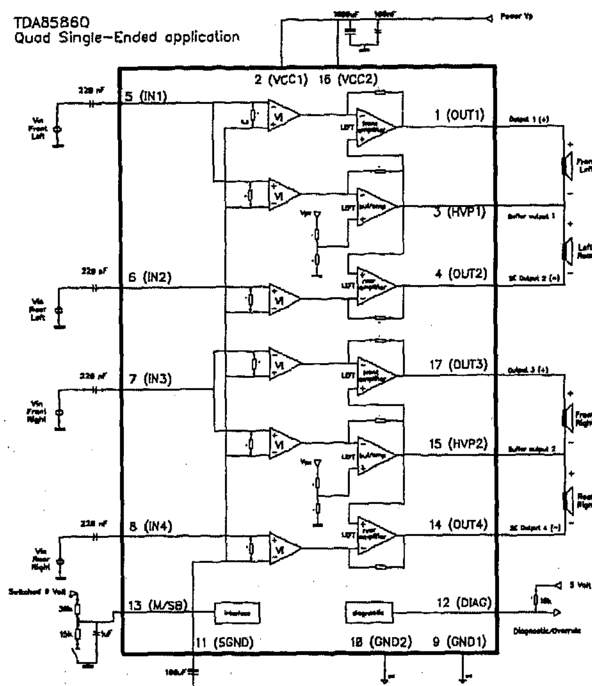

Figure 7 Application Intelligent Amplifier

For integration, the capacitor on the standby-mute-on pin (pin 13) is used. Timing is accomplished by charging the 'signal ground' capacitor on pin 11 (see Figure 7). When the amplifier is switched from 'standby' to 'mute', the 'signal ground' capacitor is being charged from 0V to 4V. During this charge action: the control signals and the voltages Va + Vd (see Figure 7) are generated. Now only one capacitor controls the complete switch on time of the amplifier. Integration is accomplished by the capacitor on the standby-mute-on pin of the IC. Normally this capacitor is needed to avoid switching pops during the transition from 'mute' to 'on'. When a load is present, an additional charge current will flow out of this control pin during the load detection, which will lift the voltage on this pin (see Figure 8 V_{msb_on} curve from time frame: 2sec<t<4sec). The extra charge in this capacitor is now being detected by the load detection control block, which will force the IC into 4 channel or 2 channel mode. In Figure 8, the curves are given when rear loads are connected (amplifier will switch to 4 channel mode).

Smooth voltage changes are generated during the load detection as can be seen from Figure 8. When 4 Ohm speakers are used, a maximum voltage of 4.5V is generated during the load detection sequence. Because of the slope, no pops are heard during the load detection. The diagnostics pin signals the result of the load detection process to allow the radio software to configure itself as needed, such as disabling the fader control. Also, there is the opportunity for the microcontroller to override the automatic amplifier configuration if there is a need.

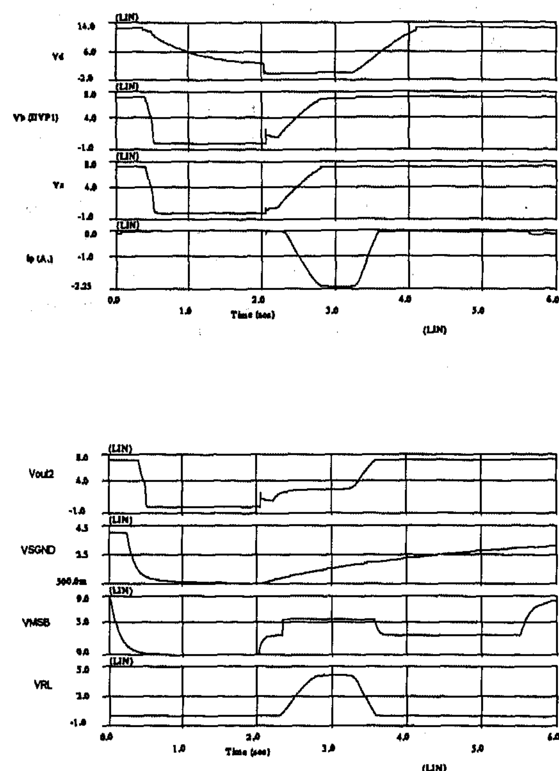

Figure 8 Wave-forms of intelligent amplifier

CONCLUSION

The intelligent amplifier offers a unique design solution to car radio manufacturers allowing a reduction in head unit complexity as well as offering flexible options to system designers.

The principle for load detection presented allows for the successful operation of the intelligent amplifier but also has other uses for future designs such as enhanced diagnostics of the system.

The detection method reuses existing components attached to the amplifier thus alleviating the need for any additional external components to the amplifier.

The principles presented in this paper have been tested in a real automotive environment and have proven to be robust. Now, a car radio can be designed which will determine its optimum configuration depending on the audio system. No changes in wiring will be needed allowing for standardized vehicle wiring.

The Evolution: From Car Audio to Digital Mobile Multimedia

Richard Zerod
Ford Motor Co.

ABSTRACT

New advances in wireless and digital communication technologies are causing the traditional car audio system to undergo a radical transformation. The historic function of providing high-quality music and sound reproduction to the consumer will continue; however, additional data and information services will soon be available to consumers using ancillary high-speed data channels available in the new Digital Audio Broadcasting (DAB) systems.

The European developed EUREKA/147 DAB system represents leading-edge technology and has already been introduced in several global markets. This proven system has demonstrated the capability for providing excellent quality music, along with significant data-casting capabilities. Potential benefits to the consumer include the ability to receive traffic management information, digital news and weather services, slow-speed video images, and even subscription services such as personal paging and messages. The traditional "audio" system will soon become an integral part of the wireless-link to the many information and data-services which are currently available.

INTRODUCTION

A HISTORICAL PERSPECTIVE - A historical perspective can often provide insight into trends for new technological developments. The evolution of sound and data-broadcasting has been based on a history of continuous innovations and developments over several decades. Some of the more significant events are shown in **Figure 1** [1].

Prior to 1980, the primary emphasis was placed exclusively on improving the sound quality of analog broadcast systems. The re-allocation of the FM broadcast band (i.e., to minimize interference during tropospheric propagation) and implementation of FM stereophonic broadcasting, represent example improvements.

During the 1980s, the initial consumer application of *data* broadcasting occurred. Initially deployed in Europe, the Radio Data System (RDS) was the first wide-spread application of data/information broadcasting that was targeted at the consumer market. With a total channel capacity of 1.2 kbps, the data throughput is relatively slow; however, the system has proven useful for conveying a traffic announcement signaling information flag via a 57 Khz subcarrier on existing FM analog broadcasts.

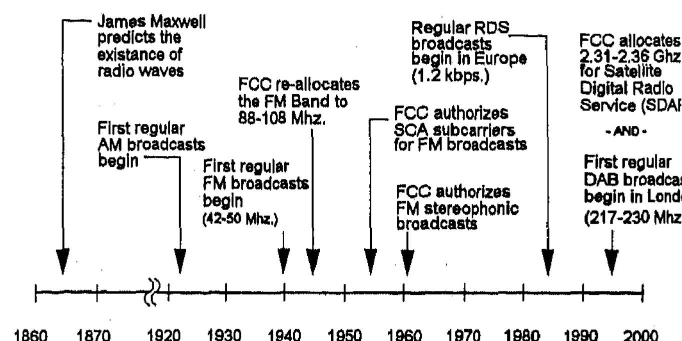

Figure 1 - A Historical Perspective

In the 1990s, initial deployment of *digital* broadcasting systems occurred. Once again, Europe is the global leader in the technology with the implementation of the EUREKA/147 DAB system. Since this system is designed specifically for the transmission of digital information, which includes digitized audio and additionally ancillary data, potential cross-talk and data-channel capacity issues – typically associated with transmitting data subcarriers on an analog FM broadcast system – are eliminated.

ENABLING TECHNOLOGIES - The synergy among several new technologies has provided the foundation for the development of the EUREKA/147 DAB system. Some of these include:

<u>Digital Coding and Bit-Rate Reduction Schemes</u> The bandwidth required for digital transmission is directly related to the serial data-rate of the source information. A clear advantage exists when audio (or video) compression techniques are utilized for eliminating perceptually unnecessary information from the source material.

The Motion Pictures Experts Group (MPEG), Layer II protocol is one of several popular audio bit-rate reduction schemes and is utilized in the EUREKA/147 DAB system. This compression technique can produce high-quality stereo audio at a data-rate of 256 kbps[1]; the resulting audio provides "no perceptible difference between an original sequence and its coded version."[2] The flexible EUREKA/147 standard also has provisions for the use of higher compression levels for applications where lower data-rates can be tolerated (e.g., talk material, etc.) and higher bandwidth reductions are desired.

The Joint Picture Experts Group (JPEG) protocol, which is widely used in Internet applications, is gaining popularity for the transmission of still-frame video images on the EUREKA/147 data channels. This lossy compression technique is well-suited for "real-life" images where some distortion of edges or boundaries can be tolerated. The variable compression technique utilized in the JPEG protocol provides the ability for the user to compress an image until a given quality-level is achieved; very useful images can be obtained using compression ratios of >10:1.

Forward Error-Correction Coding Systems - Signal fading or noise in a mobile environment can produce random or burst bit-errors which ultimately degrade the received signal quality. The addition of redundant data, used for Forward Error Correction (FEC) coding, is an essential element for successful wireless data transmission. (This is particularly important for one-way, high-speed data transmission to mobile receivers where the re-transmission of corrupted or missing data is not practical.)

A Bit-Error-Rate (BER) of 10^{-4}, after error-correction, is generally required for reproducing high-quality audio material; the requirement for video-image transmission is more stringent. To achieve a high-degree of consumer acceptance, these BER's must be attained over substantially all driving conditions and environments within the DAB service area.

The EUREKA/147 DAB system utilizes a concatenated error-correction scheme consisting of Reed-Solomon and Convolution encoding to protect against both random and burst error conditions. The amount of error-protection, which is correlated to signal reception robustness and service area coverage, can be chosen by the individual broadcaster according to their performance requirements. For audio signals, Unequal Error-Protection (UEP) is employed where the protection coding is applied non-uniformly through the audio frame to provide better protection to the more critical portions of the audio data. The UEP aids in producing a "graceful degradation" effect where the quality of the decoded audio signal slowly deteriorates as the receiver exits the DAB service coverage area.

Five different error-protection levels have been established to facilitate different operational requirements. The average code rate, R_{ave}, varies from 0.34 for very high protection, to 0.75 for applications where low protection levels can be tolerated (e.g. cable distribution).[3] For mobile broadcast applications, an R_{ave} of 0.5 is typically used.

Complex, Digital Modulation Systems - Traditional analog broadcasters have superimposed the audio source material onto an RF carrier using Amplitude Modulation (AM) or Frequency Modulation (FM) techniques. However, data-transmission systems typically utilize a combination of amplitude, phase, or frequency modulation techniques to transpose the serial data stream onto an RF carrier.

For a given modulation technique, the required RF spectral bandwidth is directly related to the serial data rate. The bandwidth efficiency, which is quantified in bits-per-second-per hertz (bits/sec/Hz), indicates the required transmission bandwidth as a function of the data rate. Through the utilization of complex, multi-level modulation schemes, bandwidth efficiencies of several bits/sec/Hz. can be readily achieved. Unfortunately, the improved bandwidth efficiency generally requires a higher signal-to-noise ratio (SNR) to maintain a good BER. Additionally, the demodulation circuitry becomes more complex, and generally, more expensive.

The EUREKA/147 system uses a form of Quadrature Phase-Shift-Keying (QPSK), where an RF carrier is shifted in increments of 90°. Four possible carrier phase states are possible, where each phase represents the logic-state of 2 successive bits (often referred to as a "symbol"). A common method for generating a QPSK signal is shown in **Figure 2**.

---

[1] Assuming each channel of a 16-bit CD source is originally sampled at 48.0 Khz, the resulting 256 kbps stereo audio is compressed by a factor of:

(2 x 16 bits x 48.0 Khz) / 256 kbps = 6.0 : 1

[2] Based on extensive testing by the ISO and ITU-R during the period between 1990-1993.

[3] The average code rate, R_{ave}, is defined as:

R_{ave} = [Audio data / (Audio data + FEC data)]

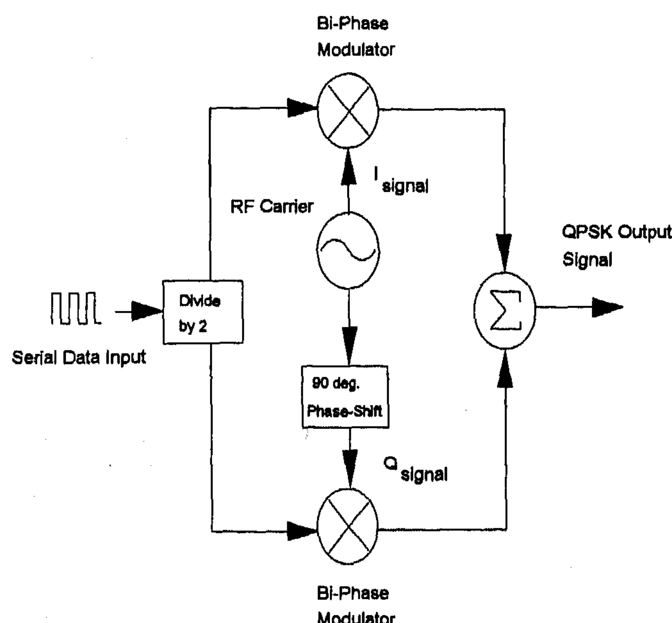

Figure 2 - QPSK Signal Generation System

The theoretical bandwidth efficiency of QPSK modulation is 2 bits/sec/Hz. However, low-pass filtering is utilized to roll-off the low-energy sideband components and minimize the occupied RF bandwidth. After filtering, an aggregate bandwidth efficiency of 1.5 bits/sec/Hz. has been achieved.

Sub-micron Levels of IC Integration - Practical implementation of the required digital demodulator and error-correction algorithms requires the use of integrated circuits employing high levels of integration. Complex gate structures, requiring several hundred-thousand gates, are required for sophisticated demodulation and decoding schemes. This requires the use of sub-micron integration levels to achieve the required functionality using only a relatively small number of IC's in the end product.

Through the use of technologies allowing IC geometries of <1 micron, high-density gate structures have been successfully developed for the EUREKA/147 DAB system. Due to the significant engineering development time required, the decoding systems are still relatively expensive and represent a major portion of the receiver cost. However, as with other new consumer technologies, increased competition and volume-levels are expected to drive costs down with time.

Direct Broadcast Satellite Systems - Direct broadcast satellite delivery can potentially provide a cost-effective, alternative solution for program delivery to large geographic areas where the development of a terrestrial broadcasting infrastructure is not economically feasible. Advances in power generation and storage systems, high-efficiency RF power amplifiers, and high-gain antenna systems have resulted in satellite broadcasting systems capable of delivering an aggregate effective radiated power between +50 dBw to +60 dBw.

However, the path-loss for a satellite in geo-synchronous orbit can approach -200 dB under line-of-sight conditions. Accounting for the relatively small receiving antennas (i.e., with relatively low-gain) that would be required for a practical automotive application, link-margins of <10 dB are to be expected. Certain geographic areas, such as the "urban canyons" encountered between tall buildings, would result in signal blockage that results in loss-of-signal. However, work is continuing on improvements in coding-gain, modulation techniques, and other parameters to further improve the system performance under marginal reception conditions.

DISCUSSION

BRIEF OVERVIEW OF THE EUREKA/147 DAB SYSTEM - The EUREKA/147 DAB system is designed to provide high-quality, multi-service digital radio broadcasting for reception by vehicular, portable, and fixed receivers. It is designed to operate at any frequency up to 3000 MHz for terrestrial, satellite, or hybrid (satellite and terrestrial) systems. The system uses advanced audio compression techniques to remove perceptually unnecessary information. FEC is provided utilizing Reed-Solomon and Convolution encoding. The transmitted signal is spread in the frequency and time-domains to provide a high-quality signal, even under frequency selective multipath fading conditions. A total channel capacity of 2.4 Mbits/sec allows for multiplexing several different audio programs, as well as high-speed ancillary data, into a 1.55 MHz wide RF channel. The conceptual block diagram of the DAB signal generation system is shown in **Figure 3** [2].

Each digitized audio channel is applied to an audio encoder that performs the MPEG, Layer II bit-rate reduction algorithm. The amount of compression is adjustable for each stereo channel to achieve a balance between the audio quality and channel capacity utilized. A channel encoder then adds the FEC data to the compressed audio serial data; R_{ave} is adjustable to achieve the desired signal robustness.

Time interleaving is performed to improve the ruggedness of the error-correction algorithms in a time-variant transmission channel. [4] The resulting signal is multiplexed into the Main Service Channel with other similarly processed signals.

The multiplexer output is subdivided into a large number of bit-streams, each having low individual bit-

[4] In the case of mobile reception where deep fading is encountered, burst-errors are likely to occur. During the de-interleaving portion of the decoding process, the burst-errors are spread out in time. The resulting bit-errors are more easily corrected by the FEC algorithms.

rates, which are used to phase modulate individual orthogonal RF carriers. By inserting a temporal guard band between successive symbols, which is larger than the delay spread expected from multipath interference, inter-symbol interference will not occur.

The multiplexer control information, which contains the configuration information of the individual service channels, is transmitted on the Fast Information Channel (FIC). Since this information must be rapidly

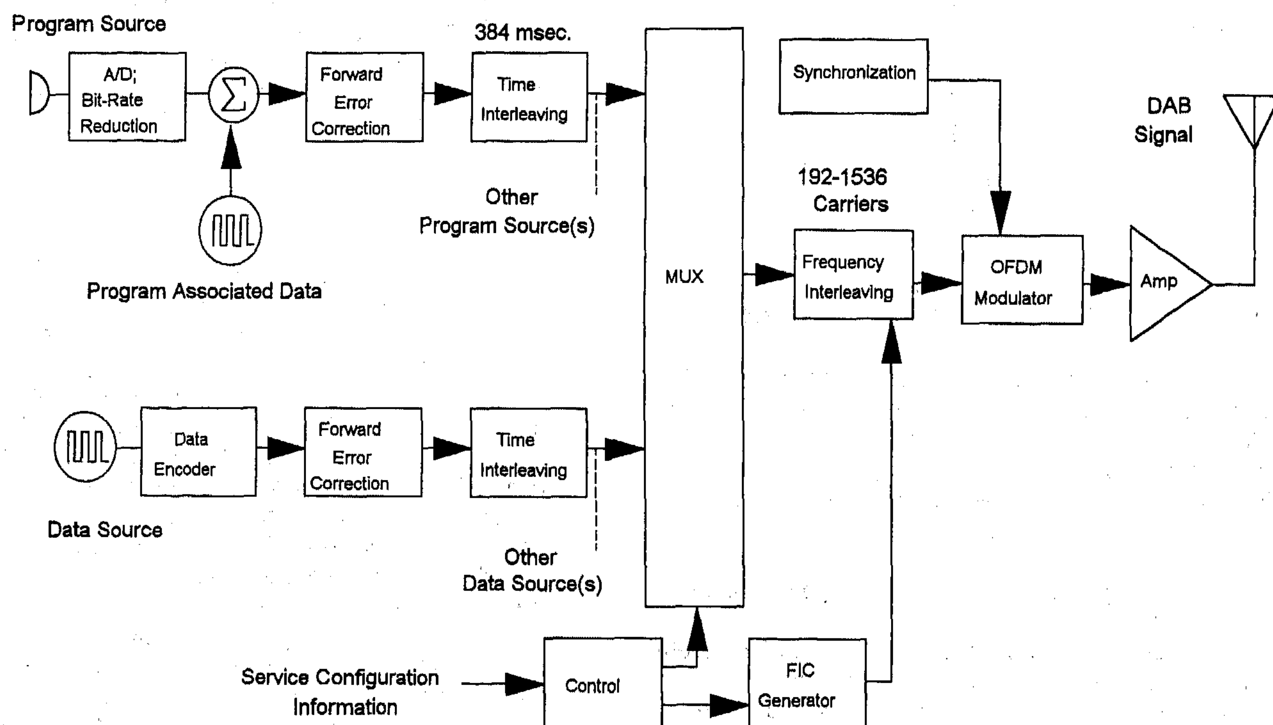

Figure 3 - EUREKA/147 DAB Signal Generation System

available at the receiver to facilitate the decoding process, it does not go through the time-interleaving process to avoid the associated time-delay. However, this data is highly-protected with a low R_{ave} and frequently repeated to assure the integrity.

The multi-carrier Coded Orthogonal Frequency Division Modulation (COFDM) system results in an output spectrum that is approximately rectangular and occupies a bandwidth of 1.55 MHz. A residual amplitude modulation artifact exists due the individual carrier amplitudes reaching their respective minima values at different times. The significance of low-noise receiving system designs, to minimize the BER during periods of low-instantaneous signal level, becomes apparent upon examining the wide-dynamic range of the COFDM signal. For reference, examples of both frequency and time-domain measurements of a EUREKA/147 DAB signal are shown in **Figure 4** and **Figure 5**, respectively.

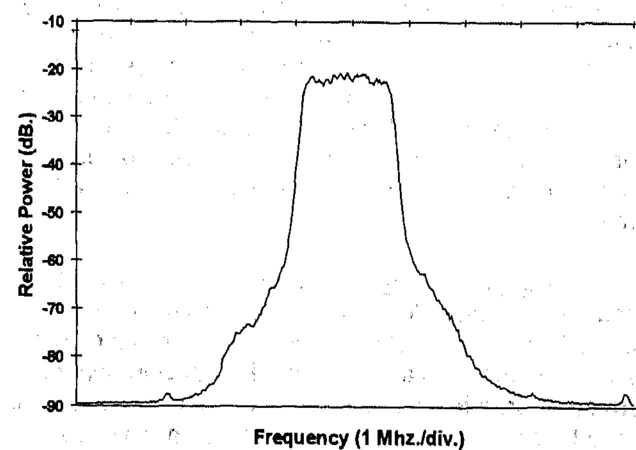

Figure 4 - EUREKA/147 Frequency Domain Signal

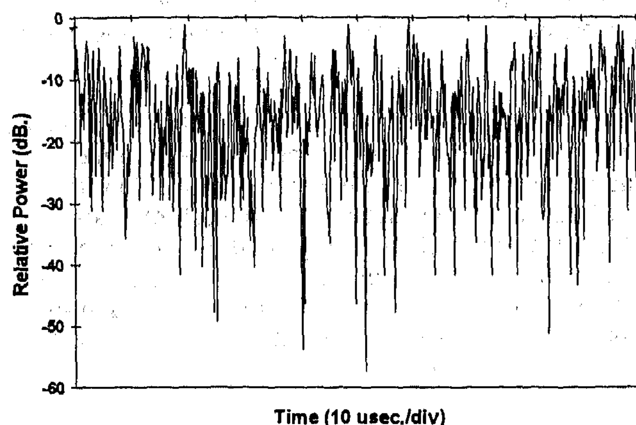

Figure 5 - EUREKA/147 Time Domain Signal

The EUREKA/147 system has a special feature which allows a broadcasting network to be extended by the use of multiple transmitters, each operating on the same frequency. The Single Frequency Network (SFN) feature permits the DAB service area coverage to be specifically tailored to suit the desired reception area contour. Through the use of an appropriate guard-interval, which is the difference between the transmitted symbol period and the symbol analysis time within the receiver, inter-symbol interference - resulting from the reception of multiple, time-delayed signals - is effectively mitigated.[5] Provided the maximum delay-spread of the different SFN signals do not exceed the guard-interval, the receiver can constructively integrate the signals into a coherent data stream [3]. This attribute also allows for the use of low-power gap-filler transmitters to supplement the service coverage in specific, localized areas of poor reception.

GLOBAL DEPLOYMENT STATUS - The EUREKA/147 DAB system has been adopted as the European Telecommunication Union Standard (ETS) 300 401, Radio Broadcast Systems; Digital Audio Broadcasting (DAB) to mobile, portable, and fixed receivers. Global implementation is leading in Europe and Canada where full-time DAB service is presently available, or shortly planned for, several major cities. Many other countries are conducting field-tests or have allocated the required frequencies necessary for the future support of EUREKA/147. The global deployment status is shown in **Figure 6**[6]; market expansion is expected to continue for the next several years.

The U.S. has not adopted EUREKA/147 as the domestic DAB standard. Efforts are presently underway to test and evaluate several different DAB systems for the U.S. market. Although the high-technical performance level achieved by the EUREKA/147 system is widely acknowledged, issues presently exist in the U.S. regarding the additional spectrum required for deployment of this system. The majority of effort is presently focused on developing an in-band DAB system that utilizes the existing FM broadcast band, and can co-exist with the present analog broadcast stations.

DATA-TRANSMISSION CAPACITY - Considerable interest exists within the broadcast industry regarding the potential benefits of *data-casting* and transmission of ancillary information to supplement the main audio program material. The flexible architecture of the EUREKA/147 DAB system contains several possible methods for multiplexing additional serial-data onto the composite transmission ensemble.

The Extended Program Associated Data (X-PAD) channel can be used for the transmission of information which is related to the audio material for the particular stereo channel. The ancillary data, which is time-multiplexed into the audio data frame, has a maximum capacity of 64 kbps. In addition to carrying information such as song title, artist, etc., initial development testing has shown the X-PAD channel could be useful for the transmission of still-frame video images (e.g., traffic and weather maps) and other types of data that could potentially be useful to the vehicle occupants.

Additional general-purpose data sub-channels are also available within the main service channel with a capacity of n* 8 kbits/sec. The information carried in this mode is not multiplexed with the audio frame data, and consequently, is not necessarily related to any specific audio program.

The high data-channel capacities available with the EUREKA/147 system provides a foundation for future, wide-area data-broadcasting applications. Initial applications are likely to include Intelligent Transportation System (ITS) functions, where the real-time transmission of large amounts of traffic-management data could be required.

CONCLUSIONS/FUTURE TRENDS

The function and role of the traditional audio system is expected to evolve into one of the principal transport mechanisms for the reception of data and information into the vehicle. Certain trends in the not-too-distant future can be reasonably extrapolated based on recent technological developments; some of these include:

- Europe and Canada will continue to lead in the global implementation of Digital Audio Broadcasting services. Multimedia applications will take advantage of

[5] In this sense, the EUREKA/147 system can be considered somewhat analogous to a "cellular-type" broadcast system. The service coverage can be extended by the use of a network of additional transmitters that provide additional reception coverage.

[6] For purposes of illustration, the EUREKA/147 deployment status is shown on a country-by-country basis. However, DAB service is not necessarily available in all the geographic areas within each country listed as "On Air".

the flexible, high-speed data channel capacity of the EUREKA/147 system; initial applications will be used as a supplement to the existing audio program material.

- "Data-casting" for vehicular applications will become increasing more significant. High-capacity data channels will be required for reliable, wide-area broadcast coverage of real-time information. Future applications will focus on information which is useful to the vehicle occupants; this is likely to include traffic management information, weather conditions, and customized subscription information services.

- Satellite DAB delivery, particularly in areas presently under-served by the terrestrial broadcast system, will likely gain in popularity. Earth-station receiving requirements will be minimized due to the relatively high satellite transmitting power.

- Significant hardware and software changes within the audio system will be required to take advantage of all the new features available with the EUREKA/147 DAB system. Initial system costs are expected to be relatively-high and the first applications will be on high-end vehicles. New opportunities exist in the design and manufacture of new antenna systems, tuners, digital decoders, displays, and the human-machine interface.

DynoCal - A Chassis Dynamometer Calibrator

Severino D'Angelo, Charles Brownell, and Curtis Brownell
Real Time Instruments

Garrett Torgerson
State of California Bureau of Automotive Repair

William G. Mears
Dynamotive Engineering

ABSTRACT

The DynoCal system for auditing chassis roll dynamometers has been developed for the California Bureau of Automotive Repair. It evaluates performance of new dynamometer designs and operational dynamometers in the field. The system includes a 50 kW electric motor with torque, thrust, and speed instrumentation. It functions as a vehicle to drive the chassis rolls under computer-controlled test modes. A trailer transports the system and houses the battery power supply, chargers, flux vector power converter, and computer. The controls are user-friendly, with graphic displays and high-speed data acquisition. Among other functions, this unique test instrument measures dynamometer road load and inertia simulation accuracy.

INTRODUCTION

DynoCal was developed to improve the State of California's new Inspection and Maintenance (I/M) program. This program requires many passenger cars and light trucks to be periodically tested on chassis dynamometers. The dynamometers for the program will come from several manufacturers. Each dynamometer design will undergo a procedure to verify that it meets the standards of the program. In addition, dynamometers being used in the field will be audited.

For verification that the dynamometers in the program comply with required operational accuracy and performance specifications, the California Bureau of Automotive Repair (BAR) contracted with Real Time Instruments to develop a dynamometer testing device.

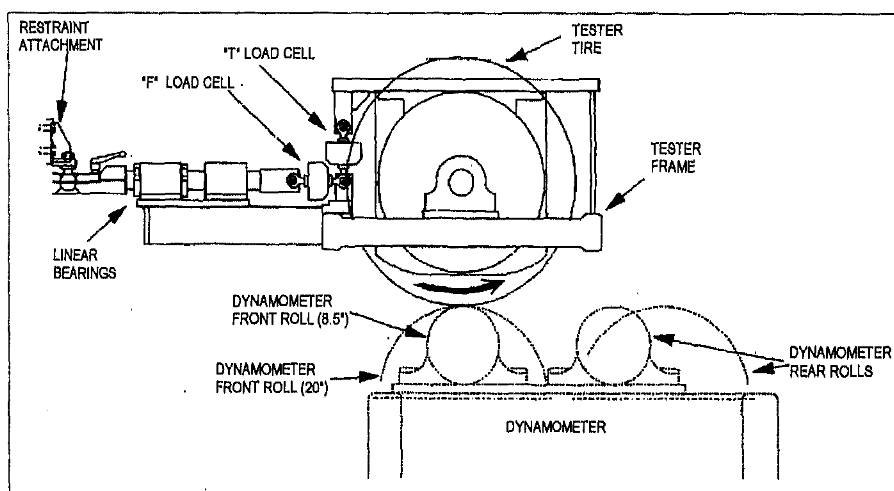
The resulting DynoCal system provides a number of features that make it a very capable and flexible dynamometer test instrument:

- Travels in a van-towed trailer.
- Exploits AC flux-vector drive technology.
- Operates on rechargeable batteries.
- Provides automated test functions.
- Uses Integrated data acquisition.
- Tests dynamometer road load and inertia simulation accuracy.
- Monitors dynamometer simulation error in real time.
- Gives color graphical displays.
- Generates comprehensive reports.

BACKGROUND

Whenever a chassis roll dynamometer is used for vehicle testing, its performance accuracy can influence test results. For valid and repeatable test results the dynamometer must be accurately calibrated and stable, so it provides the loading conditions specified for the test being conducted.

Chassis dynamometer calibration and performance specifications normally include measurement of the roll surface speed and tractive



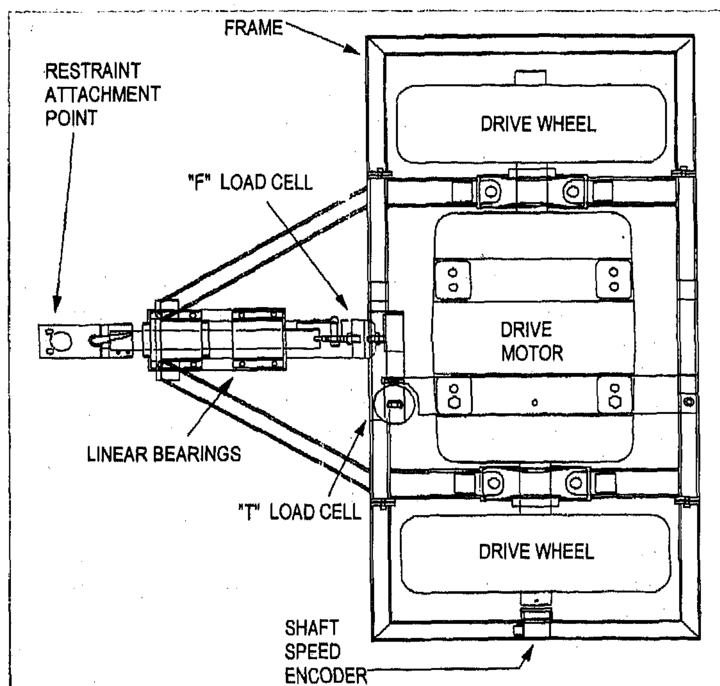


Figure 1. Side View in "F"-Mode

Fiaure 2. Toρ View Of Tester

force. Inertia simulation accuracy and response time of the load control system are also included in some dynamometer performance specifications.

Each dynamometer manufacturer interprets specifications and provides instrumentation and controls, with calibration instructions intended to demonstrate compliance with the specifications. This can result in a wide variation in methods and results, with possibly wide variation in outcome of the vehicle tests ultimately done on the dynamometers. For example, some dynamometers do not have the self-diagnostic capability needed to evaluate inertia simulation accuracy, leaving the user with the task of verifying accuracy.

Dynamometers which appear to be calibrated satisfactorily may not perform accurately when actually being driven by a vehicle. Attempts have been made to evaluate dynamometer performance using vehicles with torque wheels. Difficulties in calibration, control, and data interpretation have limited use of this approach.

To simplify the task of evaluating the many dynamometer designs being proposed and used for California consumer vehicle emission programs, the California Bureau of Automotive Repair (BAR) developed the concept of a system to test dynamometer calibration and performance by accurately measuring roll speed and tractive force independently of the dynamometer instrumentation. In this way, the tester would provide a transfer standard which could be used to compare dynamometer calibration and performance directly against specifications. This was opportune for Real Time Instruments, which has advocated standardized chassis dynamometer performance tests, [1[ ]2] and had, independently of the BAR concept, considered approaches to building a dynamometer calibration machine.

What is required to evaluate dynamometer performance independently of the instrumentation provided on the dynamometer? To answer this question, a brief description of how a dynamometer works will lead to the general approach applicable to all chassis dynamometers.

In the most general terms, a dynamometer is a device that measures mechanical power or that applies a controlled load to a mechanical power source. In the case of a chassis dynamometer, the vehicle's driving tires are the power source. The dynamometer is loading the vehicle correctly if the tangential force between the dynamometer roll surface and the vehicle's driving tires is exactly the correct value for the vehicle speed, acceleration rate, and dynamometer settings representing the vehicle inertia and road load friction. However, this tractive force cannot be measured directly when a vehicle is being driven. And when there is no vehicle on the roll, there is no tractive force at the roll surface. A "vehicle" capable of measuring tractive force and roll speed continuously and accurately under repeatable driving cycles could measure how well the dynamometer functions. By doing this the same way on all dynamometers, the tester could provide direct comparisons of dynamometer performance. DynoCal does this.

DESIGN OBJECTIVES

The design requirements from BAR can be summarized as follows:

- Capability to determine dynamometer:
  Speed and torque measuring accuracy.
  Load and inertia simulation accuracy during transient mode testing.
- Recording acquired speed, torque, and related data.
- Comprised of no more than two modules

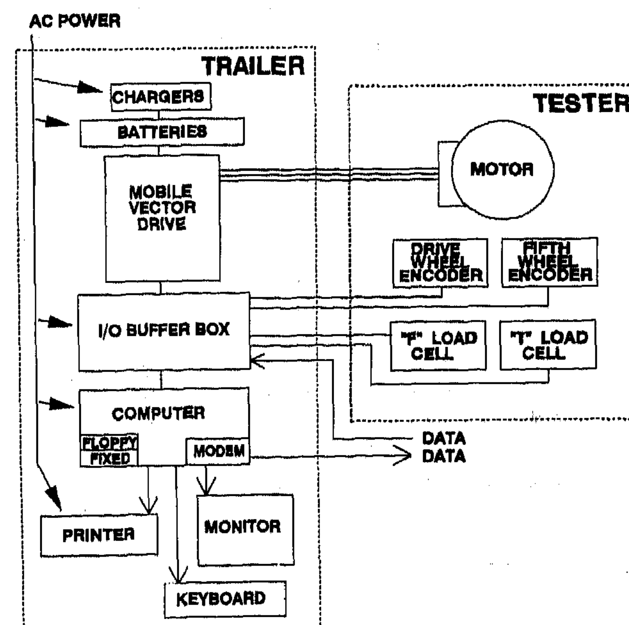

Figure 3. Schematic

- Transportable by minivan or equivalent vehicle.
- Speed and load determined independently from dynamometer sensors.
- Self-contained, with 25 hp available independent of external power, and 50 hp when connected to building power.
- Able to accommodate bi-directional dynamometers, in-ground to 24" above ground.
- Able to run ASM, BAR31, IM240 and LA92-S cycles on dynamometers simulating from 1500 to 6000 lb inertia up to 70 mph
- Instrumentation accuracy at limits of best dynamometer practice, traceable to NIST:
  - Load ±0.1% of full scale, 0.1 lb resolution
  - Speed, ±0.5% to 5 mph, then ±0.025 mph to 70 mph, 0.025 mph resolution
- Response time of torque response to step change command: 90% within 50 ms, 98% within 150 ms.
- Data acquisition:
  - Eight channels, analog (to 25 volts) or digital.
  - Selectable, high-speed sampling frequency.
- Computer, and software:
  - IBM-compatible, Pentium™ CPU
  - Minimum 16 Mb RAM
  - 1 Gb hard drive.
- Control of driving cycles, test sequences, data acquisition, data reduction, report generation, display and printing, data storage and transfer.

These were performance specifications, allowing the supplier maximum flexibility in designing the system. To develop a system to meet the BAR specifications, Real Time Instruments formed a team with expertise in dynamometer control, user application, equipment design, and fabrication, which had successfully completed earlier dynamometer projects.

DESCRIPTION

OVERVIEW. – Figure 1 shows a side view, and Figure 2 a top view of DynoCal, the device that is placed on the roll or rolls of a chassis dynamometer. The dynamometer is set up to simulate a given road load and inertia or other load such as ASM horsepower. DynoCal then "drives" the dynamometer rolls much like a vehicle. While DynoCal is driving the rolls, however, it measures the force being transmitted to the rolls, and the speed at which this force is being transmitted. Using this procedure, the DynoCal computer is able to determine how accurately the dynamometer is simulating the preset loads and inertia.

In addition to the basic driving test just described, DynoCal is capable of a variety of other procedures for determining the dynamometer calibration accuracy and performance.

The overall DynoCal system is illustrated in the form of a block diagram in Figure 3. The block labeled "TESTER" includes the components that are positioned on the dynamometer, such as the AC motor, wheels, force transducers, speed sensors, bearings, and frame. The block labeled "TRAILER" includes the batteries, charging system, computer, signal conditioners, data acquisition system, safety controls, operator station, power switches, and mobile vector drive. The entire system is housed inside the trailer for transport from site to site.

MAJOR COMPONENTS – Refer to Figures 1 and 2. The figures illustrate the locations of the motor and other major components. The tester is essentially a single-axle electric vehicle. The axle is the motor shaft, with a tire at each end carrying the weight of the tester. Bearings on the shaft support the tester frame.

The tester is transported inside a trailer, as shown in Figure 4. The trailer also houses all the other items required to operate the tester. When the tester is operated on a dynamometer, it can be attached either to a restraint mounted in the trailer, or to a floor-mounted fixture. Both restraint positions provide horizontal and vertical adjustment for DynoCal. These adjustments enable DynoCal to be positioned

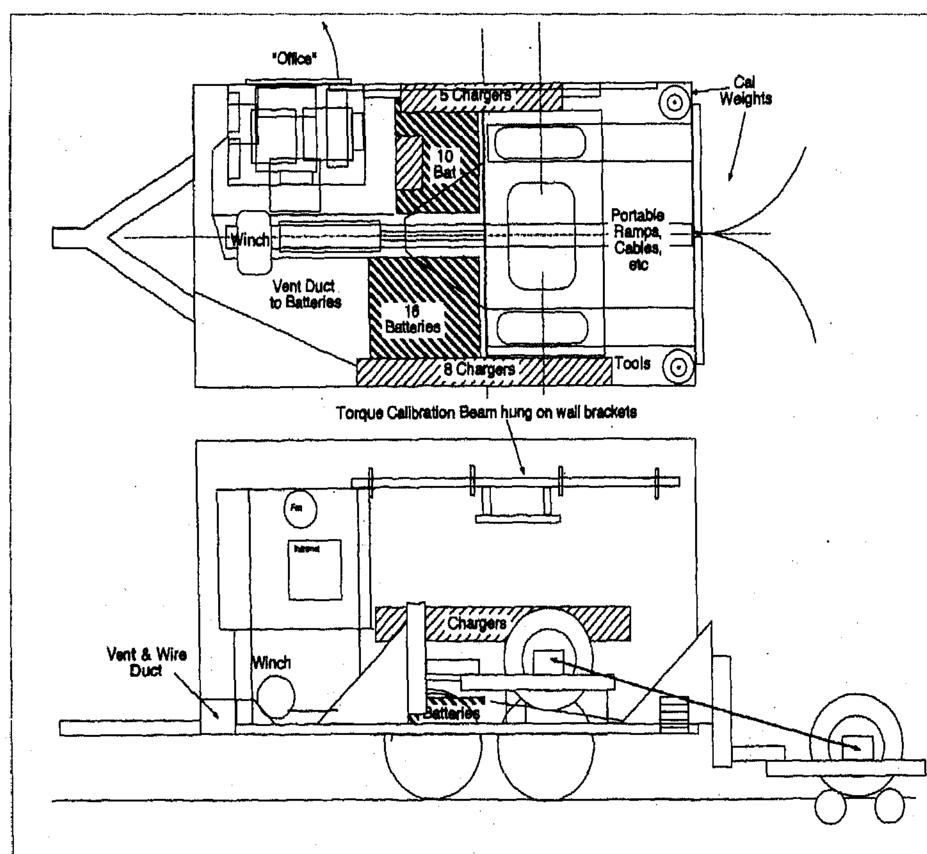

Figure 4. Layout

cradled between twin rolls, or on top of any given rolls. The two positions are needed to perform the tests described below.

LOAD MEASUREMENT – The tester employs two load cells (see Figure 5). One, termed the "Torque" load cell or "T" load cell, measures the force generated as a direct reaction to the torque produced by the AC motor. The other, called the "Force" or "F" load cell, measures the horizontal force generated in reaction to the wheels applying tractive force tangential to the dynamometer roll.

The tester can be used in either "T-mode" or "F-mode". In "T-mode", the measurement of tractive force is derived from the "T" load cell. In this mode, the tester driving wheels can be operated either in a cradled position between two dynamometer rolls as shown in Figure 5, or on top of the roll as shown in Figure 1. For the "F-mode", the tester driving wheels must be positioned exactly on top of the dynamometer roll. For twin-roll dynamometers this is normally the front roll because this is the roll that absorbs most of the thrust force from a test vehicle.

When the DynoCal wheels are cradled between front and rear rolls as a vehicle's driving wheels are, the force measured by the "F" load cell is no longer correct vehicle thrust. It also includes various force components produced by the cradling of the tires. In the cradled position, a hard acceleration tends to cause the wheel to climb the front roll, and a deceleration tends to cause it to climb the rear roll. Both of these actions result in errors in measuring true tractive force by the "F" load cell. The "T" load cell measures motor torque the same for both modes, but tire losses will be different when cradled and when running on top of one roll.

In "F-mode", if the tester wheels are not exactly on top of the roll, the curvature of the roll generates a horizontal force component from the tester's own weight. This is an artificial horizontal force not resulting directly from the thrust of the tester on the rolls, and leads to measurement error by the "F" load cell. During "F-mode" setup the wheel position is set accurately with alignment instruments, and maintained in this position by the rigid floor-mounted restraint. "F" load cell measurements are compensated for force shifts resulting from the slight deflection of the restraint produced by tractive force. Deflection vs. tractive force was calibrated by measuring movement of the DynoCal frame as the tester was operated on a dynamometer at a range of force levels. The correction is calculated for each operational force data point by multiplying the force measured by the deflection calculated for this force, and dividing by the sum of the tire and roll radius. To verify this correction, the tester was moved across the top of the roll and the change in apparent tractive force compared to measured off-center movement.

SPEED MEASUREMENT – The tester also has two speed-sensing encoders. The encoders are optical, digital devices. They are immune to drift and do not require calibration. One is mounted to the motor shaft and measures the rotational speed of the tester motor. The other is mounted to a "fifth wheel" which has a thin rubber "tire" running on the surface of the dynamometer roll. The first encoder (the "shaft speed encoder") is required by the flux vector drive to control the motor. The second encoder (the "fifth wheel encoder") is calibrated to measure the true speed of the dynamometer roll surface, which is required for accurate dynamometer performance measurement.

ELECTRICAL DESCRIPTION – DynoCal drives on a dynamometer as an electrical vehicle would. Much of the time, the tester expends energy and the dynamometer absorbs it. The energy expended by DynoCal comes from 26 12-Volt lead-acid gel-cell batteries wired in series to provide a nominal voltage of 312 VDC. Between the batteries and the AC motor that drives DynoCal is an AC flux vector power converter. This power converter is called a "Mobile Vector Drive"

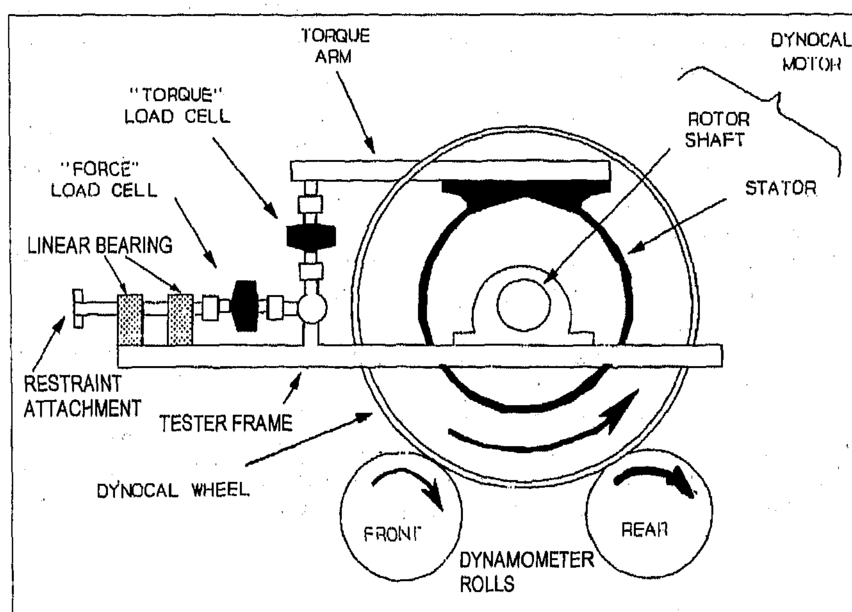

Figure 5. Load Measurement

(MVD), originally designed for electric vehicle use. It generates the appropriate 3-phase voltage and frequency to produce the motor torque required to control DynoCal operation.

The power converter in many electric vehicles can charge the batteries by absorbing power from the dynamometer during deceleration. DynoCal uses the MVD in the same way. Most of the time, however, DynoCal draws energy from the batteries, and a charging system is required to replenish battery energy.

Sealed gel-cell lead-acid batteries were selected for two primary reasons: safety, and their ability to accept a rapid charge. Some of the notable features of the batteries are:

Figure 6. Load Cell Calibration

- High volumetric and gravimetric power densities at high rates of discharge (provides more power in less space).
- Thin plates (provides high-rate discharge capability).
- Low internal resistance (better terminal voltage characteristics under high-rate discharges).
- Excellent high-rate recharge capability (>90% recharge in one hour when enough charging power is available).
- Negligible gassing.
- Maintenance-free.
- Non-spillable (can be mounted in any orientation; can be transported by air or ground without restriction).
- Excellent storage capabilities (long shelf life).
- Wide operating temperature range.

The batteries can be recharged either by the battery chargers provided or by motoring the dynamometer with DynoCal on the rolls and using the DynoCal AC motor as a generator. Each pair of batteries is charged by a separate 24 VDC charger designed for gel cell batteries.

CONTROLS – The MVD is controlled in torque mode via a ± 10 Volt analog signal generated by the computer and fed through the I/O Buffer Box. This box houses a multifunction printed circuit board and has several push-buttons and LED's on its front panel. It also receives outputs from the load cells and encoders and converts them to a format that is usable by the computer. In addition, the I/O Buffer Box provides *START*, *STOP*, and *QUICK STOP* buttons.

The computer includes a keyboard and 14" SVGA monitor to provide interfaces for the operator. It also has a 1 Gb hard drive for storing operational and data files, a modem for sending out data and reports by telephone line, and a printer for generating reports locally. The computer is IBM-compatible with an Intel Pentium™ microprocessor, 16 Mb of RAM, and a 3 1/5" floppy drive.

It is the software in the control computer that permits DynoCal to perform its many automated functions. These include calibrations, parameter setting, data logging, dynamometer checks, drive trace storage, report generation, and other functions.

FUNCTIONAL DESCRIPTION

DynoCal acts as a substitute for a vehicle on a chassis dynamometer. Instead of a human driver watching a driver's aid and controlling vehicle speed (and in turn, roll speed) with the throttle, DynoCal controls its own wheel speed (and in turn, roll speed) directly via its AC motor. DynoCal follows a drive trace that is loaded onto the hard drive in the form of an ASCII file. It can be created and modified by the user, providing flexibility in the testing program. If desired, the drive trace can be constructed to cause DynoCal to mimic a human driver (by imitating the anticipation abilities and the response time of an actual driver). But unlike a vehicle, DynoCal accurately measures and records the thrust force it applies to the dynamometer and the speed at which the force is applied. Based on this information, DynoCal is able to determine how accurately the dynamometer is simulating road load and inertia.

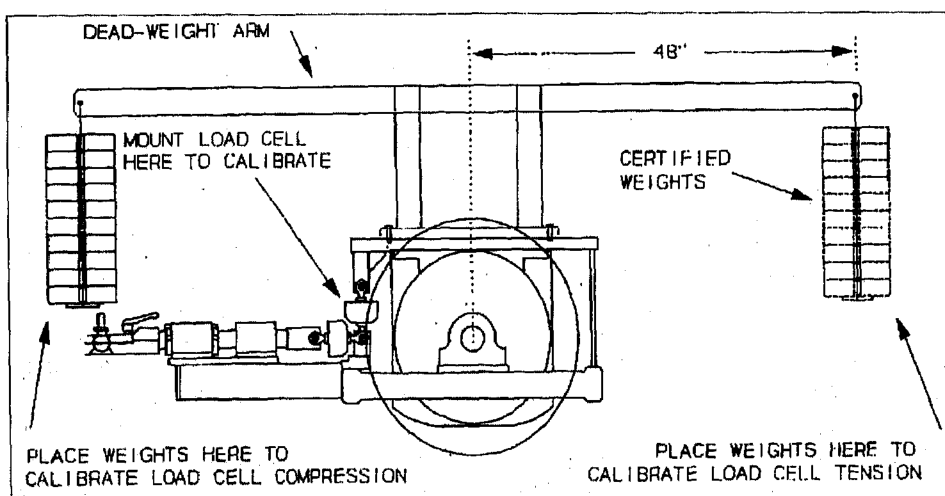

Figure 7. Load Calibration Method

In "T-mode", the tractive force being applied by DynoCal to the dynamometer is calculated by subtracting DynoCal parasitic losses, inertia acceleration losses, and tire losses from the force measured by the "T" load cell. In "F-mode", the tractive force is obtained from the "F" load cell with compensation for roll surface curvature effects.

The following is a summary of the principal DynoCal functions accessible through the computer. The first six functions form the foundation for DynoCal data measurement accuracy.

- TIMEBASE ACCURACY
- LOAD CELL CALIBRATION
- SPEED ACCURACY AND CALIBRATION
- INERTIA MEASUREMENT
- MEASURE TIRE LOSSES
- RESPONSE TIME RECORD
- DRIVING CYCLE

Dynamometer calibration and performance are also measured using all but the TIMEBASE ACCURACY and LOAD CELL CALIBRATION functions.

TIMEBASE ACCURACY – The basic 10 ms control cycle time is measured for 0.05% accuracy either by stopwatch over an extended time interval or by an NIST-traceable frequency counter

LOAD CELL CALIBRATION – The "T" and the "F" load cells are both calibrated by dead-weighting. A screen is dedicated to facilitating the calibrations. Both load cells and their signal conditioners are calibrated in the "T" load cell location to 0.1% accuracy using a balanced 8 ft (4 ft on each side) checking arm and NIST traceable weights covering the full range of operation. Figure 6 is a typical torque calibration screen and Figure 7 illustrates the torque calibration method.

SPEED ACCURACY AND CALIBRATION – DynoCal also has two speed measuring devices, one for measuring dynamometer roll speed (the "fifth wheel") and one for measuring DynoCal drive wheel speed. A screen, Figure 8, is assigned for making these calibrations. and provides for manual input of the dynamometer indicated speed for accuracy determination. The fifth wheel is calibrated by using DynoCal to motor a dynamometer at constant speed with no dynamometer load. Before starting the calibration, the dynamometer diameter is measured with a "Pi" tape accurate to 0.001", and traceable to NIST. Then, as the dynamometer roll is motored at constant speed, the roll rpm is measured with a stroboscope with 0.01% timing accuracy. The fifth wheel calibration is set from the measured rpm and roll diameter. Then the driving wheel speed is calibrated to be equal to the fifth wheel speed by adjusting the effective drive wheel radius.

Figure 8. Speed Calibration

INERTIA MEASUREMENT – DynoCal is able to determine its own mechanical inertia, the mechanical inertia of the dynamometer, and how much inertia the dynamometer is actually simulating. Figure 9 gives a typical inertia measurement screen. To calibrate the DynoCal base mechanical inertia, DynoCal is lifted off the rolls and then accelerated and decelerated over a range of measured constant torque with simultaneous speed-time and acceleration measurements. The base inertia is determined for each accel/decel pair. The average base inertia and standard deviation are computed. A standard deviation less than 4 lb is required for the DynoCal calibration. Dynamometer inertia is measured in the same way, but with wheels on the rolls and speed input from the fifth wheel.

MEASURE TIRE LOSSES – Whenever DynoCal is used on a dynamometer in "T-mode", its tire losses

Figure 9. Inertia Calibration

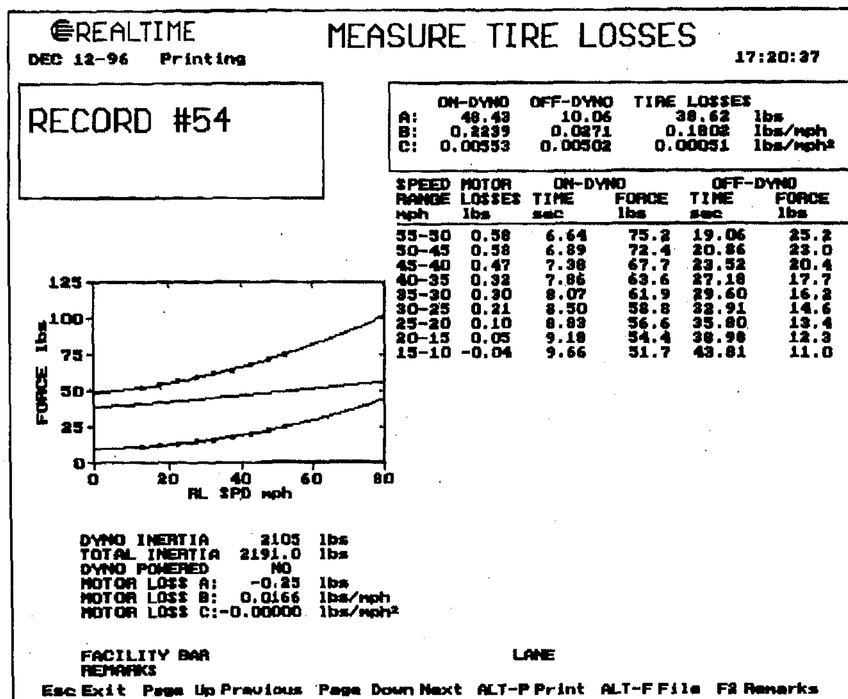

Figure 10. Tire Losses

are used in the calculations. To ensure that the values used in the calculations are correct, a function is provided to measure tire losses. Figure 10 is a typical tire loss screen. After warming up the tires and the dynamometer, a coastdown is run with the dynamometer de-energized and Dynocal on the rolls, also de-energized during the coastdown. Then the dynamometer is run through the same de-energized coastdown, but with DynoCal lifted off the rolls. The fifth wheel is used for dynamometer coastdown speed measurement in both cases. The DynoCal "T" load cell is also recorded during the wheel-on coastdown to derive the parasitic losses of the motor bearings. As shown on the MEASURE TIRE LOSSES screen, tire losses are calculated by subtracting the wheels-off coastdown and motor bearing parasitic loss coefficients from the wheels-on coastdown coefficients. The OFF-DYNO coefficients describe the dynamometer parasitic friction.

RESPONSE TIME RECORD – DynoCal uses its fifth wheel to measure the rate of acceleration or deceleration following a rapid change in DynoCal load, which is also measured. Figures 11 shows a typical screen of response time. The control drives DynoCal at a constant load and instantaneously commands a constant acceleration or deceleration load. On the RESPONSE TIME screen, acceleration, load, and time are displayed for a 4-second interval beginning just before the load change. The display can then be inspected to determine the amount of delay in dynamometer response.

DYNO LOADING ACCURACY – DynoCal measures the tractive force it is applying to the rolls while the dynamometer is simulating road load at steady speed. Inertia sumulation is not measured in this test. Figure 12 shows a typical road load accuracy test screen.

SIMULATION ERROR – During a driving cycle, Figure 13, DynoCal compares the actual thrust that it applies to the rolls to the thrust that should have been applied based on the road load and inertia settings entered into the dynamometer control. From this, simulation error is calculated according to the methods described in Reference 2.

DATA LOGGING CONFIGURATION – The computer logs up to eight channels of data on its hard drive while carrying out its standard test functions. These data are used by the computer to generate its reports. The data are also available for export to a spreadsheet or statistics package for analysis.

PRINTING REPORTS – The results of the various tests are collected in the form of reports which may be printed out.

TRANSMITTING FILES VIA MODEM – The computer includes a modem card that permits data files and report files to be sent over the phone lines.

TEST RESULTS

Testing on new and in-service dynamometers has validated the need and value of DynoCal.

Much of the initial testing has been part of evaluating the DynoCal software and control functions, and learning how to interpret test results. The ability to measure tire losses has been used to investigate tire warmup and develop the relationship between loss characteristics and tread temperature during warmup. This was done to provide a method of correcting for tire losses when DynoCal is used to evaluate a dynamometer which has been cold-soaked, and must be tested as soon as the insulated enclosure is removed. The MEASURE TIRE LOSSES function, Figure 10, was used for this study, and the resulting loss coefficients analyzed in a spreadsheet. The tread temperature for each loss determination was measured with an infrared pyrometer. Figure 14 shows the tire losses over the operating speed range for each measured temperature, and Figure 15 shows the losses expressed for the 15 and 25 mph speeds used for the two ASM cycles. The smooth plots, Poly. (25) and (15) in Figure 15, are from the equation, for comparison with the plots from the data curves on Figure 14. These results offer promise of giving excellent tire loss correction for accurate testing in the "T"-mode during dynamometer warm up.

Some other results from this early testing are summarized. DYNO LOADING ACCURACY has already found a number of dynamometer control errors. Figure 12 shows how the dynamometer overloads 34 lb when in the test mode. This error was not evident during calibration, and was traced to incorrect dynamometer parasitic friction compensation. The SPEED ACCURACY AND CALIBRATION screen, Figure 8, indicates a type of operational speed error observed. INERTIA MEASUREMENT, Figure 9, has been found to be a

quick and repeatable method for accurately determining true mechanical inertia of the assembled dynamometer. RESPONSE TIME, Figure 11, reveals the actual response of the dynamometer load control to a change in vehicle acceleration rate. This figure shows how the dynamometer load takes about 0.1 second to begin adjusting to the roll acceleration, and then takes about 0.9 seconds to reach required load.

Inertia simulation has been found to require very accurate tire loss compensation when running in the "T"-mode. In the "F"-mode, the load zero has a major influence on correlation with the "T"-mode. Obtaining a valid zero has been difficult, and may be influenced by the tendency of DynoCal to shift sideways slightly on rolls which are threaded for increased traction.

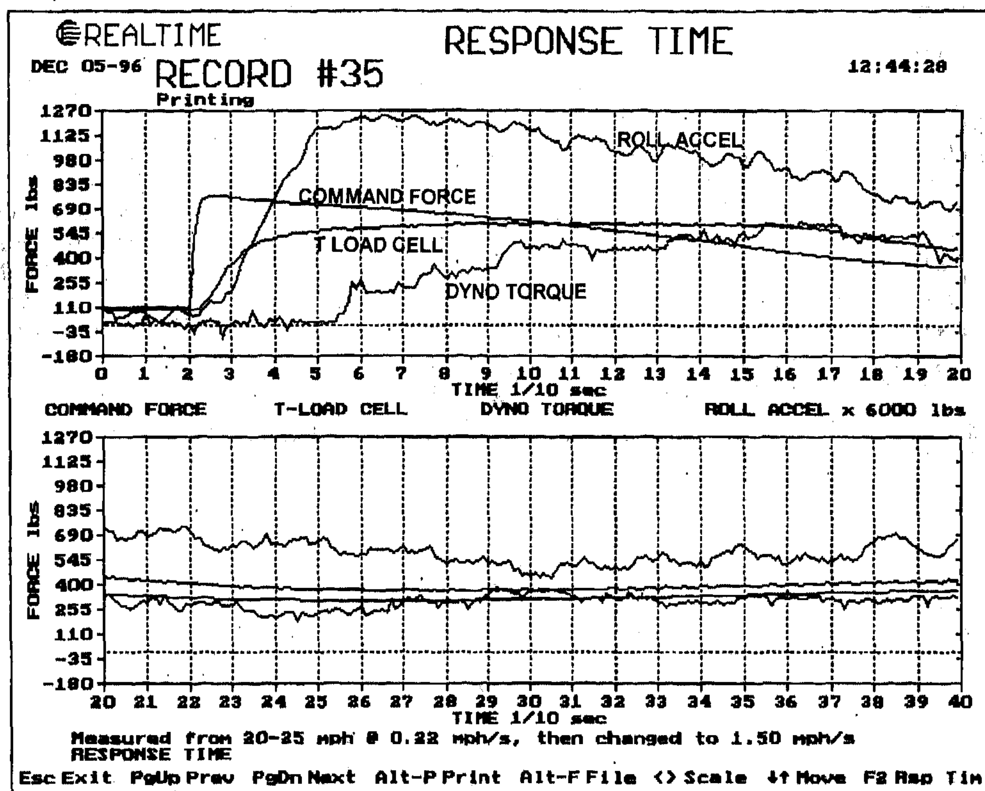

Figure 11. Dynamic Response

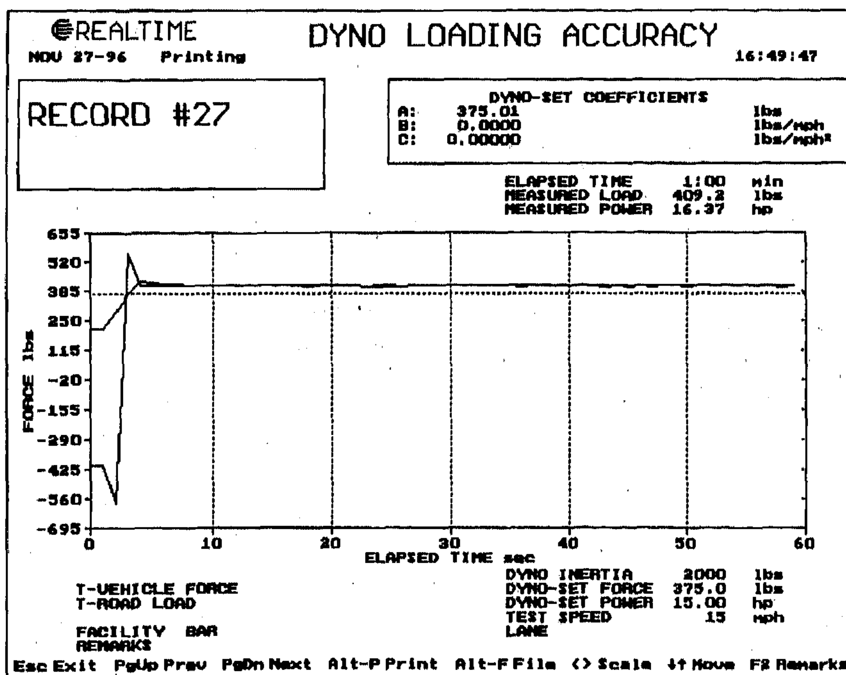

Figure 12. Road Load Accuracy

DynoCal has already shown benefits in detecting the following problems and performance characteristics in dynamometers evaluated by BAR:

- Discovery of incorrect load calibration.
- Discovery of speed-load measurement interference.
- Load command errors.
- Significant differences in inertia simulation response time.
- Non-linear speed measurement.
- Slow settling time for constant load control.
- Display of actual operation of augmented braking.

In addition, testing experience has resulted in modification to the automated test functions to accommodate inertia simulation measurement on dynamometers while augmented braking occurs on deceleration, and where eddy-current absorbers simulate inertia only during acceleration.

CONCLUSIONS

DynoCal is an innovative dynamometer testing instrument. It has speed and load measurment accuracy not previously available. The powerful, fast-responding, computer-controlled motor provides measurement of dynamometer response time, inertia simulation, road load simulation, and other critical dynamometer functions under the same operating mode as used during vehicle testing. As a result, the following conclusions are drawn:

1. A practical dynamometer tester has been developed.
2. Design objectives have been achieved.
3. Test results verify the need for and usefulness of the tester.

The Effect of Driver Age on Traffic Accidents

George Z. Libertiny
Design and Manufacturing Defect Consultants

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

There have been numerous publications on the frequency and severity of traffic accidents as effected by age. This is a recent review of the current findings.

While very old drivers have increased accident rates, the impact of their accident rate on the society is small, because they drive very short distances and thus the total number of accidents in which they are involved is low. To improve the traffic accident situation the main effort has to aim the young drivers. Due to their alcohol consumption prior to driving, their reluctance to wear seat belts and the high mileage they drive, they are one of the main causes of the high accident rates. Driver education programs aimed to improve driving skill have minimal effect on accident rates. However, driver education and law enforcement programs aimed at reducing the consumption of alcohol prior to driving and encourage the usage of seat belts could contribute to a decrease in accident rates.

INTRODUCTION

Motor vehicles are integral parts of our lives. They provide mobility for much of our society. At the same time they create the potential for injuries and death. Young people are particularly affected by motor vehicle related accidents. Half of the 19 year olds who die, die because of traffic accidents. That is, there is approximately a 50 percent chance that the death of a 19 year old will be caused by a traffic accident. This probability for traffic related death does decrease with age, as shown on Figure 1[Ref. 1]. In fact all the major factors affecting the frequency and severity of traffic accidents change with age. Some of them have positive effects (e.g., increase in seat belt usage, less alcohol consumption by drivers) and other have negative effects (i.e., decreased reaction time, increased consequence of impact). The types of accidents also change with age. Consequently the effect of safety regulations and traffic related laws have different results for different age groups. For example, older people are almost never involved in rollover accidents. Consequently attempts

(and funds) aimed to make vehicles less likely to rollover will not have any effect on the safety of older drivers. On the other hand older drivers have accidents more frequently because they do not notice oncoming vehicles when changing lanes. Thus, for older drivers, it is more important to have better rear view mirrors than to have an increase in rollover protection. It is necessary to know what is causing accidents in various age groups in order to make the most effective safety decisions.

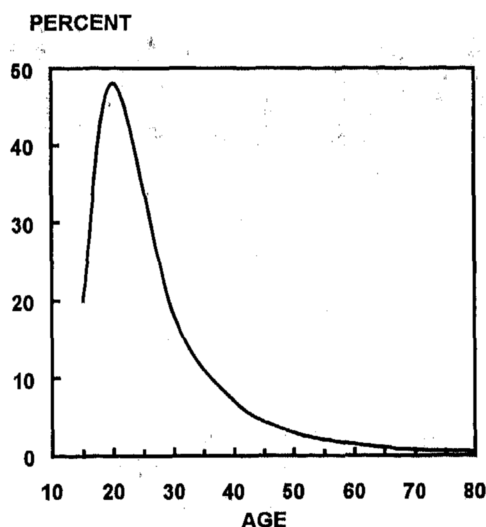

Figure 1. Probability that a given death is due to motor vehicle crash

The purpose of this paper is to review available accident data in order to establish how age effects the frequency and severity of traffic accidents.

DISCUSSION

Effect of Age and Gender on Fatality Risk - The consequence of traffic accidents increases with age. Physical changes with age cause the body to be more susceptible to serious injury in an impact. The risk of bone fractures is particularly increased. The "fragility" effect is particularly noticeable above the age of 60. In general, there is broad evidence of an increasing trend in the risk of injury and fatality with age [Ref. 2]. In a study by Oreskovich et al. [Ref. 3], it was found that 92 percent of people over 70 years of age who suffer severe trauma injuries never return to their previous level of independence. Evans [Ref. 4] found that the fatality risk significantly increases with age.

The results of Evans' study are supported by a recent NHTSA publication [Ref. 5] including the rate of injuries and fatalities at various ages. A comparison between injuries and fatalities is given in Figure 2 [Ref. 5].

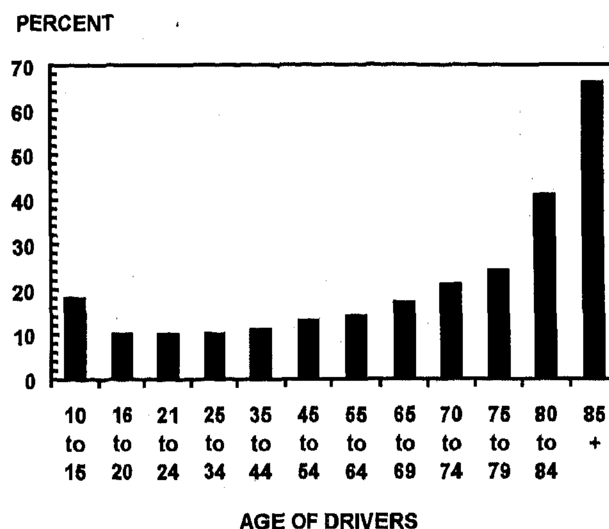

Figure 2. Fatalities as a percent of traffic injuries

Evans [Ref. 1] found that fatality risk due to a given impact is about 25 percent greater for females than for similar aged males from about age 15 to 45 years. The very young and very old males are most at risk. For both sexes, fatality risk is least at age 20; at age 70 it is about three times what it was at age 20.

On the positive side, older people tend to compensate for their increased risk of injury; they do so by more frequently using large vehicles which significantly decrease injury severity, by not consuming alcohol prior to driving, by using seat belts, and by driving less miles.

Effect of Age, Gender and Race on Vehicle Crashes - A North Carolina study [Ref. 6] indicated that the crash rate is lower for females when compared to males. The crash rate per licensed drivers decreases with

age. While young white and nonwhite drivers have approximately the same crash rates, a difference develops with age. The crash rate for nonwhite males is half at age 65 than of the 16-24 age rate. The decrease of crash rates with age is significantly larger for white males than for black males. Females have fewer crashes than males. Non-white females have more crashes than white females. These results are shown in Figure 3.

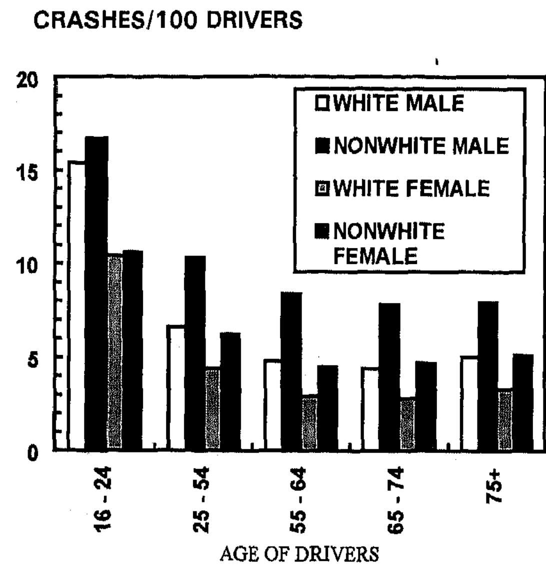

Figure 3. North Carolina Vehicle Crashes per 100 licensed drivers; in 1988.

The problem with the above chart is that it does not allow for the effects of mileage. When the same data is expressed as per estimated million miles [Ref. 6] the differences between the genders and races decreased a great deal. The effect of age also changed, as shown on Figure 4.

Recent data on fatalities in the U.S. [Ref. 7] is shown in Figures 5 and 6. As shown, the present fatality trend in the U.S. is similar to the crash trend in North Carolina at the time of that study. It is interesting to note, that while the fatality rate for the very old drivers increases with age. To put it into perspective, the fatality rate of the 80 to 85 years age group (Figure 6) is similar to the fatality rate of the 16 to 19 years age group. Furthermore, the loss of life years caused by the accidents by elderly drivers is negligibly small when compared to the loss of life years of young drivers. Consequently, the significance of the higher fatality rate of the elderly drivers for the society is an order smaller than the significance of the fatality rate of the young drivers.

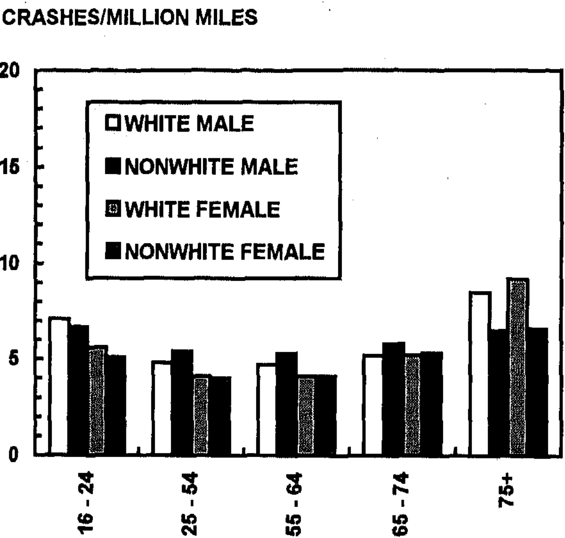

Figure 4. North Carolina Vehicle Crashes per estimated million vehicle miles; in 1988.

Fatality rates of female drivers are usually lower than male drivers at all ages. The difference is not as prominent, however, when the fatality rate is expressed as fatalities per miles compared to when it is expressed as fatalities per population (or drivers), as shown in Figures 5 and 6. From these figures it is apparent that one of the reasons for the lower female fatality rates is due to the fact that females drive less total miles than males do.

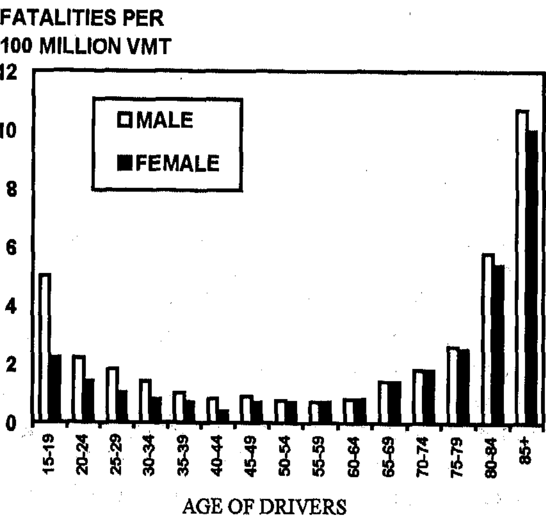

Figure 5. Fatality per 100 million VMT in the U.S.

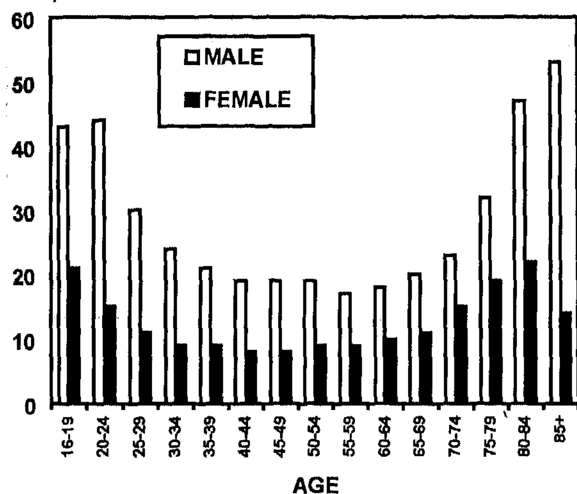

Figure 6. Fatality per 100,000 people in the U.S.

The effect of night driving and age on crash rates - The North Carolina study [Ref. 6] indicates that the older the driver, the less the difference between nighttime and daytime crash rates, Figure 7. This could be due to the fact that older drivers do not drive under the influence of alcohol and are likely be more careful when driving during at night in order to compensate for their physical impairments.

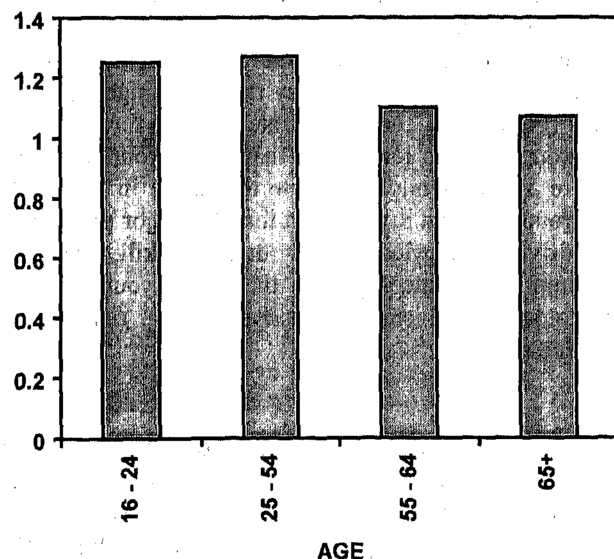

Figure 7. Ratio of Nighttime to daytime Crashes per Mile.

The effect of the very young age on crash frequency - The driving license age varies from state to state, as shown on Figures 8 and 9 [Ref. 8].

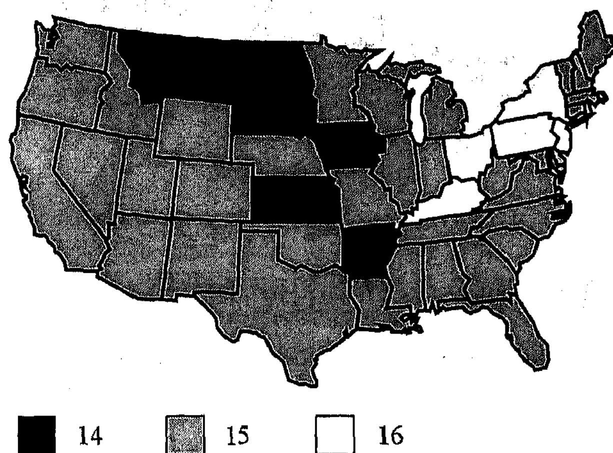

Figure 8. Minimum Age to Receive Learner's Permit

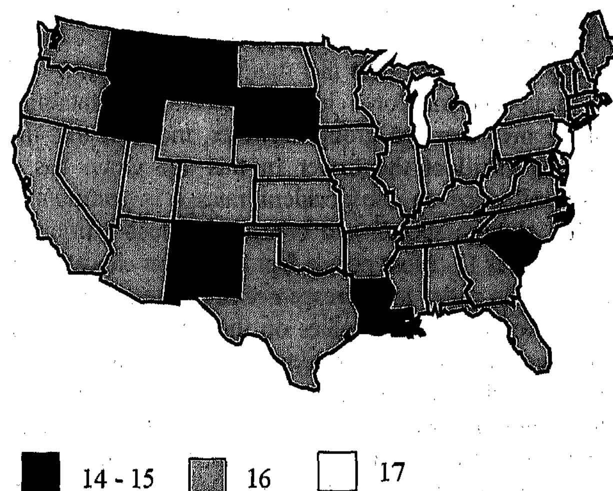

Figure 9. Minimum Age to Receive Driver license.

Intuitively, many people feel that the lower the age to obtain a driver license, the greater the problem with immature and inexperienced drivers. They reason that the better the driver education system and older the novice driver the lower the number of traffic accidents. If this is true, then one would expect high fatality rates in the 16 to 20 age groups in those states that issue driving licenses at younger ages. A comparison of Figures 8, 9 and 10, shows that such correlation is not apparent. While the accident rates are the highest in the

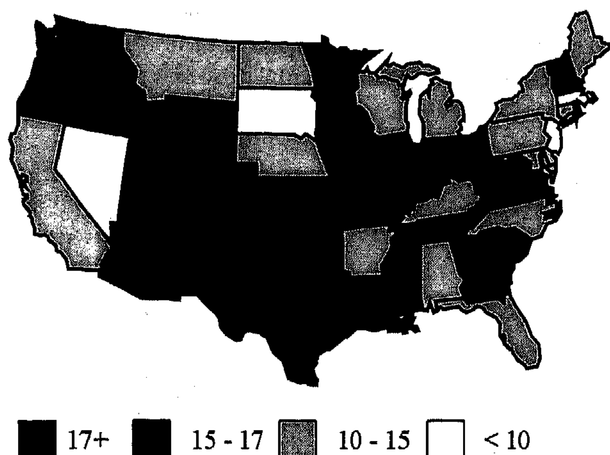

Figure 10. Fatalities in the 16-20 age group as a percentage of the total fatalities in a given state.

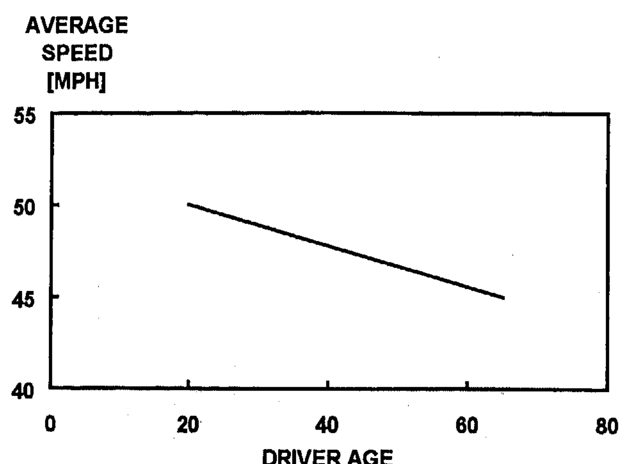

Figure 11. Observed travel speed (1984)

16 to 19 age group, these accidents are not caused by the lower age group to which the driving licenses are issued. This in turn, could mean that driver education program and driving experience are the possible causes for the high accident rates in this age group rather than is the driving license age. The fact that rollovers in the 16-19 age group account for a larger percentage of fatalities than in any other age group, however, indicates that the experience/skill of the driver in this age group has a major influence on the accident rates (in addition to driving at high speeds and consuming alcohol prior to driving) [Ref. 1]. Most people feel that driver education is important in order to decrease accident rates. Although there have been many studies on the influence of driver education programs on accident rates, none has shown that those who receive driver education have lower crash rates than those who do not. Studies show that whatever sort of driver education one received, the crash rate is typical to the age group to which that driver belongs. There is no reliable evidence for increased safety benefits from driver training [Ref. 1]. In the younger ages the driving experience and the age are the dominating factors. The age effect is strongly influenced by the mentality and local culture of the youth considered. The young age groups' affinity for "showing off" and "taking risk" may be the major factor that explains the high accident rates in this age group. The relationship between travel speed and age, shown on Figure 11 [Ref. 1] indicates that younger people more apt to take risks.

Once the driver passes the drinking age (21 yr.), then the improved driving skill is counteracted by the dramatic increase in the alcohol related accidents (as will be shown later in this paper). In any case, the driving skill itself does not necessarily decrease accident rates in most age groups (the youngest age group is a possible exception). The accident rate on public roads for very skillful racing car drivers is not any better than it is for the general public. It appears that the greater the skill, the greater the risk taking. This is also true for drivers of high quality and high performance vehicles. The old saying is that: one needs to have a high quality, high performance car in order to get out of the trouble he/she got into because of a high quality high performance car. Consequently, although the driving skills are improved by age 21, the fatality rate per population is similarly high for both the 15-19 and the 20 -29 age groups (Figure 6). Since the older (20-24) age group drives more miles than does younger (16-19) group (Figure 12), the fatality rate per mile for the 20-24 age group is much lower than that of the younger group (Figure 5). This might indicate that those in the 20-24 age group are good drivers, and that the major problem is not driving knowledge and driving skill, but the consumption of alcohol and the other youth related psychological problems (aggressive driving, risk taking, showing off, etc.).

Annual mileage driven and the age of the drivers - Annual mileage is one measure of exposure to the risk of traffic accidents. Older people usually drive less than younger people do (Figure 12). Thus, the

accident rates per drivers and the accident rate per million miles is usually very different. While the accident rate per miles is an indication of the driving

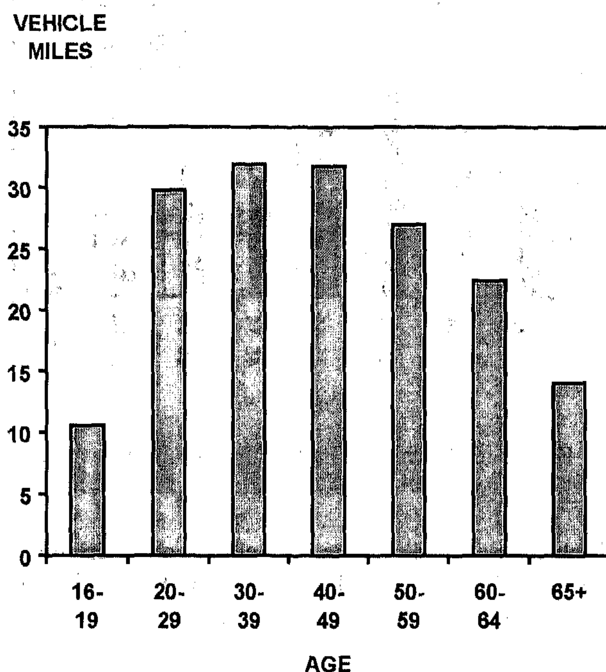

Figure 12 . Average Daily Vehicle Miles Traveled (1990)

ability, the accident rate per drivers is an indication of the effect of the driving behavior on the society. If a very old driver has great difficulty to drive without accident, and he knows this and has thus decided to drive very seldom and only for short distances in good driving conditions, then the likelihood of this driver having an accident could be less than that of a very able young driver who does, however, drive great distances each year. It appears, then, that it would be unfair to drivers to revoke their driving licenses because of age impaired driving, if other drivers, who drive large distances and thus cause and are exposed to a greater number of accidents, are not restricted. The cost to society is not different nor is the danger to the individual driver is different (young, able drivers who drive very great distances vs. old age impaired drivers who drive very limited distances). Any restrictions on older drivers appears to be unfair as long as the effect of their driving, on society as a whole, is not greater than the effect of the driving of the young drivers. When the need to restrict the driving of the older people is discussed, one should remember the effect of driving restrictions. Villeneuve [Ref. 9] attempted to draw attention to this problem and wrote: "I discovered the enormous misery that is generated by the loss or threatened loss of independent mobility. Many seniors simple refused to discuss a future without a car. Others told me that they could not conceive of such future, and some confessed they would rather die than quit driving ... [those] who were clearly unfit to drive ... denied their functional status and continued to drive in defiance of their families because independent mobility was central to their definition of self".

Fatality rates by income and age - Fatality rates in an area of residence depends upon the income of the area residence, as shown in Figure 13 [Ref. 10]. The higher fatality rates in lower income areas are not explained by differences in the amount of miles traveled, since the amount of travel increases with income (Figure 14 [Ref. 13]). Up to a given age, however, income and age are related; the older the person, the higher the income. Thus, the effect of income on traffic accidents may be partially age related. In addition to age, the socioeconomic status of the drivers is important. For example, it was found by Adams [Ref.12], that "An unskilled manual worker is four and a half times more likely to be killed in a motor vehicle accident than a self employed professional ..." We could not find direct data in the literature on the effect of income by age group on accident rates.

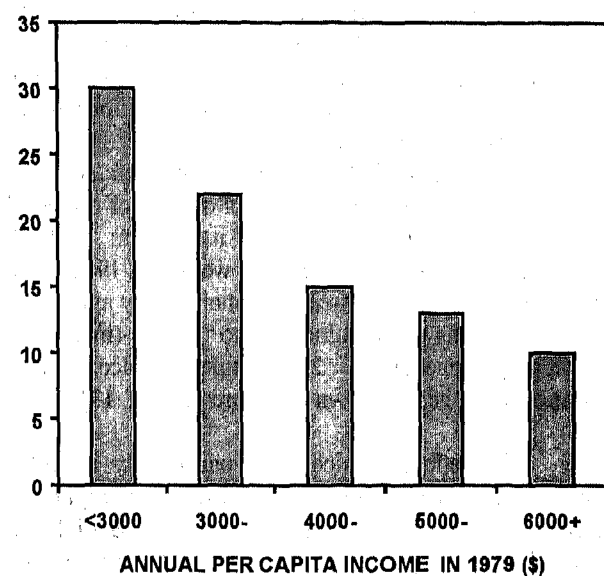

Figure 13. Fatality Rates per Capita Annual Income of Area of Residence (1977-79; Ref. 13)

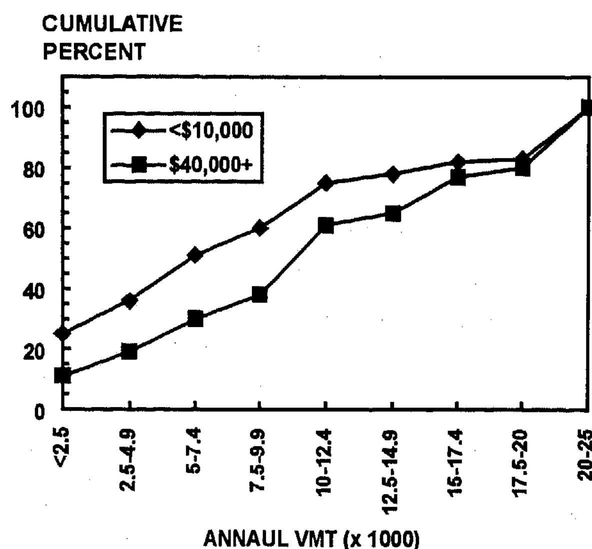

Figure 14. Cumulative Vehicle Miles Traveled for Selected Income Classes.

Type of accidents and the age of the drivers - Older drivers are less frequently involved in single car accidents, rollovers, alcohol and speed related accidents. On the other hand, older drivers are more often a party to accidents at intersections, making left turns, changing lanes and merging. [Ref. 2].

Alcohol consumption at various ages - The same amount of alcohol per body weight usually results in a higher BAC for older people. Furthermore, alcohol may also result in a greater impairment of performance in elderly persons. Women also achieve higher BAC for a given amount of alcohol per body weight [Ref. 2]. There was no material found on the effect of alcohol on elderly women, but, from the above, it appears that the significance of alcohol for elderly women is likely to be greater than for elderly men. Alcohol, in any age, makes the body organs more vulnerable to injuries (in addition to impair judgment) [Ref. 2]. Fortunately, alcohol usage declines with age, as shown in Figure 15 [Ref. 11].

The effect of alcohol is particularly important during nighttime driving. As shown in Figure 16 [Ref.17], close to 80 percent of the weekend nighttime driver fatality is alcohol related. One of the reasons why older people have much lower alcohol related accident rate is because older people less frequently go out to

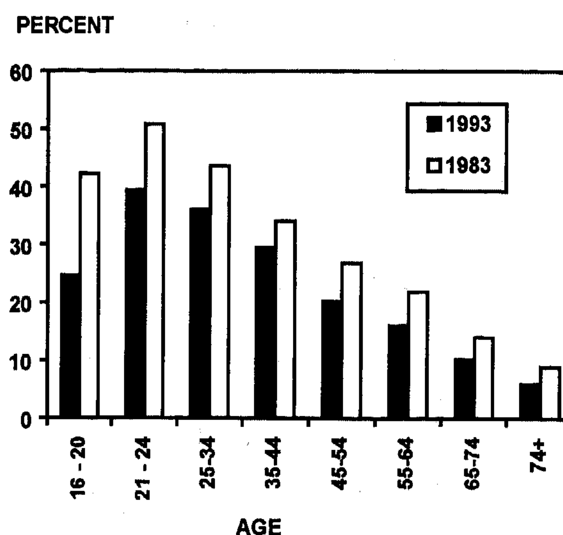

Figure 15. Drivers in Fatal Crashes; BAC = 0.01+

drink on weekend nights. Drinking and driving do not mix. The effect of alcohol drinking by young drivers is very significant on traffic accident rates.

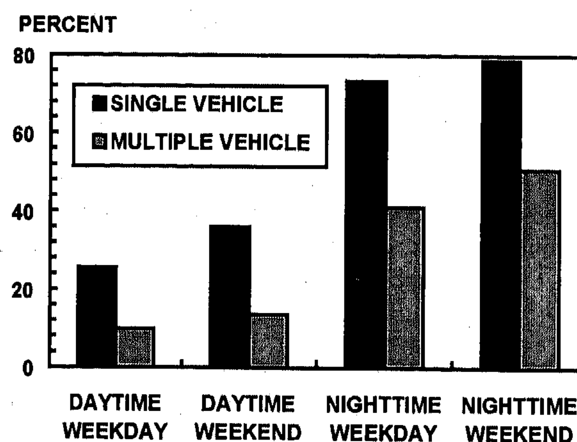

Figure 16. Percent of 21 and older drivers killed with alcohol involvement [Ref. 17]

Seat belt usage at various ages - The restraint usage by occupant survivors of fatal crashes and the occupant fatalities of passenger cars is given in Figure 17 [Ref. 14]. As it is shown, restraint usage is increasing with age. It is also apparent that those who are involved in fatal accidents are less likely to wear seat belts than are

those who survive these accidents. Seat belts clearly save lives at any age. Efforts should be made to ensure that young people do use their seat belts.

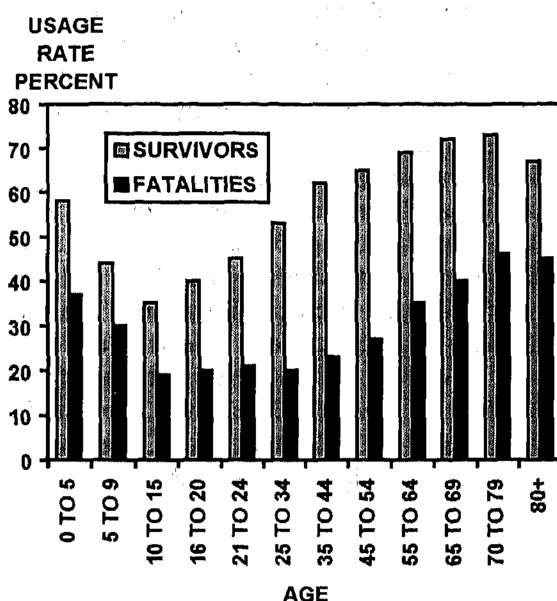

Figure 17. Restraint Usage; Occupant Survivors and Occupant Fatalities (1991; Ref. 14)

CONCLUSIONS

- A very large segment of fatal accidents are caused by young drivers who drink prior to driving and who, in addition, do not wear their seat belts. The probability that a given death is due to motor vehicle crash is fifty times higher for a person age twenty than for a person age seventy.

- Older people are more "fragile" than young people. Traffic injuries resulting in fatalities are seven times higher for an 85 year old than for a 20 year old.

- Fatality rates appear to be significantly lower for females. However, when it is defined as fatalities per miles, the difference between male and female is quite small. That is, females drive less and therefore they are less frequently involved in traffic fatalities. When both males and females drive the same distance, then the fatality rates are close (the female rate, however, is still slightly lower.)

- The importance of driver education is questionable. The skill of the drivers does not appear to effect the frequency with which a driver is involved in accidents, except for the youngest of drivers. Skilled racing car drivers do not have lower general traffic accident rates than does the general public.

- The age at which driver licenses are issued does not appear to influence accident rates.

- More traffic accidents occur at night than during the day. The likely primary cause is increased alcohol usage prior to night driving.

- The reason for lower accident rates and injuries for older drivers are due to the fact that older drivers drive at lower speeds, they are less frequently consume alcohol prior to driving, they drive fewer miles, and they are more likely to wear their seat belts.

- While very old drivers have increased accident rates, the impact of their accident rate on society is small; because they drive few miles and thus the total number of accidents in which they are involved is low. To improve the traffic accident situation, the main efforts have to be aimed at the young drivers. Their alcohol consumption, reluctance to wear seat belts and the greater number of miles they drive all contribute significantly to high accident rates. Driver education aimed at improving driving skill has a minimal effect on accident rates. However, driver education and law enforcement aimed at reducing the consumption of alcohol prior to driving and to encourage the usage of seat belts might contribute to a decrease in present accident rates.

A Study of an Evaluation Based on Physiological Responses of a Driver's Task and Stress Level While Maneuvering a Vehicle

Yuzuru Matsuura and Takatoshi Yanagida
Osaka Sangyo University

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

To evaluate a driver's task and stress level objectively while maneuvering a vehicle, we paid attention for human's physiological responses under the condition. The eccrine sweat on a palm and a forehead, heart rate and a face temperature of a subject driver were monitored and measured continuously and quantitatively using the specified direct sweat measuring equipment, the electrocardiograph and the infrared thermometer respectively.

As a result of having analyzed these data physiologically, we propose that the driver's stress level can be objectively determined by the quantity of eccrine sweat, changes of heart rate and changes of face temperature.

INTRODUCTION

The safety of a vehicle-road traffic greatly depends on a judgment and an action of a driver as well as road environments and vehicle performances. A driver's physical task to operate a vehicle is not so high, but the mental stress and the tension of a visual and hearing system and brains nervous system are extremely high.

Up to now, the evaluation of drivers' stress level of driving task and the mental stress generally depends on subjective evaluations of drivers' feeling by themselves. These values are always uneven because of their individualities and different way of their expressions.

In this study, to evaluate these levels objectively, we paid attention for human physiological responses while maneuvering a vehicle.the eccrine sweat on a palm and a forehead, heart rates and a face temperature of a subject driver were monitored and measured continuously and quantitatively using the specified direct sweat measuring equipment, electrocardiograph by a medical telemeter system and an infrared thermometer camera. These data moreover compared with similar data collected when subjects watched a TV and tried to solve arithmetic problems as conventional basic tasks.

EXPERIMENTAL APPARATUS AND METHOD

EXPERIMENTAL APPARATUS - To investigate human physiological responses, the subject's sweats on his forehead and palm were measured directly, momentarily and quantitatively with the direct sweat measuring equipment that uses carrier nitrogen gas as shown in Figure 1.

There are two types of the sweat. One is Thermal Eccrine Sweat (abbreviated as TES) and the other is Mental Eccrine Sweat (MES). Capsules pasted on two parts of a subject's forehead and left palm collected information on thermal reaction (TES) and mental reaction (MES) respectively. measured using the multi-telemeter system and their heart rates were calculated from the electrocardiograms (cf. in Figure 1).

Their face temperatures were also measured by the infrared thermometer camera (Thermotracer TH2100), Their operating behaviors were also recorded onto the 8 mm video tape recorder through a CCD camera mounted in front of them.

These data moreover compared with similar data collected when subjects watched a TV and tried to solve arithmetic problems .

EXPERIMENTAL METHOD - The experiment consists of fundamental experiments in the laboratory and experiments of a vehicle traveling in the test course.

(1) Fundamental experiments in the laboratory

From various daily occurrences that we generally experienced in our life, we selected typical tasks accompanied with visual stimuli or brains stimuli, and conducted several experiments to obtain the state of human physiological stress under these stimuli.

(2) Experiments of visual stimuli

Subjects watch a video monitor as a one of visual

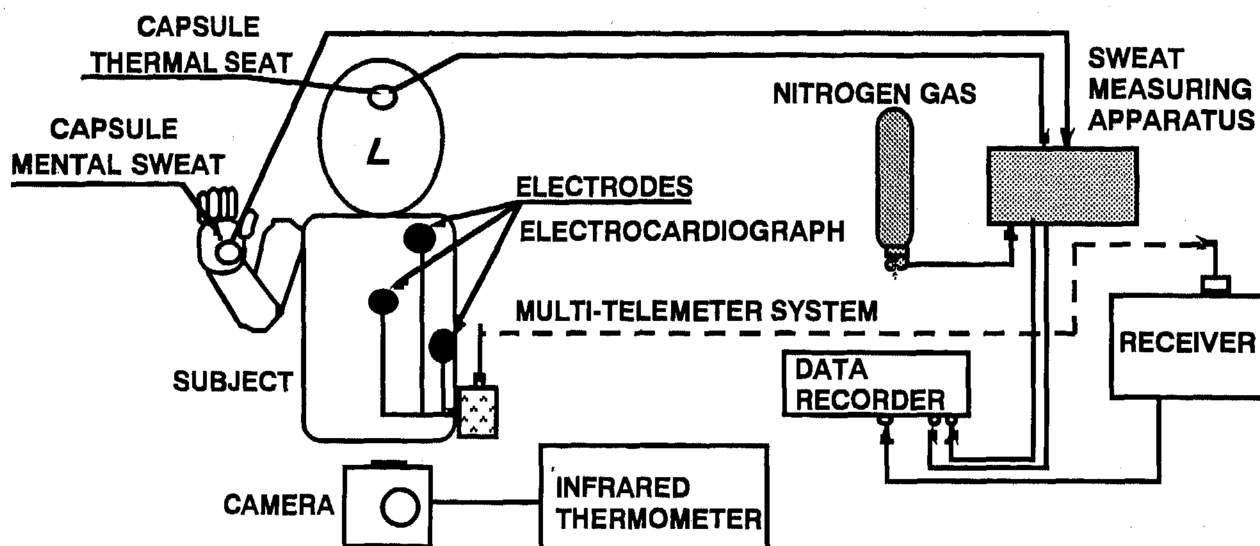

Figure 1 : The experimental apparatus

stimuli. Two subjects of pictures "mountains' nature scenery" and " motorcycle's race" were selected, so that the former gave subjects calm scenes and the latter gave them exciting scenes, in 6 minutes each.

(3) Experiment of brain stimuli

Fifty arithmetic calculation problems were given to subjects as brains stimuli. They calculated these problems for 10 minutes, and meanwhile their brains' stress were physiologically examined.

In each experiment, the room temperature kept approximately 24 centigrade. Their face temperatures were taken with the infrared thermometer camera every 4 seconds.

The subjects had the operating task of slalom-travels at 15 km/h and 30 km/h (each pylon's interval of 15m on the course) using a FF type passenger car on the test ground, and furthermore had constant radius turn travels of 15m radius at velocity of 30km/h.

It is difficult to be kept constant the inside temperature of the car cabin. It also needs to avert the subject's face from outside fresh wind or from air flow of the air-conditioner, to avoid an influence of cooling operation to the face. Therefore all windows of the vehicle were closed, and its inside conditions were kept freely without operating the air-conditioner. The face temperature was filmed every 2 seconds with the infrared camera.

The subjects consisted of 5 male adults of 21 to 23 years of age.

EXPERIMENTAL RESULTS AND CONSIDERATION

FUNDAMENTAL EXPERIMENT IN A LABORATORY - Figure 2 shows a result of sweat changes of a subject measured in the fundamental experiments of visual stimuli and brain stimuli in the laboratory. In thermal sweat of the forehead part, a change is hardly observed.

At early stage of the rest state, sweating on the forehead part was hardly found, but the quantity of the sweat on the palm part showed a high value. As this reason, many mental sweat glands are distributed on the palm part. This sweat phenomenon is considered to have shown a tension feeling of the subject just before a start of the experiment.

While the subject watched the mountains' scenery video, the quantity of his sweat didn't change greatly, but it began to rise just after the start of the experiment and afterwards its level kept high while watching the motorcycle's race video. For the continuation about exciting scenes of the race video and the delay of sweating phenomena, however the finish of the experiment of the video, the quantity of his sweat remains high level. The quantity of the average sweat in this period was 0.105 $mg/cm^2 \cdot min.$, and the total quantity of sweat during 8 minutes was 432.66 mg/cm^2. This shows the mental stress of the subject caused to be excited by the race video.

When the subject calculated the arithmetic problems,

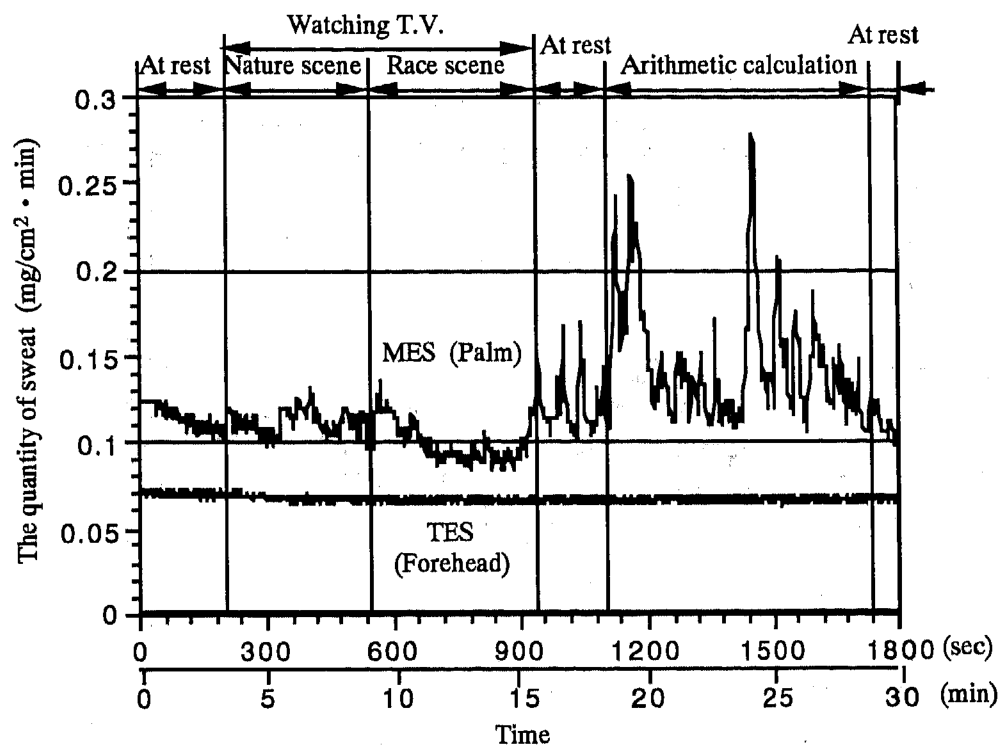

Figure 2: The result of sweating measured in the laboratory

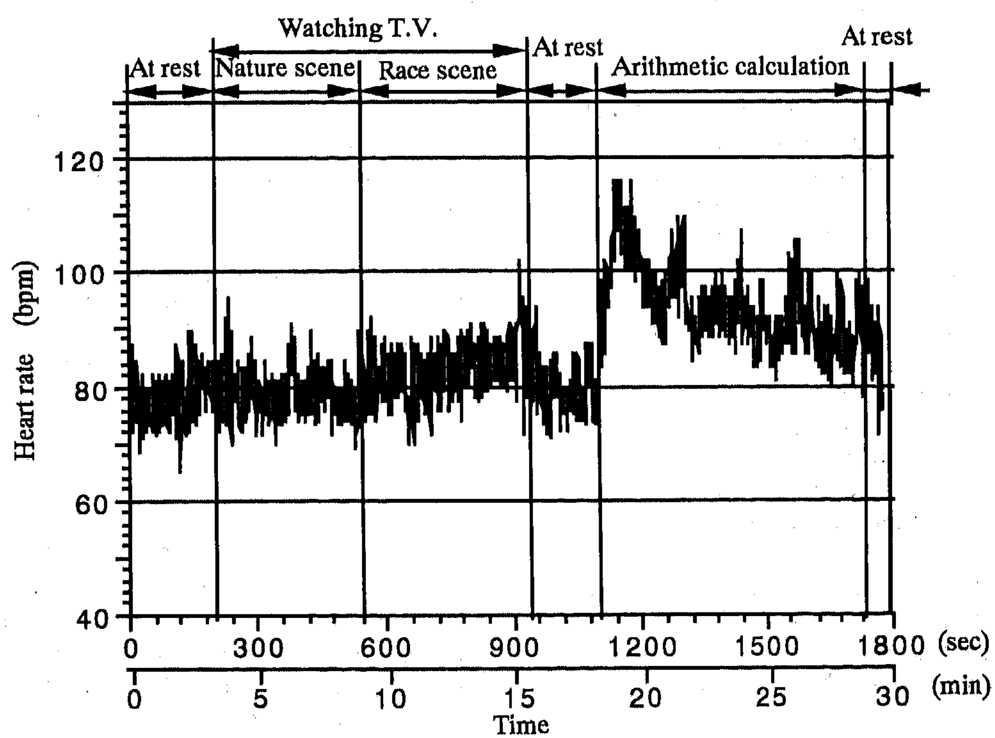

Figure 3: The result of heart rate measured in the laboratory

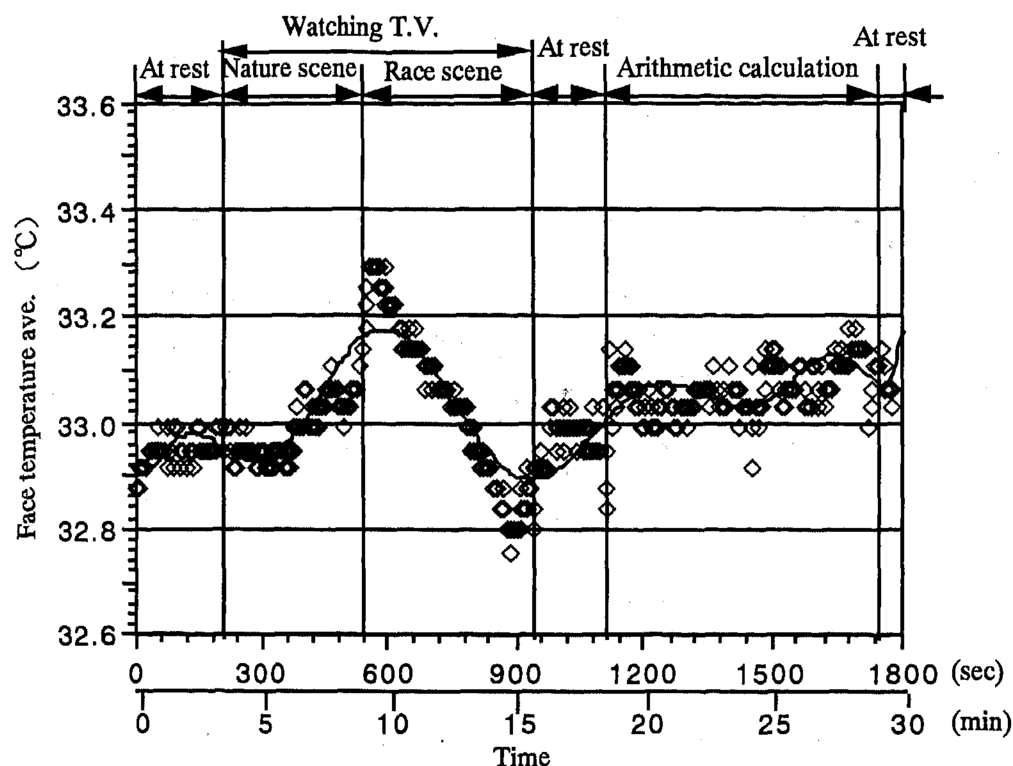

Figure 4 : The result of the face temperature measured in the laboratory

the quantity of his sweat greatly increased immediately after the calculation started, and fluctuated with a high level between 0.108 and 0.279mg/cm²•min. afterwards.

This trend was observed in all subjects. From this fact, when subjects input information, and processed and output ones, it is considered that they had many mental stresses.

The quantity of the average sweat in this period was 0.145mg/cm²•min., and the total quantity of sweat during 10 minutes was 1042.83mg/cm².

Now, let compare the quantity of the sweat in each experiment with that in each rest state, when subjects were watching the mountains' scenery on video monitor, the quantity of their sweat then is 0.73 to 1.02 times larger that in the rest state.

On the other hand, while they were watching the motorcycle's race, and were calculating the arithmetic problems, the quantity of their sweat is 0.90 to 1.23 times and 1.31 to 1.53 times larger that in each rest state respectively.

About the heart rate of subjects, the average heart rate in the rest state before the experiment showed 78bpm, and while their calculating the arithmetic problems, the heart rate is 1.16 to 1.24 times larger that in the rest as shown in Figure 3. In this way, we found that the stress state of the subject also could be shown by the change of heart rate.

Now, about a change of face temperature as shown in Figure 4, the average face temperature of the subject was fixed 32.0 degrees in the rest state and rose about 0.05 degrees while they were watching the mountains' scenery on video in comparison with the rest state, about 0.1 degrees while watching the motorcycle's race and about 0.1 degrees while calculating the arithmetic problems respectively.

We consider that the mental excitements by each stimulation have brought the rise of their face temperature.

EXPERIMENT OF A VEHICLE TRAVELING - As shown in Figure 5, a large change of the quantity of sweat on the driver's forehead part wasn't observed in the experiments of the vehicle traveling. The above fact shows that the operating task wasn't intense muscle exercise such as causing a thermal eccrine sweat.

On the other hand, a remarkable change of the quantity of sweat on the palm part was observed. The average quantity of sweat of the driver was 0.184 mg/cm²•min. in the rest state before the experiment, and the quantity of his sweat increased remarkably just when the slalom

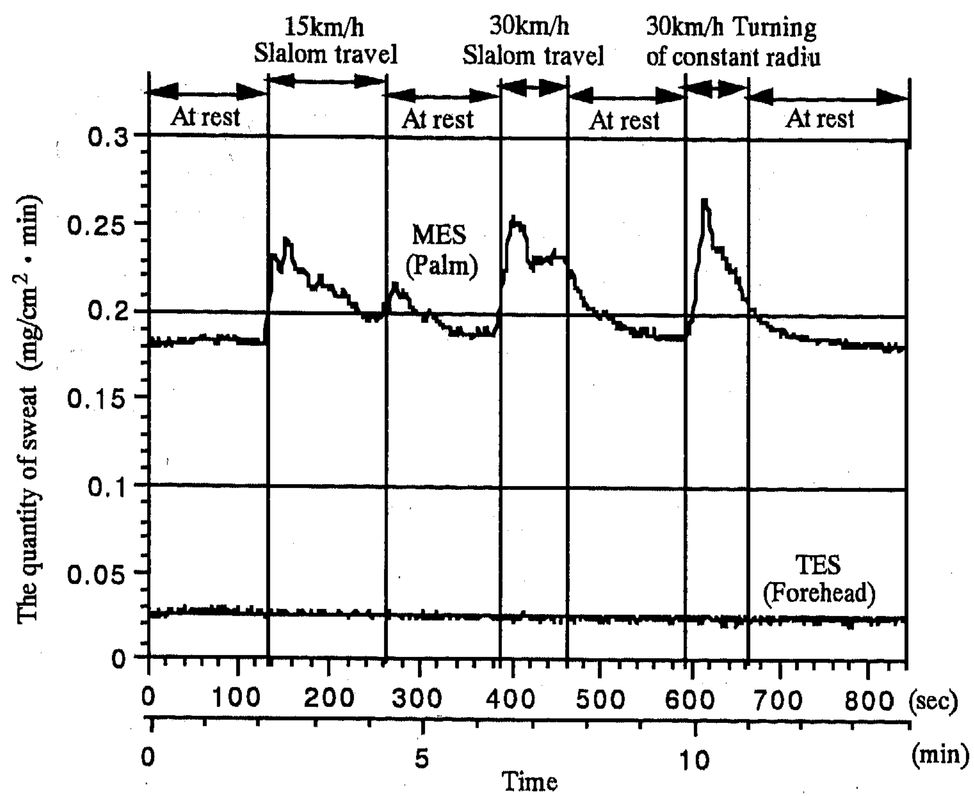

Figure 5 : The result of sweating measured in traveling vehicle

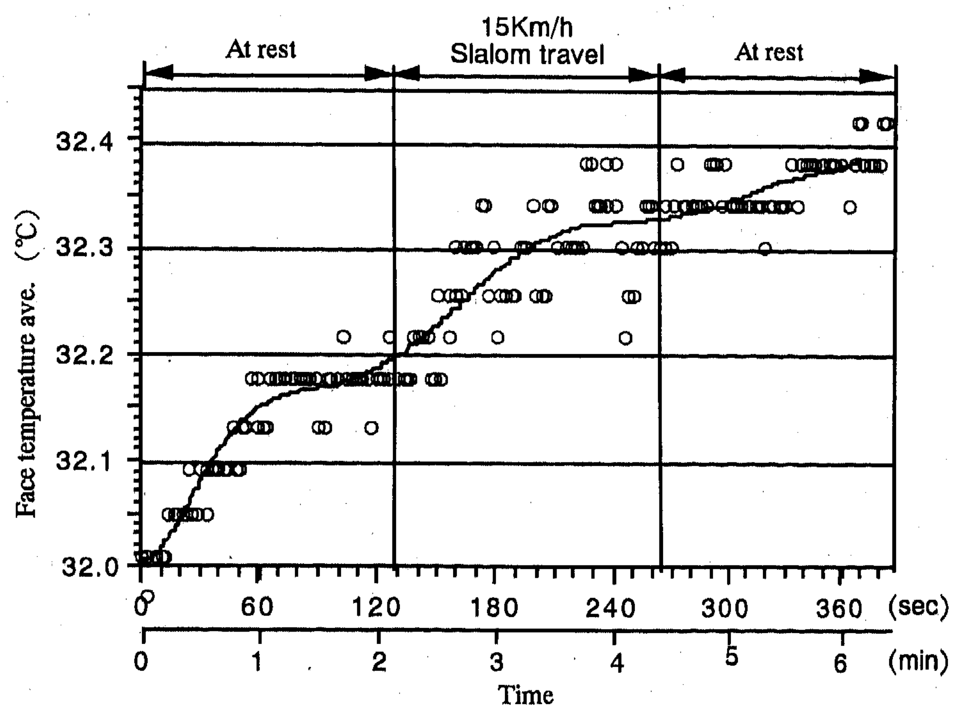

Figure 6 : The transition of face temperature while maneuvering the vehicle

Table 1: The comparison of physiological responses during the experiments on that in the rest state

* RATIO NUMBER

	HEART RATE	ECCRINE SWEAT	FACE TEMPERATURE
REST BEFORE EXPERIMENT	1	1	1
MOUNTAINS' SCENERY	1.00~1.09	0.73~1.02	0.90~1.03
MOTORCYCLES RACE	1.07~1.11	0.90~1.23	0.91~1.06
ARITHMETIC CALCULATION	1.16~1.24	1.31~1.54	1.00~1.05
SLALOM TRAVEL AT 15 Km/h	1.35~1.42	1.11~1.53	———
SLALOM TRAVEL AT 30 Km/h	1.40~1.53	1.13~1.98	———
CONSTANT RADIUS TURN TRAVEL	1.37~1.50	1.14~1.61	———

travel started at 15 km/h, and reached a peak value of 0.242 mg/cm²•min, and decreased later. The total quantity of sweat during 2 minutes was 0.217 mg/cm²•min, and the quantity of the average sweat in this period was 47.090 mg/cm². In the rest state immediately after the experiment of the slalom-travel at 15 km/h, the quantity of sweat showed a high value for the influence of that travel.

The quantity of the average sweat in the rest state that calmed down was 0.233 mg/cm²•min., and it was 0.193 mg/cm²•min. in the experiment of the slalom-travel at 30 km/h, and the total quantity of sweat for 1.5 minutes was 25.491 mg/cm². And the quantity of the average sweat in the experiment of the constant radius turn travel was 0.235 mg/cm²•min.

In next, we compare these above mentioned quantity of sweat with the average quantity of sweat in the rest state before each experiment, in the experiment of the slalom-travel at 15 km/h and 30 km/h, it was 1.11 to 1.25 times and 1.13 to 1.35 times as large as that in each rest, and in the experiment of the constant radius turn travel, it was 1.14 to 1.30 times respectively. In other words, we can propose that these numerical values show a size of the driver's mental stress. As similar as mentioned above, let compare between heart rates in the rest state and that in the experiment of the travel. In the experiment of the slalom-travel at 15 km/h and 30 km/h, it was 1.35 to 1.42 times and 1.40 to 1.53 times as large as that in each rest state respectively, and in the experiment of the constant radius turn travel, it was 1.37 to 1.50 times. The increase of a velocity in the slalom travel has a tendency to increase the mental stress of the driver, and the numerical values in the slalom travel show a high value than that in the constant radius turn travel. It shows that the driver's stress by operating a steering in the slalom travel was large.

About the change of the driver's face temperature, in the experiment of the vehicle traveling, because the driver is always moving his face during operating, It is difficult to take it by the infrared camera from the same direction angle. So, his face during the operation was taken frequently every 2 seconds by the camera, and after that his face photographs with the same direction angle only were selected out of the many face photographs.

An outline of his face in these photographs was judged individually and the temperature distribution state and the average temperature value of all of these were obtained.

In next, as shown in Figure 6, over the whole period the driver was operating, it was observed that his face temperature (a mean value) had an inclination to rise up gradually. As the reason, all of the windows of the vehicle were closed and its inside conditions were kept free, so the inside temperature in the cabin rose a little by little, from the start of the experiment (approximately 14 degrees) to the end (approximately 28 degrees). His face temperature also rose progressively by the influence of the room temperature.

Now, to analyze the influence that the operation task gave a change of the driver's face temperature, the whole transition of his face temperature accompanied with his operating progress was similar by a curved line of undulate waviness (n-powered Polynomial of Degree). It is shown with the curved line in the figure. In an early stage of the rest state, a rapid rise of the face temperature was observed because of the influence of the interception of the external fresh air caused by having closed the all windows, and it calmed down in later period.

When the experiment of the slalom-travel at 15 km/h

started, his face temperature began to rise clearly. It is considered that it was caused from the effect of the stress accompanied with the driver's operating task, as well as the above-mentioned results of changes of sweat and changes of heart rate. He entered the rest state after he finished the experiment of the slalom- travel, and the rise of his face temperature calmed down again.

Afterwards it rose slowly in accordance with the influence of the rise of the inside temperature of the cabin.

COMPARISON OF THE RESULT IN THE LABORATORY AND ON THE VEHICLE TRAVEL - We compared the experimental result of the vehicle traveling with that in the laboratory in respect with all values of the quantity of the average sweat, heart rate and the face temperature.

However there were individual differences caused by the subjects, as shown in Table 1, about a ratio of the quantity of the average sweat the former's value is 1.3 to 2.0 times as larger than the latter's one, and about changes of the heart rate, it did larger 1.2 to 1.5 times, and about changes of the face temperature, it did higher 1.0 to 2.0 times.

Accordingly, it proved that the mental stress while operating the vehicle was comparatively higher than that during watching the television and that during calculating arithmetic problems.

CONCLUSION

As the results of having analyzed the mental sweat and changes of the face temperature in respect to human physiological responses to various types of stimulation, the following results were obtained.

(1) When a mental stress burdens on a human body, his physiological responses appear such as an increase of the quantity of sweat on a palm, an increase of the heart rate and a rise of the face temperature.

(2) The human mental stress level to a stimulation can be evaluated numerically by comparing a size of his physiological responses to it.

(3 The human stress while maneuvering a vehicle is comparatively large more than that of daily occurrences in our life such as watching a TV and calculating arithmetic problems.

Driver Behavior Under a Collision Warning System - A Driving Simulator Study

Takamasa Suetomi and Koji Kido
Mazda Motor Corporation

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

Collision warning systems are expected to be an effective countermeasure to reduce traffic accidents; however there have been relatively few studies on the effects of such warning systems on the driver's collision avoidance behavior. In this study, a driving simulator which had a large motion system was used, and 45 subjects experienced crash imminent situations in which the preceding cars suddenly decelerated while the subject looked off the road. Analyzing the subjects' collision avoidance behaviors, it was found that the braking response time and the number of simulated collisions were substantially decreased with collision warnings. Furthermore, potential reduction of rear-end collisions on the road was estimated by modeling the driver's braking response.

INTRODUCTION

Most of traffic accidents are considered to be caused by drivers' errors. A study reported that drivers' errors(recognition errors, decision errors, erratic actions, drowsy, etc.) consisted about 90% of all the causal factors of traffic accidents[1]. Therefore, active safety technologies such as collision warning systems to prevent or to cover driver's errors are expected to be an effective countermeasure against such driver caused accidents.

To develop an effective collision warning system, the human-machine interface is as important as the sensing system which detects surrounding obstacles and judges hazard levels. Therefore such system should be evaluated from the following view points.

(1) Collision avoidance potential (the number of collisions which the warning system can prevent directly)

(2) Driver's behavioral changes(the driver should not take more risks and reduce the safety margin against collisions by taking advantage of the warning system)

(3) User acceptance(The system should not irritate the driver and he/she uses the system willingly)

Therefore, first the drivers' responses to collision warnings must be carefully analyzed. Then, the performance of a collision warning system must be evaluated based on its collision avoidance potential.

There is a study which used a computer simulation and predicted that a collision warning system would reduce 60 % of rear-end collisions by assuming drivers' responses and a traffic flow[2]. However, considering drivers' behavioral changes in use of such warning systems, the man-in-the-loop analysis needs to be done carefully to predict their effectiveness in real world.

For such studies, a driving simulator which can evaluate ordinary drivers' responses under crash situations is an essential testing method since such tests are difficult in real world.

Fixed-base simulators or motion-base simulators with small motion ranges have been used to investigate drivers' behaviors while using active safety systems such as intelligent cruise control[3] and collision warning system[4]. However, to fully analyze the effects of collision warning systems on the drivers' behaviors and to evaluate collision avoidance potential, the simulator must be able to simulate crash imminent situations including drivers' collision avoidance

behavior. And to reproduce drivers' emergent maneuvers such as emergent braking or steering, an accurate motion feedback to the driver would be necessary. For this purpose, Mazda has developed a driving simulator with a large scale motion system[5].

In this paper, using this driving simulator, the responses of 45 subjects when they were faced with sudden brakings of the preceding cars were analyzed. Then, based on the results, a model of the driver's braking response was developed and potential reduction of rear-end collisions on the road was estimated.

EVALUATION OF COLLISION WARNING SYSTEM USING A DRIVING SIMULATOR

DRIVING SIMULATOR

Motion System - Figure 1 shows the mechanism of the four degrees-of-freedom motion system of the Mazda driving simulator. Consisting of a rotational mechanism that controls the three axes of roll, pitch, and yaw of the movable cabin and a linear mechanism that controls the horizontal motion of the cabin, it has a large moving range in each motion direction as shown in Table 1.

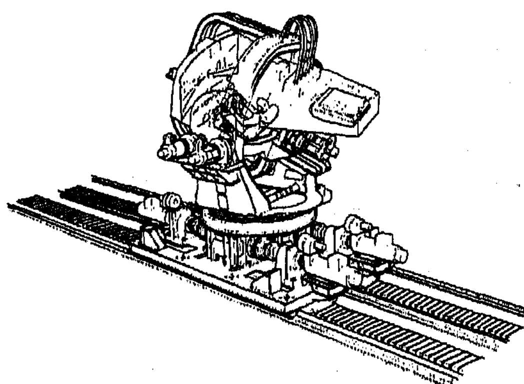

Figure 1. Driving simulator motion system

Table 1. Moving range of motion system

Coordinate	Range
Roll	+/- 40 degrees
Pitch	+/- 40 degrees
Yaw	+/- 160 degrees
Linear	+/- 3.6 meters

Rotating the moving base around the yaw axis by 90 degrees, the linear mechanism can generate either longitudinal acceleration or lateral acceleration to the driver. 0.8 G acceleration can be generated by actual linear motion, and 0.64 G acceleration can be attained by inclining pitch or roll to the maximum angle of 40 degrees. The three rotational axes pass through the driver's head where the vestibular sensors of the driver are located.

To simulate a large longitudinal acceleration in emergent braking, this motion system uses linear motion and pitch motion. The high-frequency component of acceleration is produced by the linear motion and the low-frequency component is produced as the component of gravitational acceleration by tilting the pitch of the cabin. In a short beginning stage of braking or acceleration, the linear motion system generates an actual longitudinal acceleration for a short period of time and decelerates it quickly to stay within its available displacement. And, following the stage, a constant acceleration is maintained by tilting the pitch angle.

Visual and Audio System - The visual system generates a road image onto an 80-inch screen placed 1.2 meters in front of the driver. The field of view is 68 degrees horizontally and 20 degrees up and 14 degrees down from the horizon. A full color(16.78 million colors) textured road and environment image is generated every 20 milliseconds by the road image generator. An example of road images is shown in Figure 2.

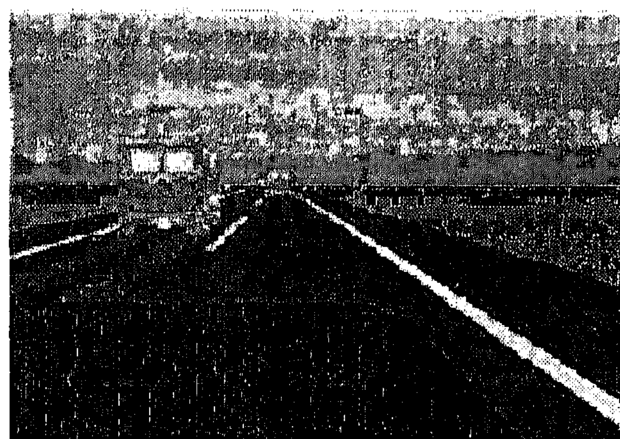

Figure 2. Road image

The road image generator which could generate road scenes and other traffics were used to produce a car following situation on a highway. Road curvatures were specified both horizontally and vertically to simulate real highway. A texture for road

surface was also used to enhance the driver's perception of the vehicle speed. Images of preceding cars on the traveling lane and adjacent lanes were also generated. The image of preceding car had brake lights so that the driver of the following car could recognize the brake operations of the preceding car. The background images such as mountains and the sky were turned according to vehicle movement.

To simulate an auditory environment of a car, sounds such as those from the engine, road, wind and tires were recorded in real environments, and they were stored in a digital sampler in the sound system. Receiving signals indicating the engine rotational speed, throttle opening level, vehicle speed and tire slipping conditions from the host computer, the sound generator reproduced the corresponding stored sounds.

Verification of Driver's Braking Behavior in the Simulator - Before evaluating collision warning systems using the simulator, whether a driver in the simulator behaves in the same way as in real world should be verified. Figure 3 shows changes of the braking headway distance with the driving speed on the simulator, an expressway, and a proving ground[6]. The headway distances were averaged over 20 km/h intervals. As shown in this figure, although the distances in the simulator were smaller at low speeds and larger at middle speeds compared with real world driving conditions, braking headway distances in the simulator were generally very close to those in real world at higher speeds. Those data proved that the driving simulator with a large longitudinal stroke is effective to reproduce driver's braking behaviors.

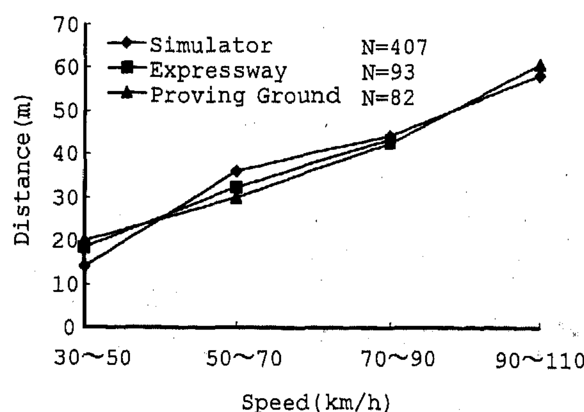

Figure 3 Changes in braking headway distance with driving speed

EXPERIMENTAL METHOD

Task - In the simulator, a subject drove on a two lane road with a lane width of 3.5 meters. The driver followed a preceding car which changed speeds from 80 km/h to 100 km/h by a sixty-second interval on the overtaking lane(right lane), while low speed vehicles(50 km/h) traveled in the running lane(left lane).

To make the subject glance off the road, he/she was asked to push a button when one of five LED lamps was lit as a secondary task. The five LED lamps were located at different places on the dashboard.

The experimenter was able to control other traffics. One hazardous scenario was preceding car's sudden braking to 30 km/h by 0.8 G, when a lamp was lit to make the subject to look at it. Another hazardous scenario was that a preceding vehicle on the adjacent lane broke into the traveling lane without blinking its turning signal just after a LED lamp was lit.

Test Procedure - At first, the subject drove until he/she became familiar with driving in the simulator and got used to the dynamic characteristics of the simulated vehicle for about 10 minutes. After a short break, in the second running, the subject drove following a preceding car, and met with a sudden braking of the preceding car or a sudden lane change of a preceding car on the adjacent lane, while executing the secondary task.

Subjects - 45 male subjects aged from 19 to 26 who had valid driving license and regular visual and auditory senses participated in the test.

COLLISION WARNING SYSTEM

The collision warning system provided a warning sound when the headway distance was shorter than the warning distance L_0 expressed by the following equation called Stopping Distance Algorithm[2].

$$L_0 = \frac{V_f^2}{2\alpha_f} - \frac{V_l^2}{2\alpha_l} + V_f \cdot t_1 \qquad \text{(Eq.1)}$$

L_0 Warning distance

V_f Following car velocity

V_l Leading car velocity

α_f Assumed following car deceleration

α_l Assumed leading car deceleration

t_1 Time margin

Table 2 shows the logic parameters used in this experiment.

Table 2. Logic parameters

α_f	5.9 m/s^2(0.6 G)
α_l	7.8 m/s^2(0.8 G)
t_1	1.0 sec

EXPERIMENTAL RESULTS

Driver's Brake Response - Figure 4 shows the relationship between the subject's brake response time and the headway distance just after the preceding car's sudden deceleration for the case of with/without warnings. The subjects who avoided collisions with the preceding car by changing the lane were excluded in this figure. Filled markers indicate that the subject couldn't avoid a collision. This result shows that the subjects who maintained small headway distances and/or responded slowly failed to avoid collisions and that the subjects' response times were generally shortened by collision warnings and also they keep longer headway distances with collision warnings.

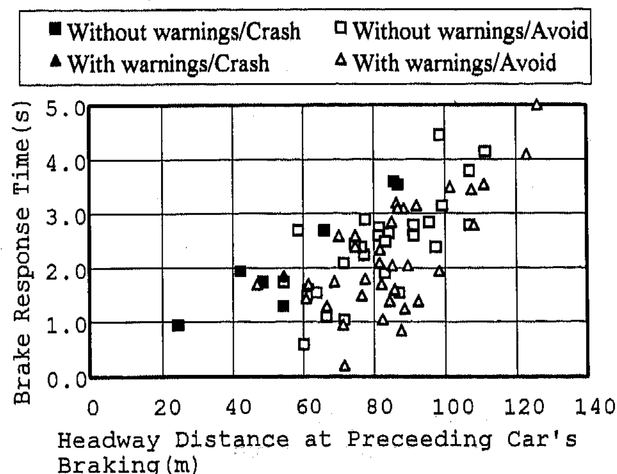

Figure 4. Braking response time with/without warnings

Before analyzing subjects' collision avoidance behavior, the subjects were grouped by the headway distance in car following situations into 3 groups: a small-headway group which kept headway less than 1 second(30%), a middle-headway group which kept headway from 1 to 2 second(52%), and a large-headway group which kept headway more than 2 second(18%).

Figure 5 shows the averaged response times of braking of each group after the preceding cars' deceleration. The average values were calculated by taking the logarithms of the response times. Table 3 shows the distribution of the logarithms of the response times with/without warnings. The results showed that the subjects in the middle-headway group responded about 0.5 seconds earlier on average with warnings than without warnings($p<0.05$), and in the other groups there were no significant differences.

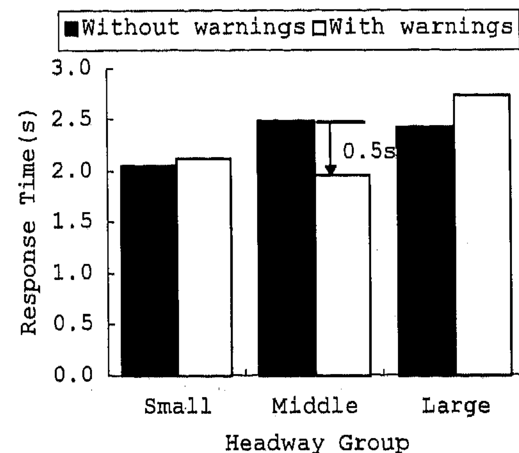

Figure 5. Averaged response time of braking for three headway groups

Table 3. Distribution of the logarithms of response times with/ without warnings

Headway Group	Average		Standard Deviation	
	without warnings	with warnings	without warnings	with warnings
Small	0.62	0.70	0.51	0.33
Middle	0.85	0.59	0.38	0.42
Large	0.83	0.95	0.35	0.36

Collision Rate - Figure 6 shows the percentage of the subjects who could not avoid collisions when the

preceding car decelerated suddenly under the conditions with and without the collision warning system. In this task, without warnings as much as 18.6 % of the subjects could not avoid collisions and the rest of them could avoid collisions successfully by braking, steering, or both braking and steering. With warnings, only 2.3 % of the subjects collided with the preceding car. Thus, the collision rate was reduced significantly (88 %)by the warning system($p < 0.05$).

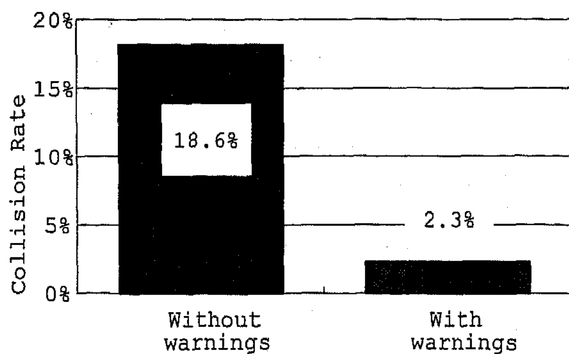

Figure 6. Collision rates with/without warnings

Figure 7 shows the collision rate for each headway group mentioned above. It shows some of the small-headway group could not avoid collision even with warnings, and the effect of warning was larger in the middle-headway group than the other groups.

Though there was no significant difference in the response time of the small-headway group between with and without warnings conditions, the collision rate of the small-headway group was much smaller with warnings than without warnings. These results indicate that the subjects in the small-headway group kept larger distances with warnings.

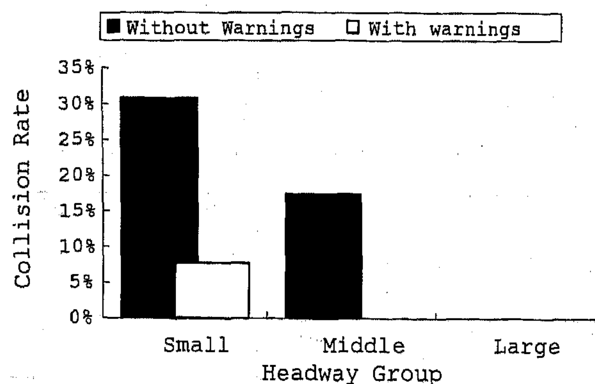

Figure 7. Collision rates for three headway groups

PREDICTION OF THE EFFECTIVENESS OF COLLISION WARNING SYSTEM ON THE ROAD

The current experiments simulated an extreme situation in which the preceding car braked at 0.8G while the driver looked off the road. Overall collision avoidance effects in general traffic situations can be predicted by assuming distributions of the deceleration and the headway distance, and by modeling the drivers' response to warnings.

Letting the initial headway distance when the preceding car starts braking at a deceleration α_l be L, and an avoidable delay time in which the following car can avoid a collision successfully by braking at a deceleration α_f after the preceding car's braking be t_a, t_a is calculated by Eq. 2.

$$t_a = \frac{L - \dfrac{V_f^2}{2\alpha_f} + \dfrac{V_l^2}{2\alpha_l}}{V_f} \qquad \text{(Eq. 2)}$$

The probabilities of collision can be calculated as the probability that the response time, which distribution is shown in Table 3, is less than the avoidable delay time t_a. Figure 8 shows the probabilities of collision when the preceding car decelerates at 0.8 G from 90 km/h(25 m/s) as the function of the initial headway distance.

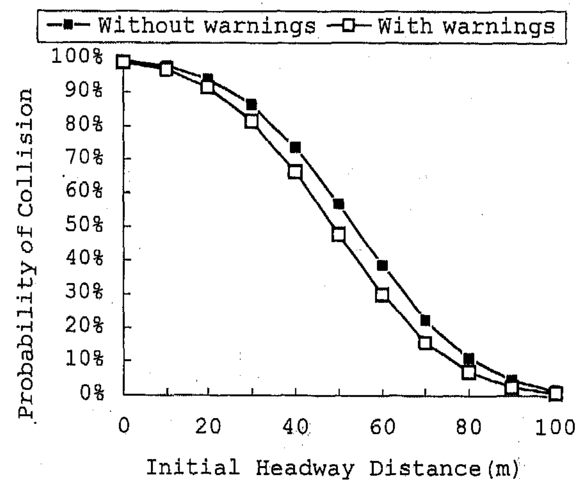

Figure 8. Probability of collision when preceding car decelerates from 90km/h at 0.8 G

To weight the initial headway distance for calculating collision probabilities, the distribution of the headway distance that the subjects kept in this

experiment shown in Figure 9 was used. And the probabilities of collision when the preceding car decelerates at 0.8 G with/without warnings were obtained as 13% and 24 % respectively. The collision reduction rate was 46 %. The estimated value for without warnings was close to 19% of the experimental result, but that for with warnings was much larger than the experimental result, 2%, and thus, the collision reduction rate was underestimated. The reason was thought that the subjects kept longer headway distances with warnings than those in this distribution.

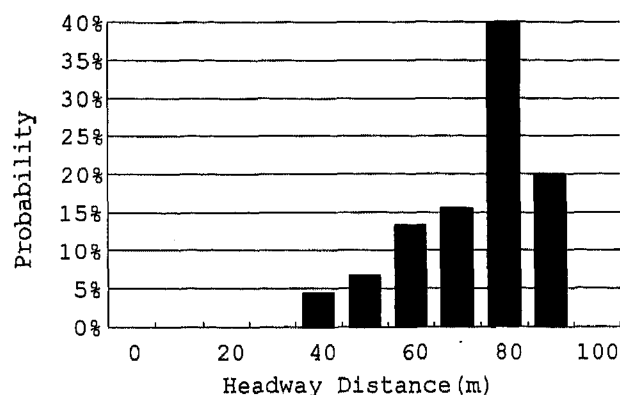

Figure 9. Distribution of the headway distance of the subjects in car following at 90km/h(25m/s)

Taking the same approach, the probabilities of collision with/without warnings for different decelerations of the preceding car were obtained as shown in Figure 10. This result indicates that as the preceding car's deceleration becomes larger, the probability of collision becomes larger for both with and without warnings and that the probabilities of collision with warnings were about a half of those without warnings.

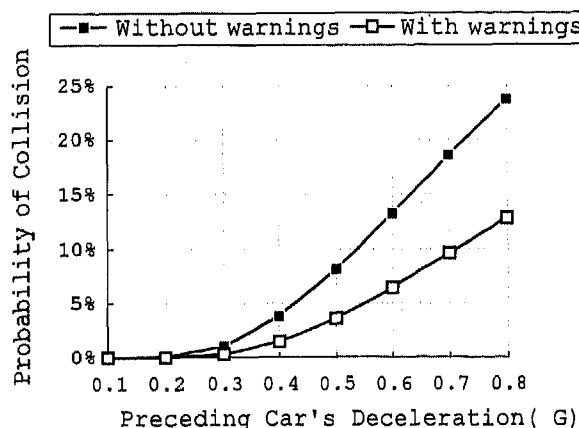

Figure 10. Relationship between probability of collision and deceleration

Using a distribution of the deceleration in a real traffic on the Metropolitan Highway in Tokyo: its average is 0.17 G and its standard deviation is 0.10G, the overall probability of collision while the driver looked off the road with/without warnings were obtained as 0.22 % and 0.58 % respectively. And it was estimated that collision warnings would reduce about 62 % of rear-end collisions. It must be mentioned here that the figures of the collision probability refer to the cases in which the driver looks off the road.

This prediction didn't consider drivers' behavioral changes; e.g. keeping longer distances with warnings than without warnings. As the longer headway distance would further reduce the probability of collision, if such behavioral changes can be modeled after obtaining enough experimental data, collision avoidance potential of a warning system would be much larger than this prediction.

CONCLUSION

With a collision warning system, the subjects were able to respond more quickly even when they looked off the preceding car; a collision reduction rate of 88 % was obtained in the simulator experiment.

However the experimental condition was an extreme case in which the preceding car decelerated at 0.8 G; therefore, assuming a distribution of deceleration in real traffic, an estimated collision reduction rate of 62 % was obtained. This value was close to that of the previous research which estimated that a collision warning system would reduce 60 % of rear-end collisions[2].

The prediction did not take into account the increase of headway distances with warnings which was observed in the simulator experiment. Therefore, if the driver's behavioral changes are modeled precisely after further experiments, the collision reduction potential of warnings would be substantially larger than the predicted value.

As the next step of research, we should optimize the warning algorithm and parameters. In this process, the collision rate will not be an effective measure, because with warnings the number of collisions will be too small to be analyzed statistically. So, a new quantitative measure to evaluate the safety margin for collision avoidance needs to be developed.

Single Shaft Parallel Hybrid Drive System

Knut Welke, Martin Ochs, and Hans-Joachim Schmidt-Brücken
Fichtel & Sachs AG

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

A joint venture of four German companies was build to develop and realize a hybrid car with a aluminium space frame. This paper summarizes the project from idea to prototype car. To find out the right drive system a comparison of alternatives was made. The result shows a clear advantage of the „single shaft parallel hybrid system with automated shift gearbox". The electric motor is a brushless permanent magnet synchronous machine with an outer rotor construction and liquid cooling system. The automated shift gearbox has a hydraulic actuator. The entire system is controlled by micro controllers.

INTRODUCTION

The goal of every automotive development project is to reach the level of mass production. A major step is to build up prototypes. A good prototype should be driveable by any person, not only by well trained specialists.

This paper summarizes the development process from an idea to a prototype car, which covers a time period of approximately 2.5 years. The car called uni1 (see figure 1) was introduced to journalists on November 6th, 1996 in Dresden by the involved German companies(2). It is planned to go ahead to mass production within 3 years.

Figure 1: The uni1 prototype car

MAIN SECTION

THE HISTORY - At the beginning of the project there was the idea to build up a car with a parallel hybrid drive system and a variable structure. The potential customers are delivery services, taxis, postal cars and other companies for urban traffic.

The target was to achieve limited zero emission capability without net fuel economy penalty. But also the possibility to drive between cities without range constraints was very important. There was no plan to develop a new combustion engine or gearbox. The fuel consumption was calculated according to the new ECE duty cycle. For the urban part (4.052 km) a power consumption of appr. 20 kW/100km was calculated, for the non urban part (6.955 km) 5.3 litre/100km was taken(VW value for Sharan TDI). With the equivalent of 5 kW per litre the overall fuel

consumption was calculated to 4.8 litre/100km. For a bigger urban part in the real duty cycle the fuel consumption will be even lower.

A joint venture of four companies was build to develop such a vehicle; it was supported by the Ministry of State for Economy and Labor of the State of Saxony.

To identify the most appropriate drive systems a comparison of eighteen alternatives, reduced to five main principles (see figure 2), was made; the systems were compared by the following factors (see table 1).

Figure 2: Five main parallel hybrid principles

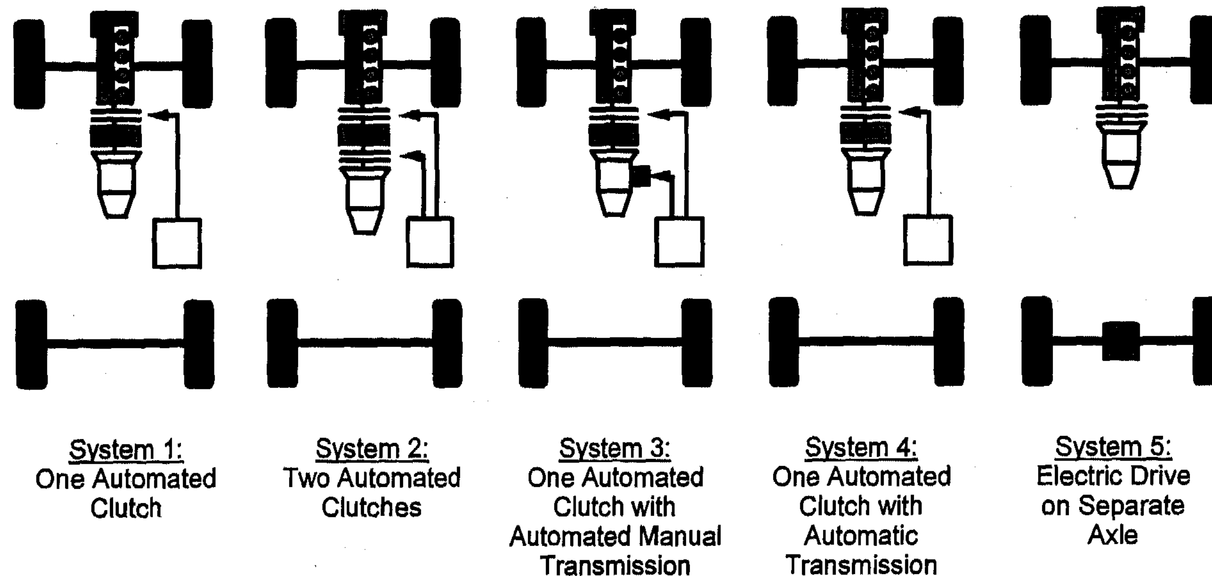

Table 1: Comparison of five main parallel hybrid principles

Evaluation Criterion's	Weight Factor	System 1: One Automated Clutch	System 2: Two Automated Clutches	System 3: One Automated Clutch with Automated Transmission	System 4: One Automated Clutch with Automatic Transmission	System 5: Electric Drive on Separate Axle
Comfort	10	1.0	3.0	3.5	3.5	1.0
Feasibility	7	1.5	2.5	2.5	2.0	3.0
Efficiency	7	2.0	2.0	3.0	2.0	2.0
Costs	5	3.0	2.0	2.0	1.0	1.0
Volume	5	3.0	1.0	2.0	2.0	1.5
Development Effort	3	3.0	2.0	1.0	2.0	3.0
Mass	1	3.0	2.0	2.0	1.0	1.0
Points		76.5	84.5	98.5	85.0	67.5
Position		4	3	1	2	5

The most important factor, which was multiplied by a factor of ten, is the comfort for the driver. The system must be easy to use for any person. Another important issue is the feasibility, which was weighted with a factor of seven. The overall efficiency is another important factor to avoid a net fuel penalty. The efficiency was roughly estimated as the possibility to allow automatic drive programs. The involved costs received a factor of five. Internal studies showed only a marginal cost difference between the various systems. Taking the costs of the batteries into consideration, the relative cost differences are negligible. Volume and mass are

only technical requirèments and their relativity depends heavily on the individual type of car.

The result of this comparison shows a clear advantage of the „single shaft parallel hybrid system with an automated shift gearbox" compared to all the other examined parallel hybrid systems (13,5 points difference). It was therefore chosen to be further developed. The reason why this system has not been developed before, is the high development effort involved in building a compact electric machine, an actuation system as well as a complex control system.

The same solution without an automated gearbox seems to be much more simple at first sight. But the synchronization rings of the transmission are unable to handle the substantially increased moment of inertia of the input shaft. Uncomfortable gear shifting (long shifting time) and shortening of the transmission life are the likely results. With the automated system the target gear is already known at the beginning of the shifting process. Therefore, the electric motor is able to synchronize the shaft speed before the gear is shifted. Due to the high acceleration capabilities of the electric machine, the shifting process can be done quickly and comfortably.

THE CAR - The potential customers for the car are delivery and postal services, taxis and urban companies. To fulfill all the customer requirements, a variable car structure and different designs are necessary. For this reason, a space frame technology was chosen (2), which allows variable axle bases and different designs (for example 1 to 7 seat van and pickup). To save weight and guarantee recycleability, aluminium was used for the hollow profiles of the space frame and for all sheet applications.

The combustion engine is the 1,9 litre VW TDI Diesel motor with a direct fuel injection system. The manual gearbox is also an unchanged high volume mass product of a big European car manufacturer.

The main data of the car is given in table 1.

Table 1: Main Car Data

Item	Value	Unit
Length	4400	mm
Weight (ready to drive with driver)	1500	kg
Maximum weight	2100	kg
Combustion engine maximum power (at 4000 rpm)	66	kW
Combustion engine maximum torque (at 1900 rpm)	202	Nm
Battery Voltage (without load)	284	V_{DC}
Battery capacity	60	Ah
Battery weight	200	kg
Maximum speed (combustion engine)	160	km/h
Maximum speed (electric motor)	100	km/h
Acceleration 0 - 100 km/h (combustion engine)	15	s
Acceleration 0 - 100 km/h (booster mode)	12	s

THE DRIVE SYSTEM - The complete drive system can be divided into four main components, which are explained in the next chapters.

The electric machine - There were three basic requirements for the electric machine. The electric motor must fit between combustion engine and manual gearbox without any rework on these mass products. The assembly of the engine-motor-gearbox system must be very easy and possible without any special tools. The electric motor must be sealed to the clutch to avoid problems with the dirt of the abrasion.

These goals are achieved with the design shown in figure 3. The electric motor is a brushless permanent magnet synchronous machine with an outer rotor construction and liquid cooling system. This machine has extremely high torque- and power-to-mass-ratios. Compared to an inner rotor construction this type of motor allows for a much smaller length, which is very important for a front drive system. The main data of the electric machine is summarized in table 2. The housing of the machine is specially designed for the mating components and can be used as an adapter for different hole pattern (e.g. if the gearbox is not designed for the used engine); the clutch is covered and sealed to the electric machine with a solid barrier.

Figure 3: The electric machine

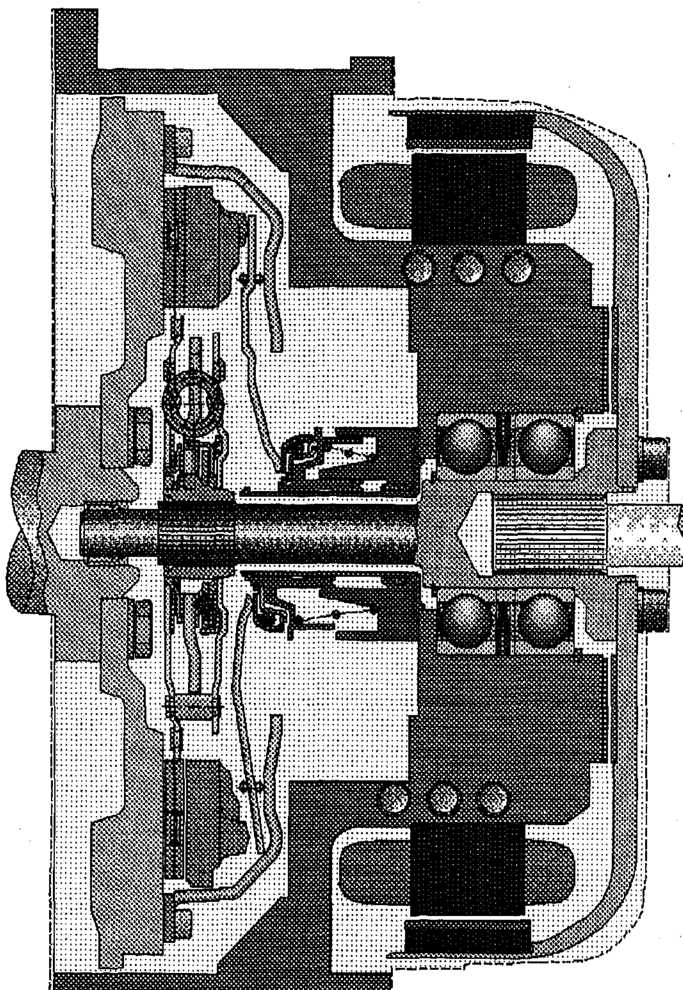

Table 2: Electric Machine Main Data

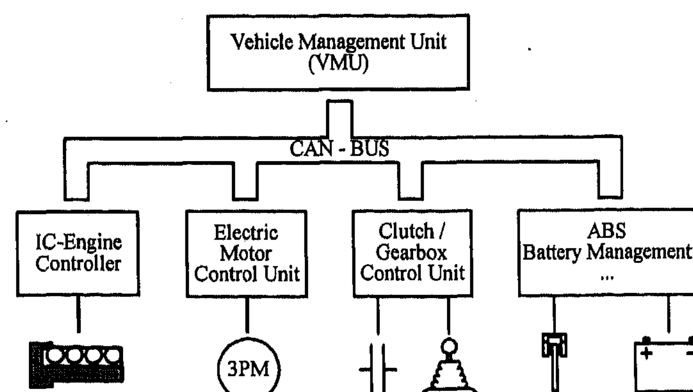
Item	Value	Unit
Maximum power	30	kW
Maximum continuous power	22	kW
Maximum torque	120	Nm
Maximum speed	5200	rpm
Maximum efficiency	93	%
Nominal voltage	200	V_{DC}
Degree of protection	IP66K	
Weight (with concentric slave cylinder)	28	kg

The rotor is fixed on a short shaft, which is guided in two ball bearings. To reduce the noise and extend the lifetime both bearings are spring loaded. Due to the forces of the permanent magnets a special device is necessary to assemble the rotor-stator unit, but in the assembled condition the motor is easy to handle. The electric motor can be guided to the rear face of block and fixed with two screws. Then the gearbox can be mounted on the electric machine and all screws can be added. The electric motor shaft is used as an extension of the gearbox input shaft and can be used as an adapter to combine different splines.

The machine is water cooled by a heat exchanging system, which is incorporated in the housing. This system is designed to minimize the pressure loss in the machine. In the prototype phase a steel pipe was wound and casted in the aluminium housing. For further motors a special casting technique is planned, which allows to make the hollow areas without additional parts; this process is based on a assembled styrofoam model, which is covered by unsolidified sand. The liquid metal melts down the foam and fills all remaining space. So a complex housing with integrated heat exchanger is possible. Using this method, the pressure loss will decrease, because the diameters inside will increase. In addition to the liquid cooling system an internal air flow system is incorporated into the structure. The „cold" air will be pumped with blades on the rotor through the gap between rotor and stator to cool down the magnets. The „hot" air will then be cooled down at the housing by flowing through the gap between rotor and housing; to complete a circle the air must flow through some holes in the rotor.

Special sintered Nd-Fe-B permanent magnets are used (3). These magnets have high energy densities and a high thermal stability. Also the target price is very attractive compared with other rare earth magnets.



The stator has copper windings on a laminated core. All materials, including the multilayer insulation materials and the impregnation is class C. The winding temperature is sensored by three thermal couples (NTC's). Planned for the future is a assembled stator with grain oriented material at the teeth . This system allows to produce the winding of every tooth separately on a simple winding machine and assemble the stator by clicking on the tooth later. Due to the use of grain oriented material the copper area is much bigger and therefore the losses will decrease. With this manufacturing process an excellent efficiency and total automation will be possible.

The brushless resolver of the motor is also a special development for the application in automotive drives. It is made of two circuit boards with big inside diameters. The overall length of the resolver system is less than 6 mm's.

The Clutch - The clutch is a modified high volume series disk clutch. The unit of flywheel, clutch and electric motor behaviours as a dual-mass-flywheel, when the clutch is engaged. This reduces the torsional oscillations by a high degree. The change of the spring-damping-ratios is necessary to move the self-resonant frequency below the idle speed of the combustion engine. The clutch is actuated by a concentric slave cylinder, which is a modified mass product.

The automated shift gearbox (ASG) -The automated shift gearbox has a hydraulic actuator for controlling clutch, gearbox selector angle and gear shift direction (3). Hydraulic fluid from the pressure accumulator is fed through a 3/2-way proportional valve directly to the clutch slave cylinder. The clutch position is controlled by a path-sensor, which is mounted on the slave cylinder. The selector angle position is regulated by a 3/2-way proportional valve and the gear shift travel is controlled by two pressure-regulating valves. The path is sensored at the gearbox actuator in both cases.

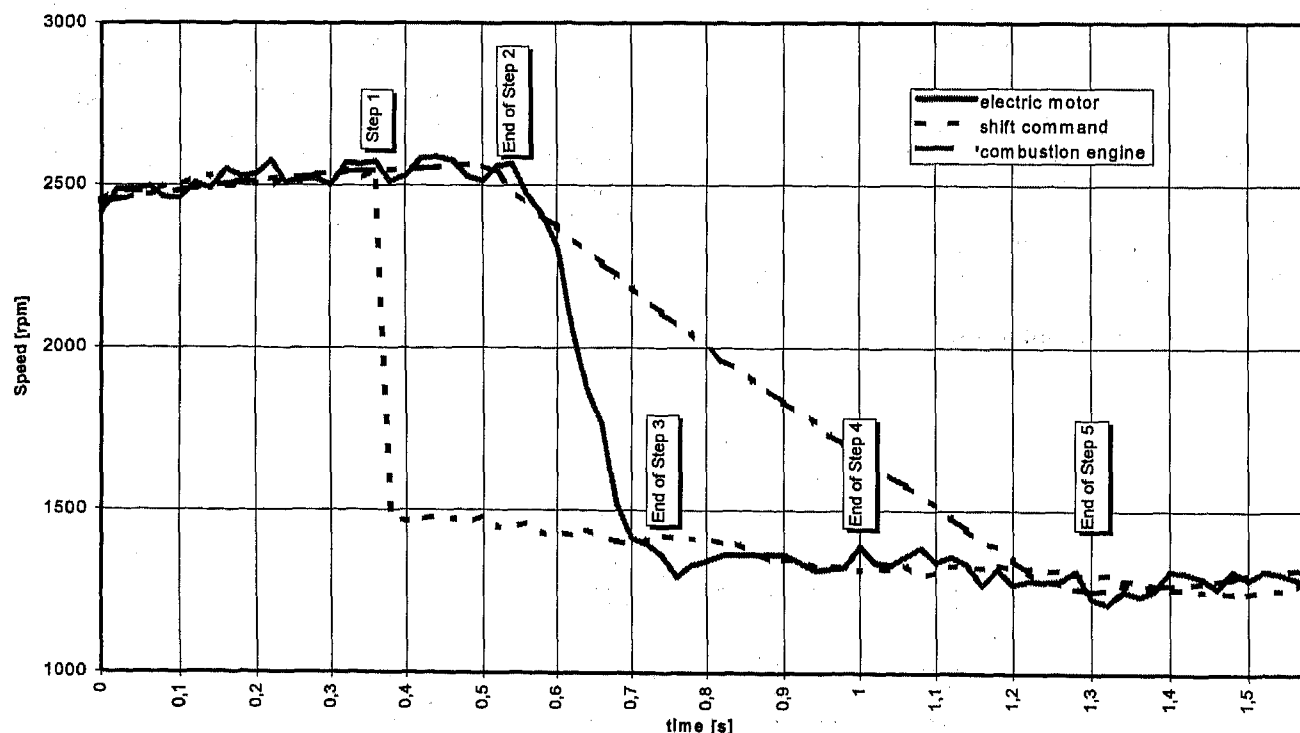
Figure 4: The electronic management

The electronic management - The control system consists of four control units. They communicate with each other via a CAN-Bus (see figure 4) The vehicle management unit (VMU) receives the key information's, e.g. road speed, speed of combustion engine, speed of electric motor, gearbox speed, accelerator pedal position, driving mode, actual and requested gear position. It coordinates the interaction of combustion management unit, electric motor control unit, clutch and gearbox control unit. The CAN-Bus is also used to transfer data from the ABS system and the battery management or to make information available for the instrument panel. There is the possibility of combining the individual control units in a later development phase in order to simplify the whole system.

THE REALIZED FUNCTIONS - The parallel hybrid drive system with automated shift gearbox offers multiple possibilities to realize driving strategies. In the simplest mode, the driver manually selects driving mode and gear setting. This is called shift-by-wire. Additional functions like regenerative braking or charging of the batteries by the electric machine, while the vehicle is driven by the combustion engine, are possible. Another driving strategy includes automated gear shifting. This allows for an automated selection of the optimal gear setting with consideration of fuel economy, driving and shifting demands. This reduces the burden to the driver having to change his or her gear selection behavior depending on the driving mode chosen. In addition, higher fuel economy can be achieved.

Figure 5 shows an active synchronized shifting process (shifting from first to second gear in combustion engine mode). This process can be divided into 5 steps. Step 1: After receiving the shifting command both torque's must be reduced to zero. Step 2: The gearbox must be shifted to neutral by the gearbox actuator. Step 3: The input shaft must be synchronized by the electric machine. After receiving the target speed signal the electric machine is braking (or accelerating in case of a down shift) to reach this speed as fast as possible. The time to synchronize in the diagram is about 0.2 seconds. Step 4: The gear must be shifted. The actuator shifts after receiving the synchronization signal. The shifting speed is selected to guarantee a „normal" wear of the synchronization rings. Step 5: The torque must be increased. The overall time for the complete process is less than 1 second, which is a good time for a comfortable shifting process. Increasing the time lets feel the shifting as very slow and the traction interrupt is uncomfortable. Decreasing the time leads into a hard „racing" shifting process. The quick torque differences are to big to achieve a comfortable feeling.

Figure 5: Shifting process



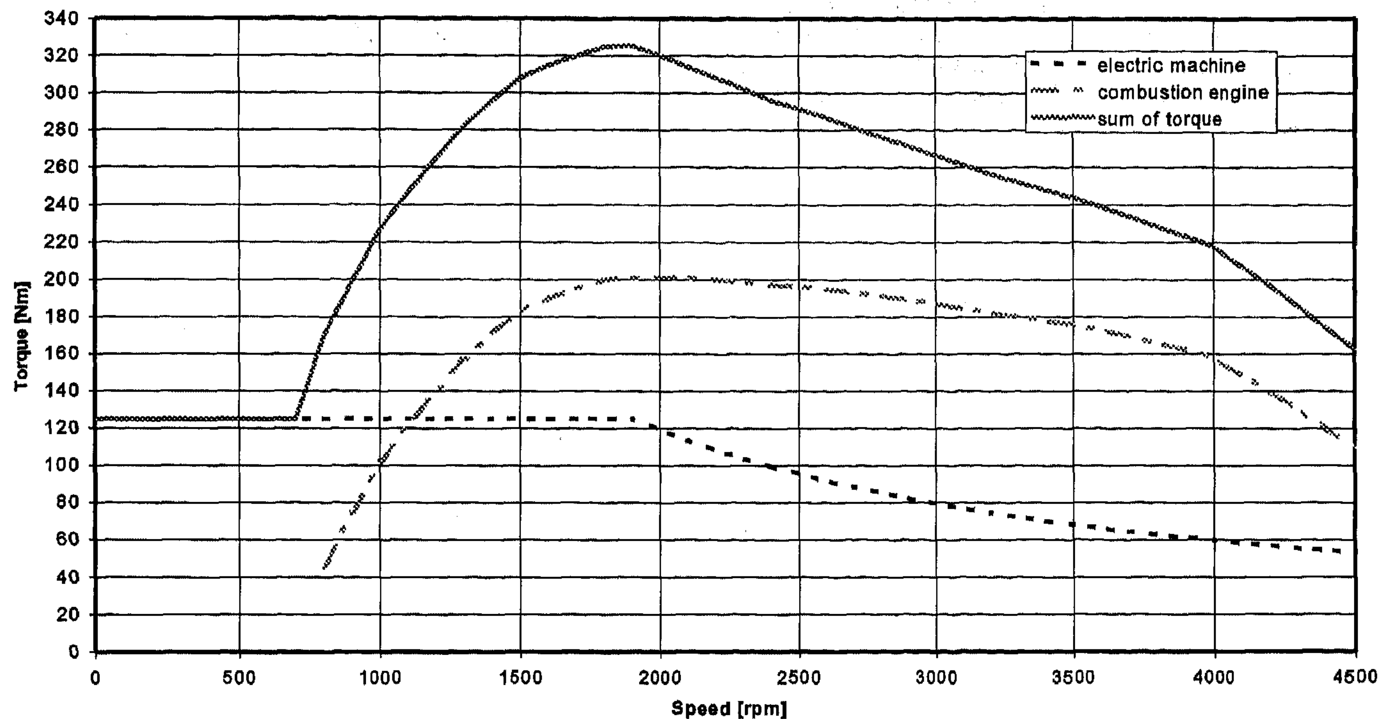


Figure 6: Torque in parallel mode

A simultaneous, parallel operation of ICE and electric motor is possible . Figure 6 shows a diagram with combustion engine torque, electric machine torque and the sum of both over the possible speed range. The maximum torque of the combustion engine (202 Nm at 1900 rpm) can be achieved in parallel mode at 900 rpm, which is only 200 rpm over idle speed. This high torque reserve of the parallel hybrid drive system allows high gear settings even at low speeds, which is desirable for fuel economy reasons. The electric motor can also support the engine during acceleration phases. The maximum torque of the system is about 320 Nm at 1900 rpm, which is comparable to a European sports car (e.g. Porsche 944 S2 has 280 Nm at 4100 rpm)

Also possible are some additional functions like a „hill-holder", which means the electric motor provide the exact amount of torque to hold the car on a hill; this is easy to realize, because all requested information is already accessible and the speed of the electric machine can be 0 rpm.

For the future it is planned to achieve a more complex strategy. It will end the strict separation of ICE-mode and pure electric mode. Depending on the demanded power, the vehicle management unit chooses the optimal drive mode. Fuel economy, driving and shifting demands, as well as frequency of switching between drive modes are being considered. The combination of automated drive mode setting as well as quick shifts into higher gears greatly increases the fuel economy.

CONCLUSION

Given the short development time, the realized prototype car is very attractive. The concept to build an alternative vehicle based on well developed series components, if they are available, is right one. The recommended variable design and the new drive system leads to an aluminium space frame technology for the car body. The hybrid drive system is also designed to use as much series components as possible. The major goals of the electric motor design are the use of combustion engine and gearbox without any machining and the easy assembly process of the drive components. The gearbox is automated by a hydraulic actuator, the clutch is actuated by a concentric slave cylinder. The entire system is controlled by micro controllers.

The realized functions and driving strategies showing the potential, what is possible with such a single shaft parallel hybrid car. The calculated fuel consumption must be verified in tests.

It is planned to go ahead with this project and realize a mass production within 3 years. The calculated number of cars is 15000 per year.

Prime Movers for Series Hybrid Vehicles

F. H. Moeller
Engineering Consultant

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

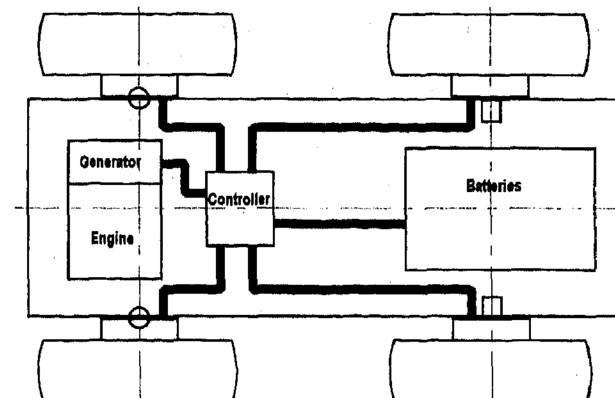
The known performance, emissions and fuel consumption of a VW Passat Estate car with a 1.9 liter Direct Injection Turbocharged and Intercooled Diesel Engine is compared with present and future power train concepts over a typical trip distance of 20 km at speeds between 20 and 130 km/h. (12.5 to 81 MPH)

The results are then used to discuss the proposals for future cars to change to electric transmission and to determine the power envelope for Series Hybrid Car Prime Movers. Various prime movers are also compared and the final choice is presented.

INTRODUCTION

PROBLEM: Most vehicles require their full wheel power only for very short bursts, i.e. for acceleration and hill climb. Additionally there is a human characteristic associated with cars, which is the desire to own and display more power than is actually ever required. This trend of greed for power is set to continue, in spite of more severe speed restrictions in the future. It is one of the main reasons for the fast depletion of oil reserves and for the global pollution problems we are facing.

The fact is, that all vehicles (including off road) are becoming more powerful and most of the prime mover development is concentrated on IC engines above 60 kW power output. The dilemma for the engine designer is, that an engine for a conventional vehicle is required to be powerful, fuel efficient and virtually emission free, not only at maximum power, but also at idle and anywhere in between. The prime mover has to have a virtually infinite power range.



The latest Direct Injection Diesel (DDI) Engines for cars have drastically cut average fuel consumption and emissions, but with an electric transmission and some energy storage in the vehicle we can do away with this need for extreme engine flexibility and save much more energy. Also we can eliminate the typical soot cloud eminating from car exhausts, when flooring the throttle after a low power run.

However, if the prime movers were to become smaller in output and size, their combustion chambers would be less efficient and if alternatively the number of cylinders would be reduced, bad vibration and noise problems would occur with unbalanced engines. These are the topics to be dealt with in this paper.

HYBRID VEHICLE: The Series Hybrid Drive vehicle is an ideal solution, to solve the prime movers problem of limited power range. The engine only requires to produce an average power.

Its required effective power range can be reduced from infinite to around 1 to 6 and in hot climates to even less.

The required maximum engine output can be lowered to approx. one third, engine efficiency increased and harmful emissions drastically reduced.

Schematic of Series Hybrid Car with 4 wheel motors

FIGURE 1

However, as these are relatively new developments, we should at first decide on how much "average" power will actually be required and how we can design a much smaller, smooth running engine which in the end must cost less than present prime movers. Also we need to forecast the fuel savings and emission improvements that can be made.

ALTERNATIVE PRIME MOVERS FOR HYBRIDS

The present alternative power for electric cars could be:

1) Energy storage only (batteries or flywheel)
2) Fuel cells + energy storage
3) Rotating generator + energy storage, with the prime mover alternatives being:
    - 3.1) Gas turbine
    - 3.2) Gasoline or Spark Ignition engine
    - 3.3) Diesel or Compression Ignition engine

BATTERIES or flywheels on their own do not have sufficient capacity or are simply too expensive at present, to be acceptable as the only power source for a family car.

FUEL CELLS continue to make progress, but the most advanced system, the polymer fuel cell requires hydrogen as fuel. The intermediate temperature solid oxide fuel cell can operate on methanol, but this system is only just beginning to be scaled up to the multi-kilowatt size. [1]

Gas turbines, with the low power output required here, tend to have very low basic efficiencies. They suffer from the scaling down effect even more so than internal combustion engines. If additionally they have to cope with part loads down to 1/6th of full power, their average efficiency would be such, that there would be no fuel saving over cars with a conventional transmission.

Small direct injection four stroke gasoline engines could quite nicely prove the concept of Hybrid Cars in general, especially if a two cylinder opposed piston layout was used. (BMW, Citroen, Velocette, Renault)

However, at the 1996 International Seminar on the "Application of Powertrain and Fuel Technologies to meet Emission Standards" where the discussions centered mainly around present and future car engines [2], it was concluded, that with low cost options, only the Diesel engine will easily meet future emission requirements. The handling of gasoline alone creates evaporation problems, which can only be eliminated by keeping the gasoline under pressure at all times. Also there is the much disputed poisonous benzene and other HC's, of which there are significant amounts in today's lead free gasoline. These can escape from present gasoline tanks and are emitted from the exhaust during the engine warm up phase. Furthermore the efficiency of gasoline engines, even with lean burn engines, is not likely to reach the levels of well designed Diesels, using high pressure fuel injection equipment.

This leaves the compression ignition engine as the best choice. We just have to make it smaller.

Scaling down conventional engines does not work, as there would hardly be any cost saving and their combustion chambers would be much too small for good efficiency and emissions.

The alternative proposed is a Completely Balanced Single Cylinder Compound Diesel Engine with Direct Fuel Injection.

MEASUREMENTS AND COMPARISONS

The fuel consumption of a VW TDI Passat was measured for distances of 20 km, at various average speeds, using the on board trip computer. This was then used to calculate mean power requirements and engine efficiencies. At the same time comparisons with other conventional engine efficiencies were made.

FIGURE 2 Photo VW Passat Estate

They were then also compared with two theoretical models of Hybrid Cars of the same size and weight, one using a gas turbine, the other the proposed single cylinder engine.

The data of the test vehicle are as follows:

VW Passat TDI Estate

weight	1360 kg (with driver)
engine power	66 kW at 4000 RPM
torque	202 Nm at 1900 RPM
engine bore/str.	79.5 / 95.5 mm, 4 cyl.
overall transm. ratio	45 km/h per 1000 RPM
vehicle top speed	175 km/h
frontal area	2.3 m², cd = 0.3
acceleration	80 to 112 km/h in 12.4 sec
quoted fuel cons. at 90 km/h	= 4.2 l/100 km

The fuel consumption at various steady speeds was measured with a warm engine. This fuel consumption compared very well with the car manufacturers claims.

They were then also measured for typical distances of 20 km at an ambient temperature of 5 ° C, starting with a cold engine each time and then averaged out, to give a meaningful result.

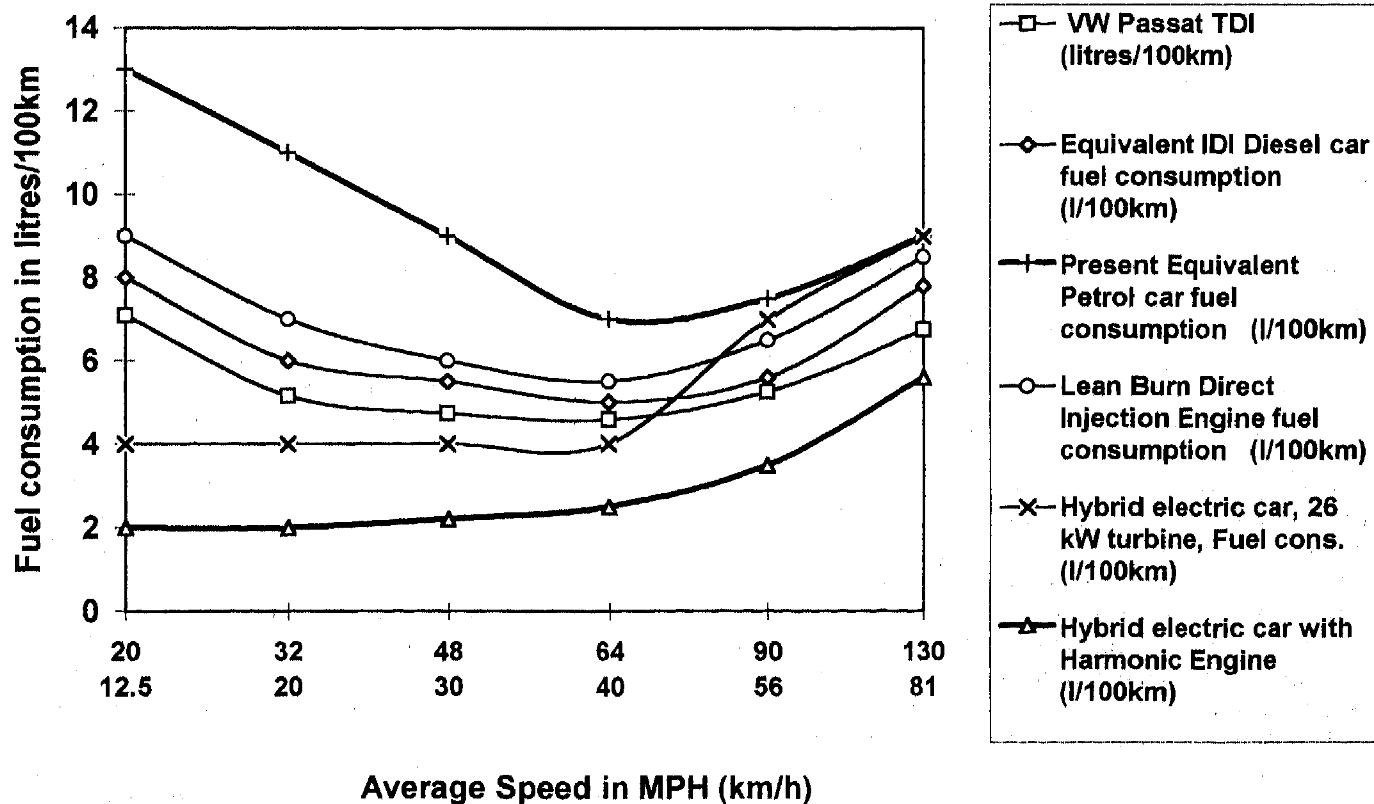
The largest influence on fuel consumption for a typical trip was found to be the time taken for the engine to reach working temperature. At temperatures colder than 5° C fuel consumption increases considerably and in the summer months it was very much lower.

The second largest influence was the strength and direction of the wind. A strong head wind would increase fuel consumption by up to 20%.

Also the type of road and traffic conditions, had a big influence. The driving style adopted was with reasonably brisk acceleration, but cruising in top gear wherever possible.

EFFICIENCY CALCULATIONS: The next step was to determine the mean engine efficiencies of this VW TDI engine, at various vehicle speeds. This was simply done by calculating the required engine power, using the following formula:

$$P = 12.8\,(V/100)^3 \times Cd \times AF / TTE + W*Cd*V/360$$



whereby
P is the power in kW
Cd the cars drag coefficient = 0.3
AF the cars frontal area = 2.3 m²
TTE the total transmission eff. = 0.86
W the weight of the car = 1360 kg
RF the rolling friction coeff. = 0.015
V the car speed in km / hour

Converting the fuel consumption to g/h and dividing this by the required engine power results in the generally quoted specific fuel consumption unit of g/kWh, which is inversely proportional to efficiency, whereby with average Diesel and Gasoline Fuels

100 % Eff. = 81.9 g/kWh

Fuel Consumption over average speed, 20 km trip   Figure 4

Average Speed in MPH (km/h)

Engine Efficiency over average speed, 20 km trip Figure 5

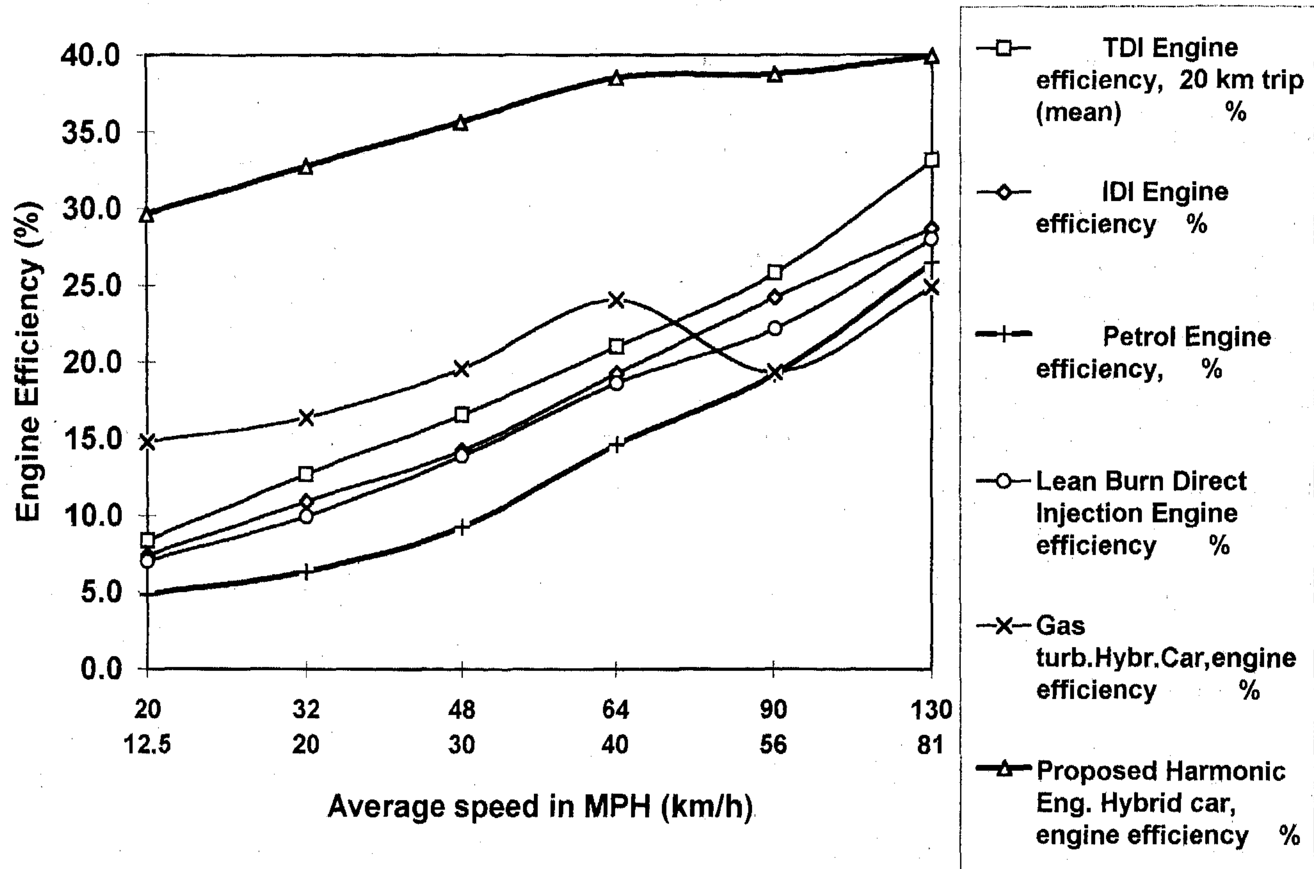

Figure 3 lists these results for the VW TDI (DDI) engine. These speak for themselves and graphs, Fig. 4 & 5 compare the fuel consumption and efficiency of all the drive lines considered. The MPG data for the alternative engines were taken from a multitude of generally available car test reports and present a reasonable average of engines presently available.

We can see, that even the DDI engine, as one of the most efficient car engines to date, has extremely low part load efficiencies. For instance, if we are driving on the level at a steady 48 km/h, when we require 3.8 kW engine power, the engine efficiency is only 21.5 %. The mean efficiency for a typical trip at an average speed of 48 km/h is lower still, at 16.6 %.

Using other prime movers, such as Diesel Engines with swirl chambers (IDI), we get 14.2% and with conventional Gasoline Engines only 9.3%.

Only the Lean Burn Gasoline engine with Direct Injection (GDI) shows reasonable results again at 13.9%, which is not much worse than the IDI Diesel. (Mitsubishi claim theirs to be equal to the IDI engine)

The point to make here is, that with all IC prime movers, especially the conventional gasoline engine, efficiency increases considerably at higher loads and if engines could be made to run at a high load rather than very small part loads, we could drastically reduce our fuel consumption, especially when traffic density limits our speeds.

This is the biggest argument for Hybrid vehicles.

ENGINE POWER FOR SERIES HYBRID VEHICLE

Power requirements are most dependent on the maximum speed the vehicle is likely to be driven at for any length of time. Long uphill gradients and head winds add to this required power.

In the end it will depend mainly on the speed restrictions which will be applied in the various countries.

If we use a prime mover power of say 30 kW and consider, that we have a series arrangement in our Hybrid Car. (Fig 1) In other words, the engine would be driving the generator, which at steady speed, would power the motors directly, with any excess power being used to charge the storage batteries (or accelerate the energy storage flywheel). The drive motors using this energy, could be mounted close to or inside at least 2 of the wheels. We then also have to assume an electrical transmission efficiency, which with the latest motors and control gear could be similar to the mechanical efficiency of a mechanical driveline, at 0.86 overall (generator 0.95, motor 0.95 and controller 0.95) (the battery is bypassed here)

Using the same car as a datum, this would then result in a continuous cruise speed of 130 km/h, or taking slight gradients and some head winds into account at least 120 km/h, which should be reasonable for future cars. Of course, short term top speeds could be very much higher and an installed wheel motor power of say 4 times 20 kW should result in very good acceleration figures and a peak top speed of 200 km/h.

PROPOSED HYBRID ELECTRIC CAR

Car size & weight, similar to VW Passat
Battery, advanced lead acid or NiCad, storage capacity 5 kWh net, max. weight = 200kg .
Two or Four drive motors with epicyclic reducers in or close to wheels,
80 kW total power, Electric Traction control, Electric Servo steering, Regenerative braking + Electric ABS
Integrated Two Stroke Diesel Engine with Brushless Generator,
Three Engine Power levels,
full load: 30 kW at 3000 RPM
part load: 12 kW at 1800 RPM
City (heating or air conditioning) : 5 kW at 1200 RPM (CHP)
(Continuous Speed and load variation should also be considered)
Max.Engine shut down period = 1h in city
Single cylinder (power) 600cc
Charge and recovery cylinder/piston 1200cc
Two Stroke Diesel cycle, max. BMEP = 12 bar
Engine in complete dynamic balance
Engine weight including generator = 80 kg

This could be the ideal car for most people. Good performance and Safety, with an infinite range, running on Diesel, Kerosene, Rape Seed or DME fuels, at a fuel consumption unheard of before and sufficiently large inside, to meet today's standards of family cars.

Regenerative braking would not require it to be especially light and in towns or cities the engine could be turned off. An additional plug in gen set (in the boot) could also make it suitable for towing trailers and caravans at reasonable speeds.

The key component for such a car is a small, smooth running Diesel Engine which should be controlled in such a way, that it either runs under load for long periods of time, or is turned off altogether.

Because the engine would generally be running at an optimum load and temperature, harmful emissions could be cut substantially. As it is smaller and running at higher specific loads, it would reach its best working temperature very much faster.

Also, depending on its utilization, it may be advisable to keep the engine warm at all times, by insulating and perhaps even electrically heating the coolant and the oil while the engine is stopped.

GAS TURBINE CONCEPT

Another theoretical model of a Series Hybrid car would be the Gas Turbine Concept, with the turbine as proposed by NoMac Energy Systems. [3]

This would be lower still as regards NOX emissions, but its fuel consumption would be very much higher.

Basic data:
Car layout and electrical concept as above
Car size & weight, similar to VW Passat.
Two Turbine Power levels assumed i.e. 26/10 kW at 96 000 RPM max, 3:1 pressure ratio, max. gas temp. 850° C, air fuel ratio 134:1, with high efficiency recuperator, weight including generator 41 kg.

The estimated fuel consumption and efficiency data of these concepts are again listed in Fig. 3, and as graphs in Fig. 4 & 5

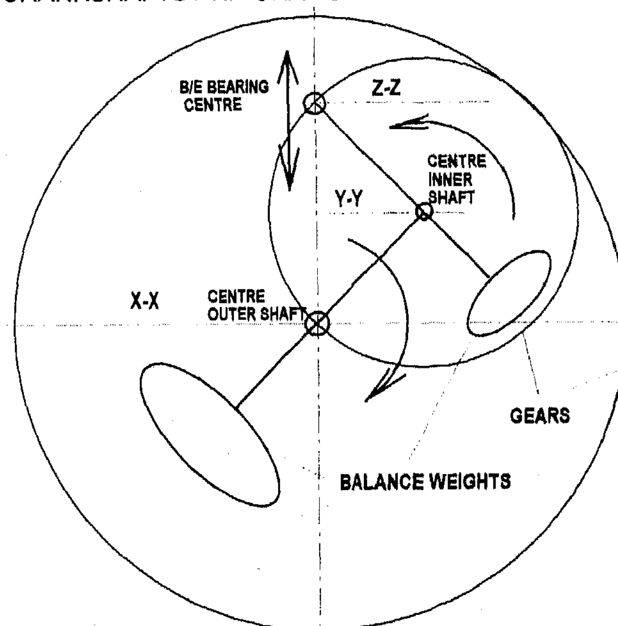
INTERIM CONCLUSIONS:

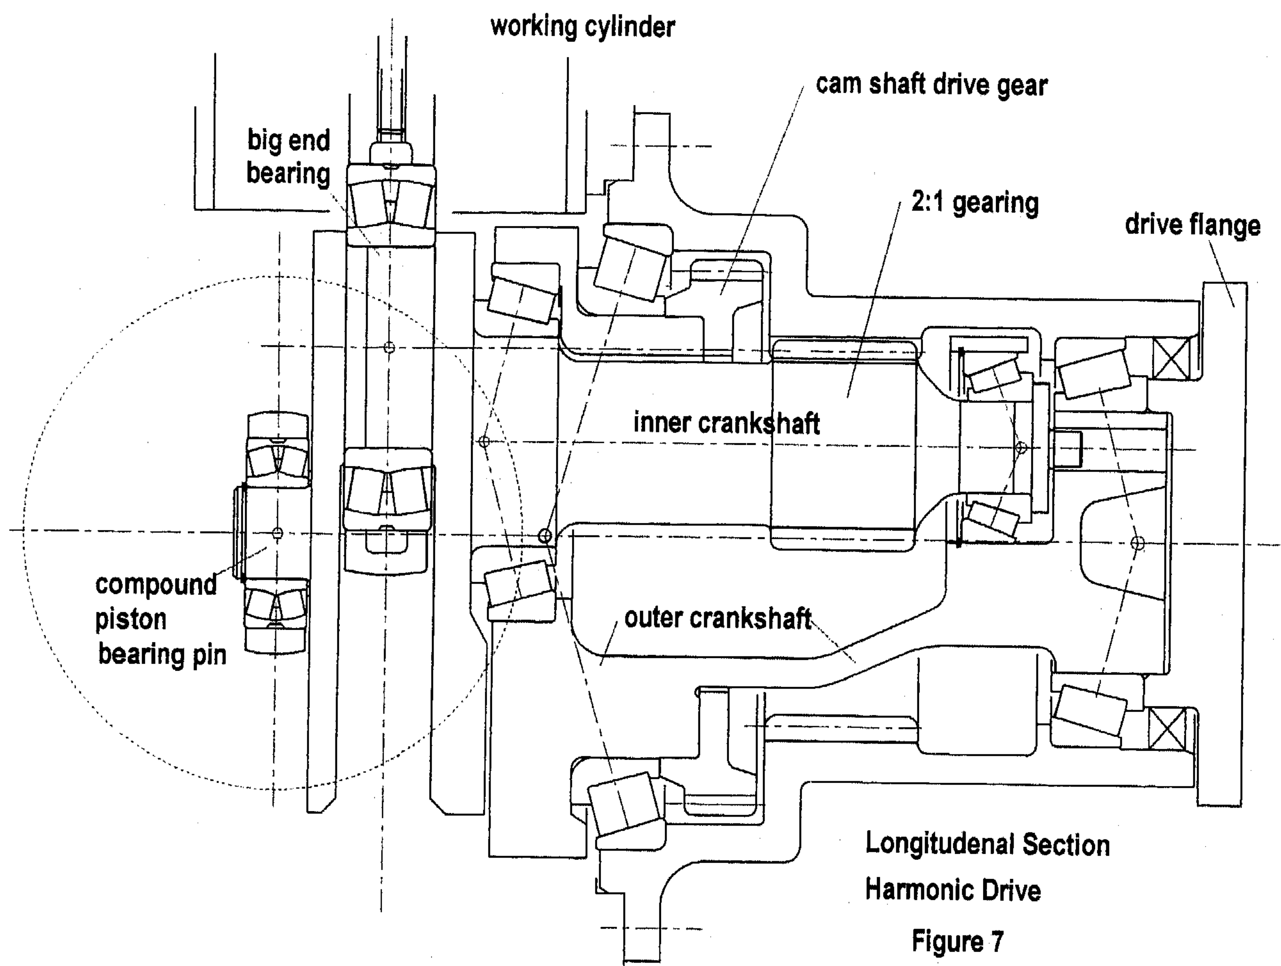
At an assumed mean speed up to 130 km/h (81 MPH) a Hybrid Electric Transmission combined with a small prime mover and some battery or electrical flywheel energy storage could approximately half the present fuel consumption of all conventional cars, in addition to drastically cutting harmful emissions. The maximum power requirement for a Series Hybrid Car Prime Mover would be in the region of 30kW.

These two statements apply to a family sized car, regardless of the initial choice of prime mover.

DESCRIPTION OF PROPOSED ENGINE

FULLY BALANCED SINGLE CYLINDER POPPET VALVE TWO STROKE DIRECT INJECTION COMPOUND DIESEL ENGINE, WITH HARMONIC CRANKSHAFTS AND CHARGE / RECOVERY PISTON.





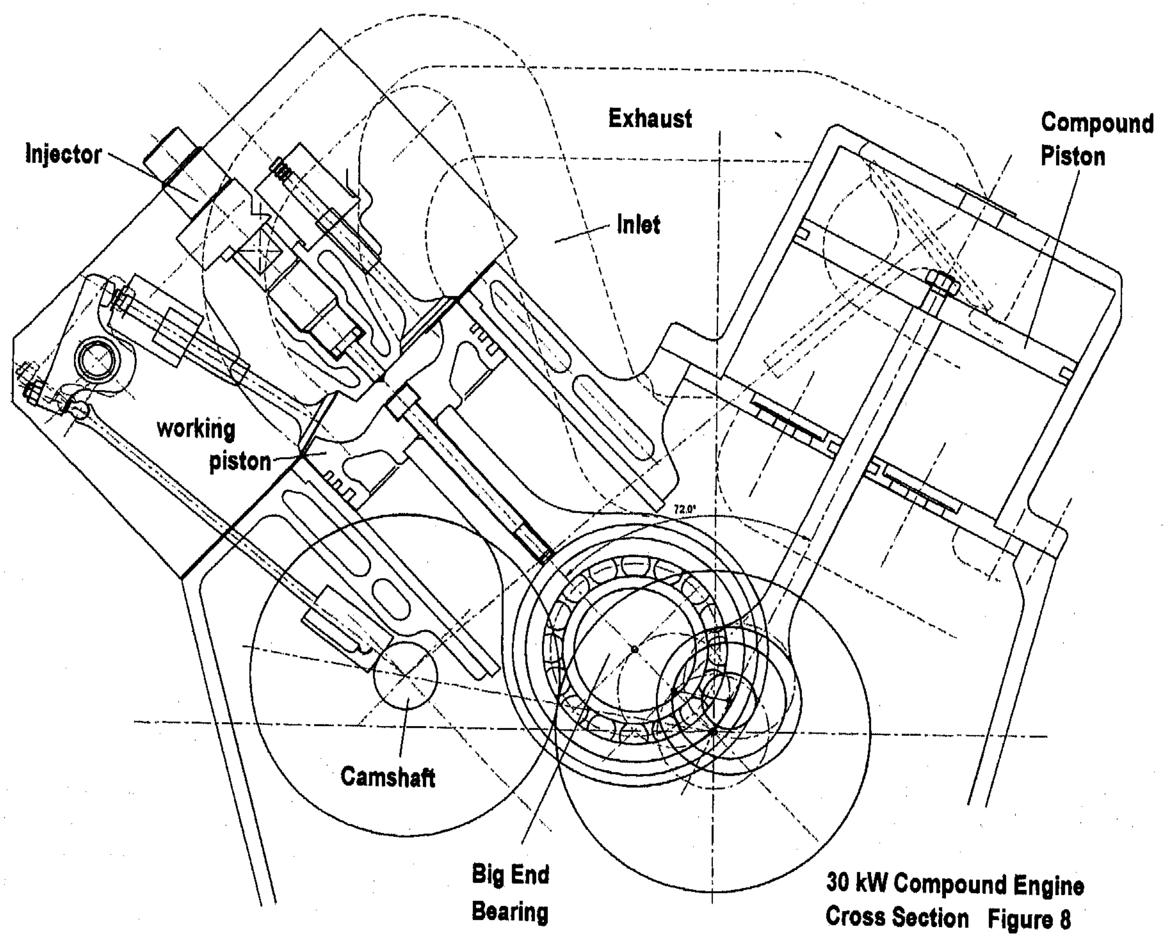


Figure 6 Basic principle of Harmonic Crank Drive

The Harmonic Crankshaft principal is not new and first proposals date back to the 19th century. There are two crankshafts mounted inside each other. They are counter rotating at the same speed and have equal crank radii, causing the big end journal, which is the crank of the inner shaft, to move in a straight line, so that no small end is required in the piston. The balance weights on the inner crankshaft counter balance the inner crank and the piston assembly. The weight on the outer crankshaft balances the whole of the inner crankshaft assembly, including the piston. The 2 : 1 ratio gears are synchronizing the two crankshafts.

Canti levering of the crankshafts and the arrangement of the balance weights are the subject of new patents. The application of these patents make a cost effective design possible. For driving the Compound Piston, a smaller canti levered pin is used, which also describes a straight line, but at a different phase angle.

Longitudenal Section
Harmonic Drive
Figure 7

30 kW Compound Engine
Cross Section Figure 8

Drawings of the complete engine are shown on Fig.7 and 8 (cross- and longitudinal section), which also provide a section through the poppet valves [4] and combustion chamber. It is here, where most of the development is taking place and the drawings do not show a final design.

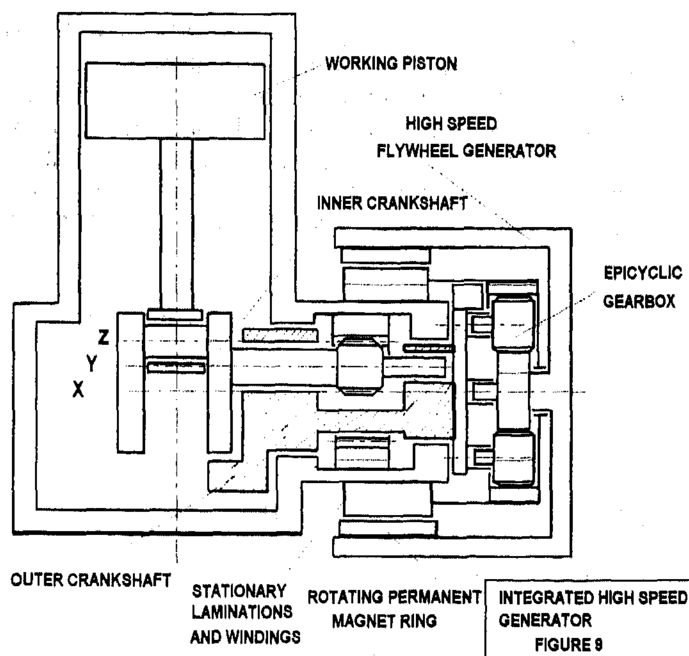

FIGURE 9

Figure 9 (schematic drawing) shows the principle of integrating a brushless generator with the engine. This drawing also shows a speed increasing gearbox, which is used to run the permanent magnets at higher speeds to generate the required current with a relatively small rotor.

PRESENT STATE OF DEVELOPMENT

There is no new technology presented here. The complete concept of a Series Hybrid car with the proposed small Diesel Engine is merely bringing present technologies together. The data presented is based on using the current level of technology on batteries, motors and generators, electronic control, shafts and gears, bearings, poppet valves, combustion chambers and fuel injection equipment. Further improvement of all these items will show better performance still.

The Cantilevered Harmonic Crank Drive has been tried in a single cylinder 4 stroke Diesel engine and has shown superior running qualities as compared with a conventional single cylinder Diesel engine. The two stroke poppet valve engine is described in a Ricardo report [4] and a Diesel version is presently under test, showing very good power levels and good efficiency. The results of these tests are partly used as a basis for the data in Figure 3.

SUMMARY OF ADVANTAGES OF SERIES HYBRID CAR WITH PROPOSED ENGINE

1) Average efficiency vastly increased, according to our predictions, we could virtually half the fuel consumption and CO2 (Fig.10) emissions of the present best Diesel cars.

2) Zero Emission range = 50 km at 48 km/h (30MPH) for local and city driving. (The possibility of Mains Charging and not running the engine, has not been taken into account)

3) Very low emissions, when the engine is running. With fuel injection, Two Stroke NOX Emissions are lower than Four Stroke. Optimum load and temperature conditions ensure very low CO, HC's and Particle emissions.

4) Infinite range as with conventional cars at average speeds up to 130 km/h (81 MPH).

5) Three engine power ranges i.e. 5, 12 & 30 kW automatically switched or varied, according to drive power or battery charge requirements and occupant heating / air conditioning, at low mean vehicle speeds.

6) Fuel can be conventional Diesel, Kerosene, Paraffin, Vegetable oil, Dimethal Ether and with Diesel pilot injection even LPG or Methane.

7) Driveability, performance and safety of vehicle is vastly improved. (ABS & Traction Control)

8) The regeneration of the cars static and kinetic energy, in brake mode, will make it less important to design for minimum total weight of the car.

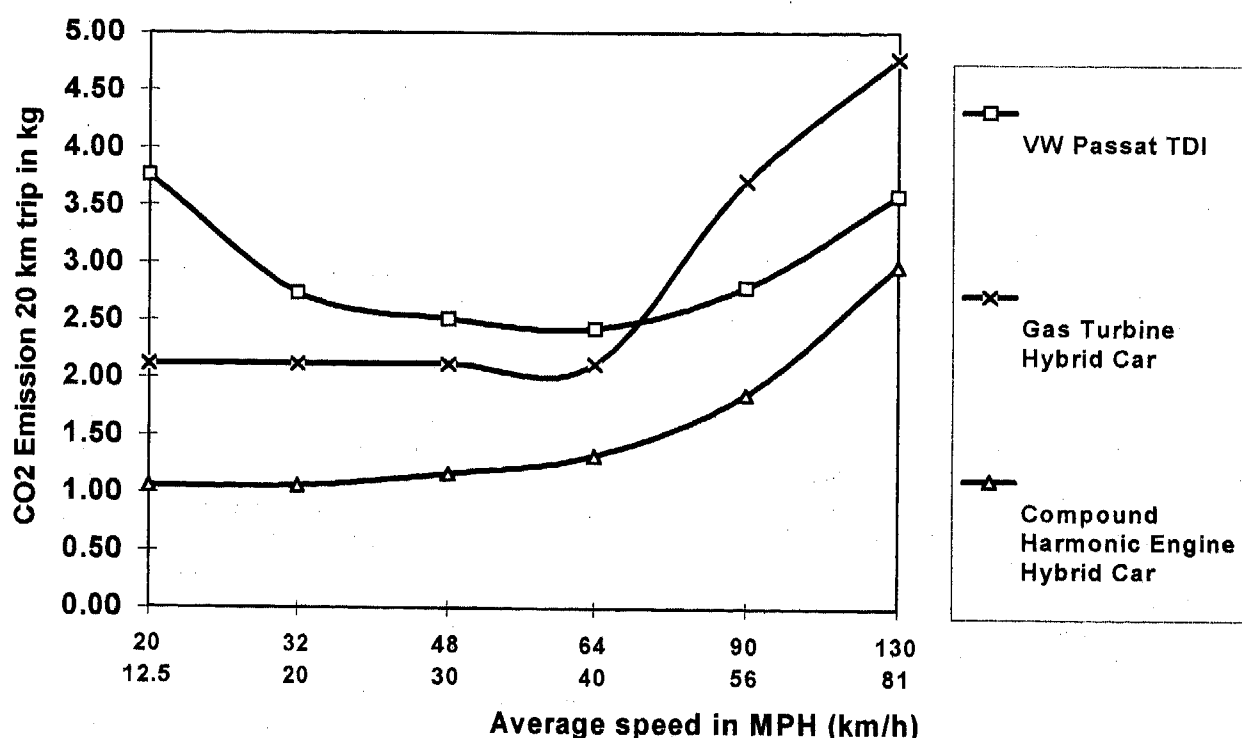
9) The removal of the conventional transmission, differential, prop or drive shafts, axles and disc brakes could, on final analysis for mass production, balance the cost (and weight) of the additional batteries and drive motors. The cost of the single cylinder engine, complete with generator and control should be no higher, than present Diesel engine costs.

FINAL CONCLUSIONS

♣ The series electric Hybrid car concept, with any type of prime mover, even a relatively inefficient gas turbine, is the only concept to date, which can combine very good fuel consumption and low emissions with present and future requirements of improved drive power, traction, safety, driver and passenger comfort and driveability.

♣ Because of the relatively low power requirement of the Hybrid Car Prime Mover, propably the most cost effective and fuel efficient engine for such a Hybrid car is a single cylinder Diesel engine with an efficiency potential of more than 40%. This therefore is the best choice, if low CO2 emission levels are a prime requirement. Based on our projections, all the other emissions from such an engine could be well below future emission standards.

♣ Vibration (and noise) levels of unbalanced single cylinder engines are not acceptable and the cantilevered Harmonic Crank Engine principle could be the most cost effective way to balance such an engine in any order and plane.



♣ The Engine proposal here also combines the high power density of the Two Stroke principal with a charge and exhaust gas energy recovery piston and cylinder, which increases the efficiency potential of the engine and considerably reduces noise levels.

This piston is added without affecting the perfect balance of the engine. No turbocharger is required to increase engine performance. The ratio of charging piston to working piston area will determine the potential output torque.

♣ The Harmonic Drive principal suits the Two Stroke Cycle, as the hitherto problematic small end in the piston is eliminated. Furthermore, there are no piston side loads, which reduces the mechanical friction and enhances the engines efficiency potential. Lubrication and cooling of the engine presents no problem, as the oil, water and combustion spaces are clearly separated.

The proposed concept makes it possible, to reduce the average fuel consumption of a family sized car to 2.5 liter per 100 km. (*)

Analysis of the Fuel Economy Benefit of Drivetrain Hybridization

Matthew R. Cuddy and Keith B. Wipke
National Renewable Energy Lab

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

Parallel- and series-configured hybrid vehicles likely feasible in next decade are defined and evaluated using NREL's flexible ADvanced VehIcle SimulatOR, ADVISOR. Fuel economies of these two diesel-powered hybrid vehicles are compared to a comparable-technology diesel-powered internal-combustion-engine vehicle. Sensitivities of these fuel economies to various vehicle and component parameters are determined and differences among them are explained. The fuel economy of the parallel hybrid defined here is 24% better than the internal-combustion-engine vehicle and 4% better than the series hybrid.

INTRODUCTION

Automobile drivetrain hybridization (using two types of energy converters rather than just one, as conventional-drivetrain vehicles do) is considered an important step to high fuel economy. The Department of Energy has established cost-shared programs with Chrysler, Ford, and General Motors under the Hybrid Vehicle Propulsion System Program to double the fuel economy of midsized automobiles, without sacrificing performance and consumer acceptability, by hybridizing their drivetrains. The government/industry Partnership for the New Generation of Vehicles (PNGV) effort has also identified hybridization as an important step toward tripling mid-sized sedan fuel economy. Recent and ongoing work seeks both to identify the likely fuel economy gains hybrid vehicles can deliver, and to ascertain the hybrid configuration that will lead to the best fuel economy [1-6].

Tamor, of Ford Motor Co., uses energy throughput spectra of current internal-combustion-engine vehicles (ICEVs) along with Ford Ecostar electric-drive data and an idealized battery model to estimate the greatest possible benefit of drivetrain hybridization to be 50% [6]. Given a 100% efficient energy storage system and ideal control stragegy, Tamor estimates a parallel hybrid will have a combined federal fuel economy of roughly 1.5 times the fuel economy of an ICEV of similar mass and engine technology. (Combined federal fuel economy is computed assuming 55% of miles are driven on the USEPA Federal Urban Drive Schedule (FUDS) and 45% on the USEPA Federal Highway Drive Schedule (FHDS).) Further, Tamor concludes that engine and road loads being equal, a parallel hybrid is more fuel-efficient than a series hybrid. Mason and Kristiansson, however, assert that series hybrids are likely to be more fuel-efficient than parallel hybrids [7]. Initial studies at NREL using current and projected component data indicated that series and parallel hybrids have similar fuel economy potential [8].

This analysis predicts the fuel economy differences among a series hybrid, a parallel hybrid, and an ICEV of similar levels of advancement and performance, using component and vehicle data adapted from current technologies. The methods of analysis and assumptions required are presented. The dependence of the fuel economy of each vehicle upon the assumptions are presented, allowing an understanding of the various projections of hybrid fuel economy made in the literature. Sensitivity coefficients, required for the fuel economy sensitivity analysis and analogous to the "influence coefficients" discussed by Sovran and Bohn are also presented [9]. These sensitivity coefficients may be used to estimate the fuel economy of derivatives of the vehicles presented.

The National Renewable Energy Laboratory's (NREL's) ADvanced VehIcle SimulatOR (ADVISOR), was used along with data from the literature and from industry contacts to define and evaluate charge-sustaining hybrids (which may operate without wall-charging, as long as there is fuel in their tank) and a ICEV for comparison. ADVISOR was also used to determine numerically the sensitivity of each vehicle's fuel economy to changes in vehicle and component parameters. These sensitivities were then used to analyze the predicted fuel economy differences among the three vehicles.

The only vehicle figure of merit being considered here is fuel economy. We recognize that there are many other important issues to be resolved in the development of a

vehicle such as cost, reliability, and emissions. Our focus here, however, is solely on the likely potential to improve fuel economy by drivetrain hybridization. With that focus, we found the series hybrid defined here is 18% more fuel-efficient than the ICEV and the parallel hybrid is 24% more fuel-efficient than the ICEV. A 10% drop in battery turnaround efficiency (from ~88% to ~80%) causes a 1.5% drop in series hybrid fuel economy (for this particular control strategy) and a 1.3% drop in parallel hybrid fuel economy. The sensitivity to regenerative braking effectiveness is likewise small: a 10% drop in regenerative braking effectiveness causes a 0.7% drop in parallel hybrid fuel economy and a 1.0% drop in series hybrid fuel economy.

BASELINE VEHICLES

The vehicles used in this study were defined using current and projected vehicle and component data. Using NREL's vehicle performance simulator, ADVISOR, (which has been benchmarked against industry simulation tools,) the components were sized to meet performance goals, and transmission and hybrid control strategies were optimized for fuel economy subject to performance constraints. ADVISOR was then used to evaluate the vehicles' fuel economy. The vehicles in this study are shown schematically in Figure 1.

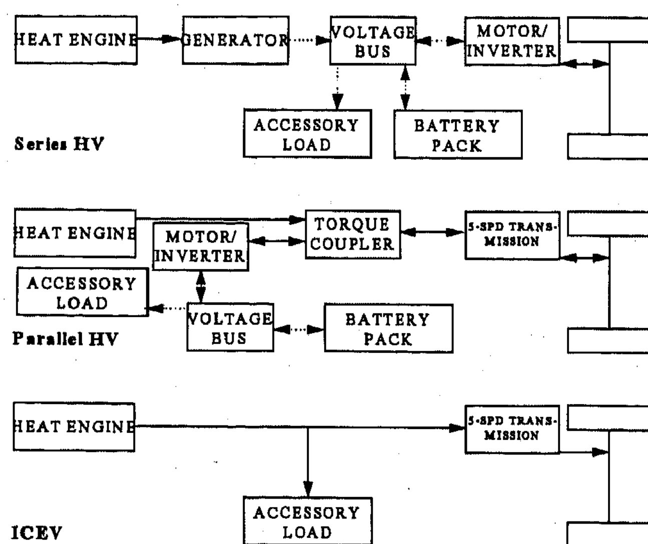

Figure 1. Energy-flow schematics of the series hybrid (top), parallel hybrid (middle), and ICEV (bottom). Solid lines indicate mechanical energy, and dashed lines indicate electrical energy.

VEHICLE SPECIFICATION

Component Specification - Table 1 lists the main component efficiencies and road load parameters assumed for this effort.

The heat engine used here is a direct-injection (DI) diesel, with a fuel-use map from the 5-cylinder, 85 kW Audi engine [10], scaled to peak efficiencies given in Table 1. See the "Scaling" section below for discussion of efficiency-versus-size-and-year considerations. The generator coupled to the diesel in the series hybrid vehicle (HV) is based on a permanent magnet motor/controller set from Unique Mobility. The traction motor/inverter set modeled here is based on the AC induction system being developed by Westinghouse. The batteries modeled here are advanced lead-acid, with characteristics adapted from Optima [11]. Vehicle drag parameters were chosen to define a Partnership for the New Generation of Vehicles (PNGV)-like vehicle with an aluminum-intensive body, heavy by Moore's standards but deemed achievable by those in industry interviewed by Duleep [2,4]. The "regenerative braking fraction" in the table is defined here as the fraction of braking energy during a given cycle that is provided to the electric drivesystem, with the balance, 60% in this case, handled by friction brakes.

regenerative braking fraction	0.4	0.4	0.4
5-6 pass. glider mass	840 kg [4]	840 kg [4]	840 kg [4]
passenger/cargo mass	136 kg	136 kg	136 kg
test mass (including driver/ passenger/cargo)	1243 kg	1218 kg	1214 kg

Table 1 also indicates propulsion component size and average energy efficiency over the combined federal cycle. Propulsion system components for each of the three vehicles were sized, using ADVISOR, in order to meet performance requirements set out by the US Consortium for Automotive Research (USCAR) for the PNGV effort [12]:

1. 0 to 96.5 km/h (0 to 60 MPH) in 12 s
2. 64.4 to 96.5 km/h (40 to 60 MPH) in 5.3 s
3. 0 to 136.8 km/h (0 to 85 MPH) in 23.4 s, and
4. 6.5% gradeability at 88.5 km/h (55 MPH).

The PNGV targets listed as 1-3 above must be attained at curb weight plus 136 kg for the driver and passenger, while the gradeability requirement is prescribed at gross vehicle weight with full accessory load for 20 minutes. We have differed from the PNGV specifications in that the gradeability requirement placed on the vehicles in this study is 6.5% at 88.5 km/h indefinitely (until the fuel runs out), with average accessory load, at curb weight plus 136 kg.

The HPU size for the hybrids is determined by the continuous gradeability requirement. Note that the HPU for the series HV is smaller than for the lighter parallel HV. This is because the 88.5 km/h requirement, for a given gear ratio, requires the parallel HV's HPU to provide adequate climbing power at a certain speed which, in this case, is not the speed at which it develops maximum power. The series HV's HPU may operate at maximum power regardless of the vehicle speed; thus, its maximum power can be set to exactly the climbing power requirement. With the HPU sized for both vehicles, the motor and batteries are sized to meet the acceleration requirements, numbered one through three above.

Scaling - In this study, the efficiency map for an 85-kW engine introduced in 1990 is used to describe the behavior of 32-, 35- and 62-kW engines [10]. For the 32- and 35-kW engines, the original map shape and peak efficiency value were maintained, while the torque axis was compressed. We acknowledge the significant technical challenge involved in achieving such high peak efficiencies with a small engine, but are encouraged by continued progress by VW/Audi (which introduced a 66 kW DI diesel with 41.8% peak efficiency two years after the 85 kW benchmark) [17]. We believe 43% peak efficiency in 32- to 35-kW diesel engines in 2005 is consistent with the Office of Advanced Automotive Technology's 2004 target of 45% peak efficiency for 40- to 55-kW engines, which is a goal at least some diesel manufacturers find reasonable [13,18]. We have assumed a peak efficiency of 46.5%, the peak efficiency of current state-of-the-art heavy-duty diesel engines, for the 62-kW engine in 2005, with its higher peak efficiency due to its larger size [13]. We expect the smaller (HV) engines to have lower specific power; the effect of changes in engine specific power can be derived using the data in Table 5.

The tractive motors in this study, at outputs of 53 and 27 kW, are significantly smaller than the 75-kW motor from which their maps come. However, motors of these lower power levels with peak efficiencies of over 92% are available now [14]. We have not attempted to scale the efficiencies up, as would likely result from further development, for lack of data.

Series Hybrid Control Strategy - The strategy chosen here was a close-power-follower strategy where the hybrid power unit (HPU) power output closely follows the tractive motor output. Figure 2 shows the behavior of the vehicle propulsion system following this strategy over the first 315 s of the FUDS. The HPU power (represented by the dots) varies directly with the tractive motor power (represented by a solid line), but is higher by a state-of-charge-dependent factor to allow for losses in the generator and battery. In this strategy, the HPU power is given by (K1*(tractive_motor _power) + K2)*(SOChi-SOC)/(SOChi-SOClo), where SOChi and SOClo are threshold SOCs.

As the third chart in the figure indicates, this control strategy leads to nearly constant battery pack state-of-charge (SOC). (See the "Results and Discussion" section for a more detailed discussion of the control strategies considered here.)

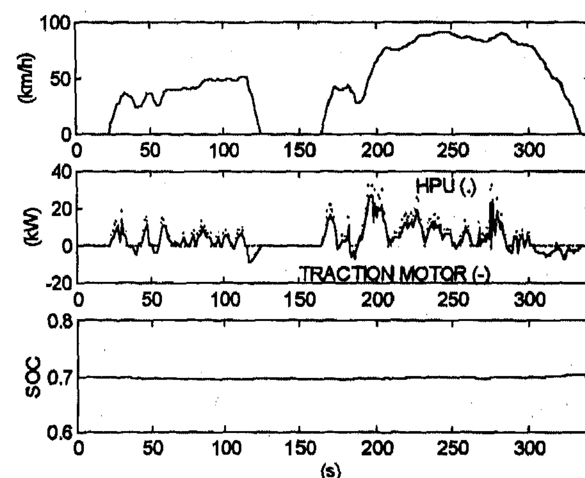

Figure 2. Close-Follower Control Strategy

We have chosen a power-follower strategy where the HPU power follows the motor power's second-by-second variation, which defines a vehicle that achieves 29.5 km/L (69.4 MPG) on the combined federal drive schedule. This strategy was chosen because:

1) it leads to the best fuel economy in the control strategy design space of power-follower approaches considered here, and

2) it requires the HPU to immediately follow tractive power requirements, as occurs in the parallel hybrid and ICEVs. This leads the fuel economy estimate of each vehicle to be overestimated roughly equally due to the consistent neglect of transient effects, minimizing the effect of transient fuel use on the differences among the three vehicles' fuel economy.

This approach likely has no emissions benefit over ICEVs, and is chosen only for its fuel economy characteristics. Alternative control strategies with potentially

better emissions characteristics are presented later in this paper.

Parallel Hybrid Control Strategy - The parallel control strategy can be defined as follows:

- The HPU does not idle (it turns off when not needed).
- The motor performs regenerative braking regardless of the batteries' SOC.
- The HPU generally provides the power necessary to meet the trace, and
- the motor helps if necessary by providing additional torque, or accepting extra torque provided by the HPU for recharging the batteries.

The parallel hybrid control strategy was defined by two parameters: a vehicle speed below which the HPU is turned off, to allow for electric launch and no idling, and minimum HPU operating torque defined as a function of engine speed, which is the lowest torque output at which the HPU would operate whenever the tractive torque requirement is positive. When the minimum-allowed HPU operating torque exceeds that required to meet the trace, the balance of torque is used to drive the motor as a generator, recharging the batteries.

Figure 3 shows a sample portion of FUDS for this parallel vehicle. Note that the motor provides power when the vehicle needs additional torque to meet the driving, as described above. During the constant velocity portion of the driving cycle (from ~90 to ~115 s), the motor power is negative as the HPU provides recharging torque to the motor. As soon as the vehicle begins decelerating, the HPU shuts off, and the SOC increases while the motor captures regenerative braking energy. Note that during the final, slow deceleration, the motor power is negative but small in magnitude, leading to only a slight rise in SOC.

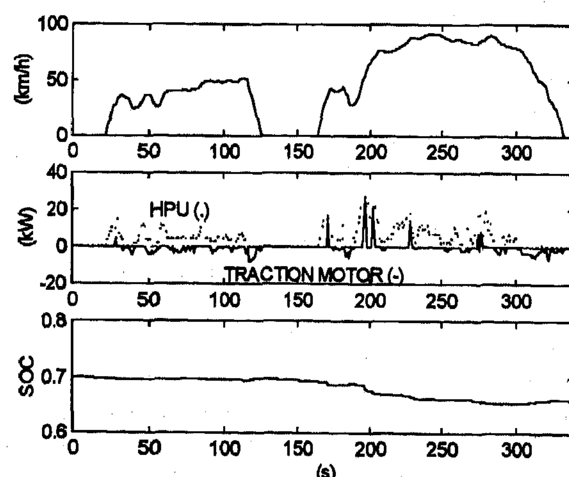

Figure 3. Parallel HV control strategy

VEHICLE EVALUATION

Vehicle Performance Simulator - ADVISOR is an empirical, physics- and map-based ADvanced Vehicle SimulatOR developed in the Simulink®/MATLAB® environment, the flexibility of which allows the development and evaluation of arbitrarily complex control strategies. ADVISOR uses fundamental equations of vehicle dynamics coupled with efficiency and/or power loss component maps to predict hybrid, internal-combustion-engine, and electric vehicle performance, range, and fuel economy. It has been compared to industry vehicle simulation programs and has been used by engineers in the hybrid program at the Chrysler Corporation. Reference eight provides more detail on this tool's application to vehicle system analysis.

Fuel Economy Calculations - The fuel economy results presented here must be understood as estimates: some uncertainty is introduced both by the model and the input data to the model. Additionally, the test procedure for determining hybrid vehicle fuel economy is a difficult problem on which debate on proper methodology continues. Due to the two energy-storage-modes of hybrid vehicles, the fuel economy calculation approach taken also may introduce uncertainty.

A Society of Automotive Engineers (SAE) task force has developed a draft hybrid vehicle test procedure which aims to properly account for changes in stored energy in charge-sustaining hybrids [19]. The unique feature of this approach is the running of two series of consecutive FUDS (for example) to determine fuel economy. The first series is started at the highest expected battery pack SOC and ends at some lower SOC, resulting in a fuel use and associated change in SOC. The second cycle is started at the lowest expected SOC and ends at some higher SOC, resulting in another fuel use and associated change in SOC. Linear interpolation is then used to predict the fuel economy estimate for the vehicle if the batteries had no net change in SOC. The benefit of using a test procedure such as this is that the uncertainty due to stored or discharged energy can be estimated by comparing the two fuel economies which bound the interpolated zero-ΔSOC fuel economy.

Because the hybrids in this study tend to reach some nearly steady SOC after a number of cycles, a different approach was used to estimate their zero-ΔSOC fuel economy. The vehicles were run over four repeated cycles (one set of FUDS and one set of FHDS) with fuel economy and SOC measured only over the last cycle, and any fuel economy measurement associated with a $|\Delta SOC| > 1\%$ (on the last cycle) was discarded. Because an exact match ($\Delta SOC=0$) is not required, some uncertainty is introduced by this method. However, we found it to be more repeatable than the SAE draft test procedure described above *for the computational evaluation of these vehicles.* It should be noted that our approach only works for hybrids whose SOC reaches some steady-state mean value over the cycle, is expected to be useful only for computational evaluation of hybrids, and is not as generally applicable as the draft SAE procedure.

RESULTS AND DISCUSSION

FUEL ECONOMY ESTIMATES - The above defined vehicles were evaluated as described, and the resulting fuel economy estimates are in Table 2. From previous comparisons with automobile manufacturers' models, we estimate the model to be accurate to ±10%, while uncertainty in the component data projections is difficult to estimate. Thus these fuel economy estimates should be treated with care. On the other hand, inasmuch as the vehicle model over- or underestimates each vehicle's fuel economy equally, the model's uncertainty contribution is bias uncertainty and does not affect the accuracy of the computed fuel economy *differences* among the vehicles.

Table 2. Estimated gasoline-energy-equivalent fuel economy estimates on USEPA cycles

Driving Cycle	Series HV	Parallel HV	ICEV
FUDS	26.6 km/L (62.6 MPG)	27.4 km/L (64.5 MPG)	21.1 km/L (49.6 MPG)
FHDS	34.1 km/L (80.2 MPG)	36.4 km/L (85.6 MPG)	32.0 km/L (75.3 MPG)
combined (55/45)	29.5 km/L (69.5 MPG)	30.8 km/L (72.5 MPG)	24.9 km/L (58.6 MPG)

DRIVE-CYCLE EFFECTS - The parallel HV is 30% more fuel-efficient than the ICEV on the urban cycle (FUDS), 14% more fuel-efficient on the highway cycle (FHDS), and 24% more fuel-efficient on the combination. The series hybrid follows the same trend, being 26% more fuel-efficient than the ICEV on the FUDS, 7% more fuel-efficient on the FHDS, and 18% more fuel-efficient on the combination. Note that both the parallel and series hybrids get similar fuel economy improvement on the FUDS, but that the parallel hybrid gets over twice the fuel economy improvement of the series on the FHDS. This is due in part to the parallel hybrid's HPU efficiently (especially on the FHDS) supplying power directly to the wheels, rather than having its output converted from mechanical to electrical and back to mechanical power, as occurs in the series hybrid.

The dependence of the fuel economy benefit of hybridization on drive-cycle is due to differences between the cycles in the number and nature of braking events, amount of idling time, and average power requirement. As braking frequency increases, so does the opportunity to recover braking energy. The more time an ICEV's engine idles in a given cycle, the more fuel may be saved by disallowing idling, as is done in both hybrid control strategies here. (Recall that the parallel vehicle powers its accessories electrically, and does not idle its heat engine). Also, the lower the average power requirement, in general, the lower the ICEV's average efficiency, and the greater the opportunity for hybridization to improve upon that efficiency [6].

The fuel economy improvement of the series and parallel hybrids over the ICEV is strongly dependent upon the driving cycle being considered. This is largely because the ICEV's fuel economy is much more sensitive to idling time and braking frequency than fuel economy of the hybrids considered here.

VEHICLE DRAG PARAMETER AND COMPONENT EFFICIENCY EFFECTS - The sensitivity of the fuel economy of each of the three baseline vehicles to various vehicle and component parameters were calculated using ADVISOR, and are presented in Table 3. The values presented indicated the percentage change in fuel economy due to a 1% increase in the given parameter (only). We took care to accurately estimate constant-performance sensitivity coefficients for each vehicle. Detailed discussion of the sensitivity coefficients is in the Appendix.

Table 3. Fuel economy sensitivity coefficients (% change in fuel economy on the combined federal cycle for a 1% increase in the given parameter)

Parameter	Series HV	Parallel HV	ICEV
average HPU eff.	1.00	1.00	1.00
average motor eff.	0.91	0.05	--
average motor-as-a-generator eff.	--	0.14	--
average battery turnaround eff.	0.15	0.13	--
mass	-0.60	-0.63	-0.75
C_DA	-0.25	-0.25	-0.22
coeff. of rolling resistance	-0.26	-0.25	-0.22
accessory load	-0.17	-0.15	-0.16
regenerative braking fraction	0.10	0.07	--

Three of the sensitivity coefficients in Table 3 require some explanation. The sensitivity coefficient for average motor efficiency indicates the percent change in fuel economy due to a 1% improvement in the tractive motor's efficiency while acting as a motor rather than as a generator. The sensitivity coefficient for the motor-as-a-generator refers to the dependence of fuel economy upon the *tractive* motor's efficiency when driven as a generator by the HPU (which occurs only in the parallel vehicle). The sensitivity coefficient labeled "regenerative braking fraction" refers to the dependence of fuel economy upon the tractive motor's efficiency when driven as a generator by the brakes.

We can use these sensitivities to estimate the effects of uncertain component efficiency assumptions. For example, the estimated 87.6% average turn-around efficiency for a high-power lead-acid battery in a hybrid vehicle may be optimistic, and we may choose a more conservative estimate of 80% average efficiency. The result of this revision is to change the fuel economy of the series vehicle by [(0.80 - 0.876) / (0.876)] x 0.15 = -0.013 = -1.3% = -0.38 km/L (-0.9 MPG), and the parallel hybrid's fuel economy changes by [(0.80 - 0.876) / (0.876)] x 0.13 = -0.011 = -1.1% = -0.34 km/L (-0.8 MPG). Of course, similar analyses can be performed with any of the parameters presented in Table 3, with good accuracy at changes of up to ±10% and reasonable accuracy at changes of up to ±20% in size.

To summarize, with the exception of mass, road load parameters have a roughly equal effect on the fuel economy of all three vehicles, and therefore do not significantly affect the differences among them. Because this series hybrid uses a close-power-follower control strategy, its fuel economy is nearly as insensitive to battery efficiency as is the parallel hybrid's fuel economy. Hybrid fuel economy is less sensitive to regenerative braking effectiveness than to all other parameters considered here except the motor efficiency for the parallel vehicle.

Comparing fuel economy estimates to previous work - Using the sensitivities presented in Table 3, we can develop an estimate of the fuel economy benefit of hybridization assuming 100% efficient components, for comparison with Tamor's estimates. We use

$$FE = FE_{table_2} + FE_{table_2} \times \sum_i \xi_i \frac{(X_{i,Tamor} - X_{i,table_1})}{X_{i,table_1}}, \quad (1)$$

where FE is the new, estimated fuel economy, FE_{table_2} is the fuel economy presented in Table 2, ξ_i are the sensitivity coefficients, and X_i are the associated vehicle parameter values. Equation 1 implies that sensitivities may be used independently, which is true to a limited extent. Because the power flows in hybrid vehicles depend upon each other and the states of the vehicle components in complicated ways, hybrid vehicle fuel economy is a *non-linear* function of drive-cycle and vehicle and component parameters. The effects of *small* vehicle-parameter changes may be combined reasonably with Equation 1, but using such an approach to combine large changes will lead to significant uncertainty in the result.

Equation 1, along with the combined federal fuel economies for the series HV and ICEV presented in Table 2, and the baseline vehicle mass, motor and battery efficiency, was used to predict the "Current" series-hybrid normalized fuel economy presented in Table 4.

Tamor used energy-throughput spectra (along with component data) to estimate the fuel economy of series and parallel hybrids relative to a lightweight Taurus using a "perfect" CVT. The hybrids' fuel economies were calculated for a range of vehicle masses and battery pack efficiencies. In this comparison, we consider one point in Tamor's range of estimates: the series HV with a 100%-efficient energy storage system and the same mass as the baseline conventional-drivetrain vehicle in his study. We choose the 100%-efficient energy storage for comparison to reduce the effect of uncertainty about Tamor's control strategy. (See the Appendix for a discussion of the battery-efficiency-sensitivity/control-strategy relationship.)

To develop a fuel-economy-improvement-from-hybridization estimate for comparison to Tamor's estimate, we begin with the series HV defined in Table 1. We then apply Equation 1 to account for the differences between the point in Tamor's space chosen above and the Table 1 vehicle. Tamor's vehicle had all braking energy done by the electric drivetrain, while in our case, only 40% of braking energy was available for regeneration. Also, the point we chose from Tamor's calculations has a 100%-efficient (round-trip) battery pack, while that of Table 1 is 87.6% efficient. Finally, our conventional-drivetrain vehicle has lower mass and a higher peak-efficiency-engine than does the series HV. The result of these modifications to the series HV computed here is shown in Table 4. We have used second-by-second simulation, component maps, and sensitivity coefficients to derive, within 5%, the same fuel economy benefit of hybridization as did Tamor using different methods, for a somewhat heavier vehicle.* This comparison is not a validation of either work, but indicates reasonable agreement using different approaches.

Table 4. Comparison of current normalized fuel economy on combined federal cycle estimate with Tamor's estimate for a *series* HV with equal mass and 100% efficient motor and battery pack [6]

	Tamor	Current
Normalized Fuel Economy (1=ICEV)	1.47	1.54

COMPONENT SPECIFIC POWER EFFECTS - It was noted above that neither hybrid vehicle's fuel economy (using the given control strategies) is particularly dependent upon battery efficiency. Let us examine the effect of battery specific power. The batteries in this comparison were assumed to have a power density of 800 W/kg, which results in a baseline battery mass of 78.4 kg for the series hybrid and 39.7 kg for the parallel hybrid. If we make the more conservative assumption of a 400 W/kg battery pack, both pack masses double. We can estimate the fuel economy effect of this change using the mass sensitivity coefficients for the two vehicles and their baseline data from Table 1. The series vehicle's mass would change by (78.4/1243)=6.3%, and with a mass sensitivity coefficient of -0.60, the series hybrid's fuel economy would change by 6.3% x (-0.60) = -3.8% = -1.12 km/L (-2.6 MPG). The parallel vehicle's fuel economy change can likewise be estimated: (39.7/1218) x (-0.63) = -2.1% = -0.65 km/L (-1.5 MPG). Thus, the fuel economy of the series vehicle defined here is significantly more sensitive to battery specific power than the parallel hybrid because of the series hybrid's larger battery pack. Similar analyses can be performed with the specific power of other components as shown in Table 5.

Table 5. Fuel economy sensitivity coefficients (% change in fuel economy on the combined federal cycle for a 1% increase in the given parameter) for component specific power

Parameter	Series HV	Parallel HV	ICEV
HPU specific power	0.03	0.04	0.08
motor/inverter specific power	0.03	0.02	--
battery pack specific power	0.04	0.02	--

These results indicate that hybrid fuel economy, and thus the fuel economy benefit of drivetrain hybridization, does not depend strongly upon any *one* of the drivetrain

* Tamor's vehicles had a mass of 1020 kg, while the ICEV mass here, to which we "corrected" the series hybrid mass using sensitivity coefficients, was 1214 kg.

components' specific power. It does indicate that the fuel economy of the series hybrid, with its more powerful motor and battery pack, is significantly more sensitive to changes in specific power of these components than is the fuel economy of the parallel hybrid.

TRANSMISSION EFFECTS

Number of gears - A 5-speed transmission was used here. It has been shown that increasing the number of gears in a transmission can improve fuel economy [4]. This is principally because the engine associated with a transmission with a greater number of gears may be able operate more of its time in good thermal efficiency regions, reducing the opportunity for hybridization, and reducing the fuel economy benefit of hybridization. The continuously-variable transmission (CVT) represents the limit of an infinite number of gears. As commercially available CVTs become more efficient, so that their losses do not negate the benefit of improved engine efficiency they offer, they may be used to make ICEV fuel economy more competitive with hybrid vehicle fuel economy.

Drivetrain configuration - A reasonable modification of the parallel hybrid analyzed here would be to move the motor closer to the wheels. That is, we might expect greater fuel economy by not having the motor transmit torque through the transmission, but rather directly to the vehicle's differential (through a single speed-reducing gear). This would reduce losses in the transmission by reducing the energy passed through it, while increasing losses in the motor by forcing its speed to be a fixed fraction of the tire speed. See Figure 4 for a diagram of this alternate configuration.

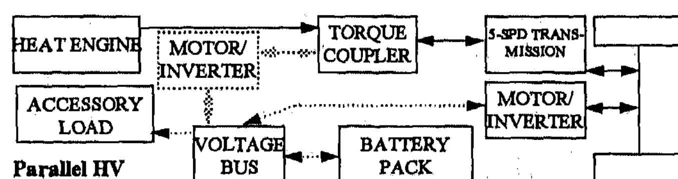

Figure 4. Parallel hybrid vehicle with motor connected directly to differential

We can estimate the fuel economy value of the motor-differential configuration over the one previously analyzed using the sensitivity coefficients presented above. Three energy-transfer modes will be affected: 1) motoring--mechanical energy provided by the motor will be subjected to fewer losses by circumventing the transmission, 2) regenerative braking--regenerative braking torque will likewise suffer fewer losses, and 3) HPU-to-motor charging--using the HPU to drive the motor as a generator will be significantly complicated by the interposition of the 5-speed transmission, but that effect notwithstanding, the transmission will incur losses on the charging torque it transmits. We assume that the parallel motor's motoring and regenerative efficiencies are unchanged from the baseline, although its torque and speed output are tied to the wheel requirements by the motor-differential setup and not by the baseline motor-transmission-differential setup. We also assume that HPU-to-motor charging through the 5-speed transmission is feasible, despite the control challenges involved.

In the motoring regime, the motor-to-wheels efficiency is improved by the ratio (1-spd transmission efficiency)/(5-spd transmission efficiency)=98%/92%=1.065, for a 6.5% improvement. Likewise, the regenerative braking, wheels-to-motor efficiency is improved by 6.5%. The HPU-to-motor efficiency is decreased by a factor of 92%/98%=0.939, for a 6.1% decrease. The combined effect of the motoring, regenerative braking, and charging efficiency changes can be computed using the sensitivities listed in Table 1 as "average motor eff.", "regenerative braking fraction", and "average motor-as-a-generator eff.", along with the changes computed above: +6.5%, +6.5%, and -6.1%. We have

$$(6.5\% \times 0.05) + (6.5\% \times 0.07) + (-6.1\% \times 0.14) = -0.9\%, \quad (2)$$

indicating a 0.9% drop from the baseline parallel vehicle fuel economy due to the change illustrated in Figure 4. This result is dependent the assumptions made about the transmission and motor efficiency and the drivetrain layout analyzed here, but indicates that the parallel hybrid fuel economy is not strongly dependent upon which of the two layouts analyzed is chosen.

EFFECT OF HPU TYPE ON FUEL ECONOMY DIFFERENCES - The size of the opportunity to avoid part-load operation depends greatly on the type of HPU used in the vehicles compared. The diesels used in this effort have relatively large operating torque-speed regions of high efficiency compared to some spark-ignition engines. The fuel economy benefit due to the hybridization of certain spark-ignition engine vehicles may therefore be greater than predicted here for the diesel engines. That is, the fuel economy *difference* between a spark-ignition hybrid and ICEV should be greater than the difference between a diesel-powered hybrid and ICEV, although both diesels should have better fuel economy than both spark-ignition engine vehicles. Although we have not quantified the difference between the fuel economy benefit of drivetrain hybridization of diesel- and spark-ignition-engine-powered ICEVs, we suggest that said quantification is perhaps not necessary. Given that one of the main aims of hybridization is high fuel economy, it seems reasonable to use a high-fuel-economy diesel as the ICEV benchmark.

Another opportunity hybrid vehicles offer is the use of alternative HPUs, such as gas turbines, fuel cells, and Stirlings in series (or perhaps parallel, in the case of the Stirling) HVs. Strictly speaking, we cannot isolate the benefit of drivetrain hybridization for vehicles using these powerplants because a conventional-drivetrain vehicle using them would undesirable, generally because of their poor dynamic response. However, we may wish to attribute the fuel economy benefits due to the use of alternative HPUs to the hybridization that makes them possible. These alternative HPUs offer the possibility of offering significantly more flexibility in fuel choice and improving vehicular emissions.

EFFECT OF HYBRID CONTROL STRATEGY - In order to compare the hybrid vehicles fairly with the ICEV simulated in this effort, significant effort was expended in developing and selecting advantageous hybrid control strategies.

Parallel HV - The parallel hybrid control strategy was defined by two parameters: a vehicle speed below which the HPU is turned off, and minimum HPU operating torque defined as a function of engine speed, which is the lowest torque output at which the HPU would operate whenever the tractive torque requirement is positive. Where used in the control strategy, these parameters were multiplied by an SOC-dependent factor ((SOChi-SOC)/(SOChi-SOClo)) designed to keep the SOC within a desired range. Changes in these parameters did not strongly affect the fuel economy of the vehicle, but rather only the steady average SOC that was attained. As stated before, significant work in control strategy development and evaluation is necessary to make hybrids reach their full fuel economy potential. This initial effort in parallel hybrid control strategy evaluation could be more fully developed, and future work is planned. In this work, the parallel hybrid fuel economy was nearly independent of the control strategy parameters used.

Series HV - A 'thermostat' hybrid control strategy (in which the HPU operates at a constant power level starting when the battery pack SOC reaches some bottom setpoint and stopping when the SOC has climbed to some upper setpoint) was evaluated along with a spectrum of power-follower control strategies. A power-follower control strategy, as discussed by Anderson and Pettit, is one in which the HPU power is dictated by the tractive motor power, but perhaps limited in its rate-of-change [20].

The spectrum of power-follower strategies that were investigated is defined by two independent variables: 'minimum HPU power' and 'averaging time'. Minimum HPU power is the power command below which the HPU is turned off. Averaging time is the size of the time window over which tractive motor power is averaged to derive the HPU power command. The HPU power command is the sum of an SOC-dependent factor and a scalar multiple of the averaged motor power. Figure 5 shows the dependence of this power-follower series hybrid fuel economy on the combined federal cycle upon these control strategy parameters.

Note that as the averaging time falls, fuel economy increases. Physically, as the averaging time falls, the HPU power level changes more quickly, following the power requirements of the tractive motor more closely. Thus, a smaller averaging time means more of the electric power generated by the HPU is used by the motor without passing through the batteries, and battery losses are decreased.

Two effects of 'minimum HPU power' are competing, particularly at low averaging times, leading to a best-fuel-economy point vertically in the center of the plot. As the minimum/cutoff power decreases, the HPU is allowed to operate at low powers which correspond to low efficiencies. As the minimum power increases, the HPU more frequently alternately charges the batteries (operating at or above its cutoff power) and shuts off, allowing the batteries to discharge. The shape of this map, then, is largely determined by battery turnaround efficiency and to a perhaps lesser extent by the HPU efficiency map.

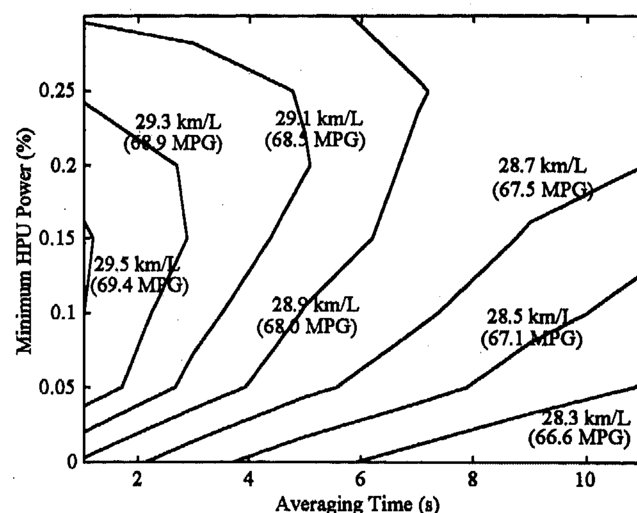

Figure 5. Fuel economy vs. control strategy parameters for series hybrid

The thermostat control strategy, using the peak HPU efficiency point and high and low SOC points of 80% and 40%, leads to a fuel economy of 31.1 km/L (73.2 MPG). Over the range in Figure 5, the power-follower strategy leads to a maximum fuel economy of 29.5 km/L (69.4 MPG) and a minimum of less than 28.3 km/L (66.6 MPG). Series hybrid fuel economy variations of at least 9%, then, can be traced to reasonable but suboptimal control strategies. Control strategy selection is an *extremely* important step in the design of hybrid vehicles for good fuel economy and emissions which we have not fully addressed. The sensitivity of fuel economy to control strategy shown here is likely a conservative estimate due to the simplifying assumptions (for example, neglect of the fuel economy effect of thermal and throttle transients).

CONCLUSIONS

With the understanding that hybrid vehicle design decisions are made for many reasons other than to maximize fuel economy, we have analyzed the dependence of hybrid fuel economy upon various vehicle and component design parameters. The main conclusions of this paper are as follows:

1. The parallel hybrid defined here achieves fuel economy that is 24% better than the ICEV while the series betters the ICEV by 18%.

2. The parallel hybrid is 4% more fuel-efficient than the series hybrid.

3. Lightweight midsized hybrid vehicles with low aerodynamic drag and rolling resistance using near- to mid-

term technology can achieve 30 km/L (70.6 MPG) (gasoline-equivalent).

4. The series hybrid control strategy strongly influences its fuel economy, and a 'thermostat' control strategy, neglecting thermal transient effects, is among the best of those examined here, *considering fuel economy only*.

5. When a series hybrid uses an HPU capable of following motor power demands on a second-by-second basis, a control strategy can be used that reduces the sensitivity of fuel economy to battery efficiency to the same level as in a parallel hybrid.

6. The parallel and series hybrid fuel economies are not strongly dependent upon component specific power, but series hybrids are more sensitive to battery and motor specific power than are parallel hybrids.

7. The series hybrid's fuel economy is less sensitive to regenerative braking effectiveness than to any other vehicle-level parameter, and the parallel hybrid's fuel economy is less sensitive only to motor efficiency than to regenerative braking effectiveness. Doubling regenerative braking capture effectiveness improves series hybrid fuel economy by 10% and parallel hybrid fuel economy by 7%.

8. This parallel hybrid's fuel economy is not significantly changed by connecting the motor directly to the differential rather than to the 5-speed transmission.

9. Control strategy development for a charge-sustaining parallel HV is challenging and warrants further investigation.

ACKNOWLEDGMENT

This work was sponsored by the Department of Energy (DOE) as part of the MRI-managed DOE Hybrid Vehicle Propulsion System Program. We would also like to gratefully acknowledge the inputs of Terry Penney, Robert Rehn, Robert Farrington, Michael Tamor, and the anonymous SAE reviewers.

APPENDIX

Fuel economy sensitivity coefficients for the vehicles were computed using the following equation:

$$\xi_i = \frac{FE_{110\%} - FE_{90\%}}{FE_{baseline(100\%)}} \times \frac{1}{1.10 - 0.90}, \quad \text{(A1)}$$

where i indicates the parameter being considered, $FE_{baseline(100\%)}$ is the fuel economy for the parameter at its baseline value, and $FE_{110\%}$ and $FE_{90\%}$ refer to fuel economies corresponding to parameter values of 110% and 90% of the baseline value.

Sensitivities to road load parameters other than mass (C_DA, coefficient of rolling resistance, and regenerative braking fraction) were computed using constant-efficiency vehicle representations. This approach was used to minimize the effect of the road load parameters on driveline component efficiencies. For example, if the coefficient of rolling resistance increases, the force required to propel the vehicle at any time over the cycle (regardless of speed) increases, leading to higher torque requirements of the transmission and motor and/or heat engine. Generally, increasing the torque output of a component increases its efficiency. Thus, the effect of increasing the coefficient of rolling resistance in a vehicle whose drivetrain component efficiencies depend upon torque (and speed) would be to increase those average component efficiencies. This must be avoided to isolate the effect of the coefficient-of-rolling-resistance increase.

To compute the fuel economy sensitivity to mass, drivetrain components for the 10% more massive and 10% less massive vehicles were sized to provide 0 to 96.5 km/h times equivalent to that of the baseline vehicle.

Fuel economy sensitivities to drivetrain component (HPU, motor, and battery) efficiency were computed using vehicle representations that included power loss maps. This approach, in contrast to the constant efficiency approach, was used to preserve the baseline vehicle's time history of power flows among the components. These flows depend upon the battery SOC at a given time as well as motor power demands, both of which are dependent upon the drivetrain component efficiency history.

Note that the sensitivity coefficient for the HPU for all three vehicles is unity, implying that for a 1% increase in engine efficiency (for example, from 40% to 40.4%), there will be a 1% increase in fuel economy. Another way of stating this is that fuel economy is directly proportional to HPU efficiency. This is as one would expect: all energy used on-board the vehicle (assuming it is charge-sustaining, and the fuel economy test is corrected to zero change-in-SOC) comes from fuel conversion occurring in the HPU.

The sensitivity coefficient for the motor for the series hybrid (0.91) is over 18 times that of the parallel hybrid (0.05). This difference is due to the much smaller amount of motor energy used by the parallel hybrid than by the series. In the parallel vehicle, most tractive energy is supplied directly by the HPU, while in the series, all tractive energy must pass through the motor. Note that the motor and HPU sensitivity coefficients differ for the series hybrid because while all energy used by the vehicle passes through the HPU, the same is not true of the motor: accessory draw is independent of the motor.

Table A1 (reprise of Table 3). Fuel economy sensitivity coefficients (% change in fuel economy on the combined federal cycle for a 1% increase in the given parameter)

Parameter	Series HV	Parallel HV	ICEV
average HPU eff.	1.00	1.00	1.00
average motor eff.	0.91	0.05	--
average motor-as-a-generator eff.	--	0.14	--
average battery turnaround eff.	0.15	0.13	--
mass	-0.60	-0.63	-0.75
C_DA	-0.25	-0.25	-0.22
coeff. of rolling resistance	-0.26	-0.25	-0.22
accessory load	-0.17	-0.15	-0.16
regenerative braking fraction	0.10	0.07	--

The vehicle fuel economy sensitivities to the remaining parameters in Table A1 are nearly independent of vehicle type. For the battery efficiency, the closeness of the series and parallel hybrid sensitivities is somewhat coincidental, as this sensitivity is highly dependent upon control strategy. However, the control strategies used in the two vehicles are (intentionally) similar in that they minimize battery energy throughput. Changes in battery efficiency become more important as more energy is passed through the battery. The sensitivity of a thermostat-control-strategy series hybrid's fuel economy to battery efficiency would be much higher than shown here, since the effect of the thermostat control strategy is to alternately fill and empty the batteries.

The small differences among the sensitivities to road load parameters, mass, $C_{rolling\text{-}resistance}$, and C_DA (the aerodynamic drag product) are to be expected. The relative values of these sensitivities depend only upon the relative values of the road load parameters themselves. Road load parameters are identical for all vehicles, with the exception of mass, which differs by less than 2.4% among the three. Accessory load sensitivities are likewise dependent upon road load parameters, and are nearly identical for the three vehicles. Vehicle-to-vehicle differences in any one of these parameters can be ascribed to uncertainty in the calculation.

Sovran and Bohn use the standard vehicle tractive force equation, $F=(1/2)\rho C_DAv^2+mg(C_{rolling\text{-}resistance}+C_{rr1}v)+ma$, along with driving cycle data to analytically determine sensitivity coefficients or "influence coefficients," as they are called in the paper [9]. We can use the equations presented there to develop sensitivity coefficients against which to compare the coefficients we developed here, for each vehicle.

The sensitivity coefficients developed using Sovran's methods are presented in Table A2.

Comparing Tables A1 and A2, we can see that all the predicted sensitivities to aerodynamic drag product (C_DA) and coefficient of rolling resistance agree to within 9.1%. The mass sensitivity coefficients for the ICEV agree to within 2.7%. Using Sovran and Bohn approach for the sensitivity of fuel economy to mass is inappropriate, however, as evidenced by the difference between the two sets of estimates (-0.60 vs. -0.76 for the series and -0.63 vs. -0.76 for the parallel). Sovran and Bohn's equations were developed for a ICEV, without regenerative braking. The hybrids in this study employ regenerative braking; therefore they recover some of the energy expended to accelerate the vehicle, reducing the effect mass has on the total tractive energy required, and thus, fuel required for a given cycle.

Table A2. Fuel economy sensitivity coefficients developed using the methods of Sovran and Bohn (% change in fuel economy over the combined federal cycle for a 1% increase in the given parameter). Note that Sovran and Bohn's "influence coefficients" were positive; their signs were changed for consistency with previous sensitivity coefficients presented.

Parameter	Series HV	Parallel HV	ICEV
mass	-0.76	-0.76	-0.77
C_DA	-0.24	-0.24	-0.23
coeff. of rolling resistance	-0.26	-0.24	-0.24

ABSTRACT

Hydrogen-fueled, spark-ignited, homogeneous-charge engines offer an alternative for providing Equivalent Zero Emission Vehicle (EZEV) levels, along with a range and performance comparable to today's automobiles. Hydrogen in a spark-ignited engine can be burned at very low equivalence ratios, so that NO_x emissions can be reduced to less than 10 ppm without a catalytic converter or EGR. HC and CO emissions may result from oxidation of engine oil, but by proper design are negligible (a few ppm). Lean operation also results in increased indicated efficiency due to the thermodynamic properties of the gaseous mixture contained in the cylinder and due to reduced heat transfer. The high effective octane number of hydrogen allows the use of a high compression ratio, further increasing engine efficiency.

In this paper, a time-dependent engine model is used for predicting hydrogen engine efficiency and emissions. The model uses basic thermodynamic equations for the compression and expansion processes, along with an empirical correlation for heat transfer, to predict engine indicated efficiency. A friction correlation and a supercharger/turbocharger model are then used to calculate brake thermal efficiency. The model is validated with many experimental points obtained in a recent evaluation of a hydrogen research engine.

The validated engine model is then used to calculate fuel economy and emissions for three hydrogen-fueled vehicles: a conventional, a parallel hybrid, and a series hybrid. All vehicles use liquid hydrogen as a fuel. The hybrid vehicles use a flywheel for energy storage. Comparable ultra capacitor or battery energy storage performance would give similar results. This paper analyzes the engine and flywheel sizing requirements for obtaining a desired level of performance. The results indicate that hydrogen lean-burn spark-ignited engines can provide a high fuel economy and Equivalent Zero Emission Vehicle (EZEV) levels in the three vehicle configurations being analyzed.

INTRODUCTION

Hydrogen has very special properties, including a very high laminar flame speed, a high effective octane number, and no toxicity or ozone-forming potential [1]. Homogeneous-charge spark-ignited piston engines can be designed to take advantage of these characteristics. The high laminar flame speed allows the use of very low equivalence ratios (as low as 0.2), reducing NO_x emissions to near-zero levels without requiring a catalytic converter, that may deteriorate with time. The use of low equivalence ratios also increases the indicated efficiency, and reduces the need for throttled operation [2]. The engine can have a high compression ratio, due to the high octane number of hydrogen.

This paper analyzes the applicability of hydrogen homogeneous-charge spark-ignited piston engines to Equivalent Zero Emission Vehicles (EZEV).[1] The analysis uses an engine model that is calibrated to match the data obtained in a recent experiment [4], and a vehicle simulation code that can be applied to calculating fuel economy and emissions [5]. The engine model is used to generate optimized engine performance maps for supercharged operation, with constraints of limited NO_x emissions, limited manifold pressure and maximum mean piston speed.

The engine maps are applied for predicting fuel economy and emissions for a conventional vehicle, a parallel hybrid vehicle, and a series hybrid vehicle. All these vehicles use liquid hydrogen as a fuel, and hybrid vehicles use a flywheel for energy storage. Although liquid hydrogen is not a common fuel, its safe

[1] Equivalent Zero Emission Vehicles are defined here as those that generate less emissions when operating inside the Los Angeles Basin than the power plant emissions generated as a result of electric car operation. These emission levels are being considered for approval by CARB [3]. Proposed EZEV levels are: 0.0025 g/km (0.004 g/mi) NMHC; 0.11 g/km (0.17 g/mi) CO; and 0.012 g/km (0.02 g/mi) NO_x. These values are equal to one tenth of CARB ULEV standards.

use has been demonstrated by BMW for a number of years [6]. The parallel hybrid operates almost identically as a conventional car, with a flywheel for regenerative braking and for complementing the power of the engine during sudden accelerations. The series hybrid vehicle engine operates in an on-off mode to keep the flywheel charged. When the engine is off, the flywheel provides all the energy for transportation and accessories.

ENGINE MODEL

The engine model uses first principles and correlations to predict piston engine efficiency and power output. The engine model is a lumped (zero-dimensional), time-dependent model which solves the basic differential equations for the compression and power strokes. An empirical equation [7] is used for calculating heat release. The heat release equation has three free parameters which determine the shape and duration of the heat release function as a function of crank angle. These three parameters are determined for each experimental run by using an optimizer [8]. The optimizer finds the combination of the three parameters that minimizes the differences between the experimental pressure trace and the pressure trace calculated by the model. The results have been very satisfactory. The relative errors in matching the pressure traces at MBT timing have been of the order of 0.5%, with a maximum error of 1% over all engine speeds, equivalence ratios and manifold pressures.

The engine model uses Woschni's correlation [9] to estimate engine heat transfer. It was found during the analysis that the heat transfer correlation underpredicts heat transfer losses. Woschni's correlation includes two constants, C_1 and C_2, which determine the effect of fluid flow on heat transfer. To obtain a better match with the experimental data, the original values of these two constants were multiplied by 1.8. The increased heat transfer coefficient reduces the predicted engine efficiency by about 1% with respect to the engine model with the unmodified Woschni's correlation. It is noted that Woschni's correlation has been applied in the past to diesel and gasoline engines, so some adjustment to the coefficient is to be expected as a result of using a different fuel. It is encouraging that the adjustments to those coefficients, which are not directly proportional to heat transfer, have a small effect on engine efficiency.

The engine model includes a friction model and a supercharger/turbocharger model to predict brake thermal efficiency. The friction model uses a detailed correlation [10]. Supercharger and turbocharger performance are calculated by using a thermodynamic model and assuming a constant (0.7) isentropic efficiency for both the turbine and the compressor. Selection of a supercharger to optimally increase the power as required to meet the power demands is outside the current experience of the authors. However, a detailed supercharger map could be incorporated into the model if further refinement is desired. A water-cooled intercooler is assumed with a thermal effectiveness of 0.7. Based on reported data for typical engines [2], volumetric efficiency is assumed to vary linearly from 85% at low engine speeds, to a maximum of 95% at 4000 rpm, down to 90% at 5000 rpm.

The engine model is validated by comparing the calculated results with the experimental results obtained in a recent engine evaluation [4]. The engine used in the experimental evaluation is an Onan engine which was modified by incorporating a head containing two spark plugs, along with the original two valves. The intake valve was modified with a 1.5 mm high, 180 degree shrowd to add some swirl which resulted in improved efficiency. The combustion chamber is a simple right circular cylinder with no squish and a flat top piston. This geometry has been shown to be the most efficient shape for reducing heat transfer losses in lean-burn engines [11]. Engine characteristics are listed in Table 1, along with the range of conditions used in the experiment.

Table 1. Modified Onan engine characteristics and experimental conditions.

Bore, mm	82.55
Stroke, mm	92.08
Displacement, cm^3	493.0
Geometric compression ratio	14.0
Experimental range for equivalence ratio	0.2-0.5
Experimental range for engine speed, rpm	1200-1800
Experimental range for volumetric efficiency, %	90-215

Figure 1 shows a comparison between experimental and calculated indicated efficiencies, as a function of equivalence ratio, for all the experimental points at MBT timing. Engine speeds are indicated with different symbols. A 0.39 equivalence ratio was selected for most supercharged runs. Figure 1 shows gross indicated efficiency, defined as including only work done on the piston during the compression and expansion strokes [2]. The experimental engine was supercharged by directly supplying the fuel and air from pressurized sources. Pumping work is accounted for as a part of the engine friction model.

Figure 1 shows that the model predicts absolute values as well as trends with good accuracy for engine indicated efficiency, over the whole range of operating conditions, with the maximum error of the order of 1%.

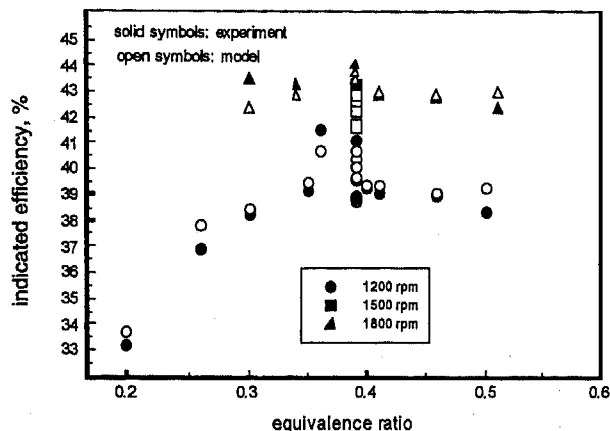

Figure 1. Indicated efficiency for the Onan engine as a function of equivalence ratio. The figure includes both the experimental results and the model predictions.

No validation is done for brake thermal efficiency, because the Onan engine used in the experiment has substantially more friction per cylinder than a current automotive engine, for which the friction correlation applies.

Figure 1 shows that indicated efficiency increases as a function of engine speed, as a consequence of reduced heat transfer losses. The variation of indicated efficiency with equivalence ratio is best observed for 1200 rpm operation, for which the greatest fuel/air range was used. Indicated efficiency reaches a maximum near a 0.40 equivalence ratio. Increasing the equivalence ratio from this point results in a decreased indicated efficiency, due to increased heat transfer and a decreased specific heat ratio ($\gamma = c_p/c_v$) for the gas products in the cylinder [2]. Decreasing the equivalence ratio from the optimum point increases the timing losses, due to slower heat release, thereby reducing the indicated efficiency. Supercharged operation results in small indicated efficiency gains due to slightly lower heat transfer losses per unit mass of fuel at the higher densities. Supercharged operation has a larger effect on brake thermal efficiency by increasing the output work relative to the frictional work.

The engine model also includes a correlation for calculation of NO_x emissions. Experimental results (Figure 2) have indicated that emissions of NO_x are mainly a function of engine equivalence ratio, being very insensitive to engine speed or intake pressure. The correlation of NO_x as a function of equivalence ratio predicts emissions accurately. The model uses a correction for supercharged and turbocharged operation, to take into account the higher intake temperature resulting from the compression process

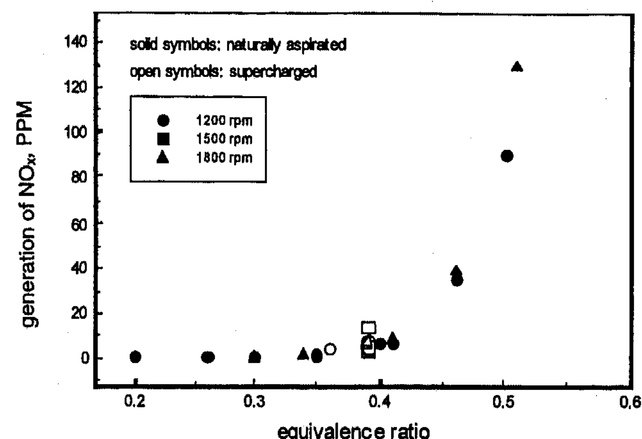

Figure 2. Emission of NO_x in parts per million for the Onan engine as a function of equivalence ratio, for all the experimental points at MBT timing obtained in the analysis. Engine speeds and supercharged operation are indicated with different symbols.

and the less than perfect effectiveness of the intercooler.

The engine model is then applied to predicting the engine performance that results if a 4-cylinder (1.97 liter) and a 3-cylinder (1.48 liter) hydrogen engines are built with the same cylinder characteristics of the Onan engine. The applicability of the 4-cylinder and 3-cylinder engines to conventional and hybrid vehicles is discussed later in this paper. The geometry and dimensions of the engine cylinders are not changed in the analysis, because small changes in geometry may result in significant changes in efficiency. It is expected, however, that larger engine cylinders will improve engine efficiency.

Using the engine model for predicting vehicle performance requires extrapolating from the engine speeds used in the experiment (1200-1800 rpm) to engine speeds that are required for vehicle operation. A maximum engine speed of 5000 rpm is assumed. Extrapolation is done by assuming that the heat release correlations developed from the experimental data apply throughout the desired range of engine speeds, along with the previously cited volumetric efficiency assumptions. It is recognized that this extrapolation may result in errors. Errors are due to turbulence variations with engine speed which influence heat release rate, thus changing both timing losses and heat transfer losses. However, Figure 1 shows that the model predicts the efficiency trends with good accuracy for the range in which experimental data exist, and it is considered that the model can do a reasonable job at predicting efficiency

for high and low engine speeds. In addition to this, engines in conventional and hybrid vehicles are most often operated at low to moderate speeds, which is the range for which the model has been validated. For the conventional and parallel hybrid vehicles analyzed in a later section of this paper the mean engine speed is 1500 rpm for the urban cycle and 2700 rpm for the highway cycle (see Figure 8). Maximum engine speed for the driving cycles is 3300 rpm. The series hybrid vehicle is set to operate at a constant 2400 rpm during the driving cycles.

Engine brake thermal efficiency is required for applying the engine code to vehicle calculations, and brake thermal efficiency is calculated with a friction and a supercharger/turbocharger model that have not been validated for this particular application. While the model cannot replace experimental runs, it is considered that the brake thermal efficiency calculated with the model gives a good idea of the performance that can be obtained with such an engine. Engine emissions are very insensitive to engine operating conditions other than maximum temperature within the cylinder, and it is therefore expected that the engine NO_x model can provide accurate predictions for emissions levels throughout the operating range.

The engine model is applied to generate engine emissions and performance maps, necessary for predicting vehicle performance. A gasoline engine has only one degree of freedom for controlling the output torque at any given speed: the inlet manifold pressure. This is due to the use of three-way catalysts that require near-stoichiometric operation for high conversion efficiency. A hydrogen engine has two degrees of freedom, because equivalence ratio can also be varied. Generating an engine map therefore requires determining a control strategy that specifies how to adjust these two parameters to obtain the desired torque for any given engine speed. In this analysis, an optimizer [8] is used to determine the combination of equivalence ratio and inlet manifold pressure that satisfies the torque requirement while providing the maximum engine brake thermal efficiency. A constraint is used in the optimization: engine NO_x emissions are less than 10 ppm under all operating conditions. An engine generating 10 ppm of NO_x is well below the EZEV standards (a tenth of ULEV), provided that it is installed in a vehicle with a fuel economy of 40 mpg or higher. While emission levels for a car are set in grams per mile and not in ppm, setting a maximum allowable ppm limit guarantees that the vehicle is intrinsically an EZEV, regardless of how the vehicle is driven.

Lean operation results in low power output, and therefore turbocharged or supercharged operation is required for providing adequate power output for the chosen displacement. Both supercharged and turbocharged operation have been considered for generating the engine performance map. The performance maps for both cases are very similar, with turbocharged operation having a slight efficiency advantage over supercharged operation. Only the results for supercharged operation are shown in this paper. Supercharged operation is preferred to turbocharged operation due to the lag time that may exist in turbocharged operation for the conventional and parallel hybrid vehicles.

Figures 3 and 4 show the predictions for engine efficiency and emissions maps, for the 4-cylinder supercharged engine. Performance maps for the 3-cylinder engines can be obtained to within a good approximation by multiplying the torque scale by 3/4. Not everything scales by a factor of 3/4 when the number of cylinders is decreased (for example, the number of bearings). However, the effect of these changes is small, and the scaled maps give a very good approximation for the 3-cylinder engine maps.

Figure 3 shows lines of constant brake thermal efficiency (in percent) as a function of engine speed and engine torque. The figure also shows a dotted line corresponding to the conditions at which the engine generates 10 ppm of NO_x, and a dashed line that indicates the maximum torque that can be obtained within the upper bounds of equivalence ratio (0.5) and inlet pressure (2 bar) used in the analysis. The 10 ppm NO_x curve is the lower of the two, and therefore sets the limit on the maximum torque and power that can be obtained from the engine. The maximum power approaches 60 kW at 5000 rpm. The contour lines in this and the following figures spread beyond the 10 ppm line, showing the potential power gains obtained by relaxing this restriction. A square in the figure indicates the approximate range of experimental conditions covered.

Figure 3 shows that the engine is predicted to have a broad area of high efficiency, for intermediate speeds and high torques. The efficiency drops for lower speeds due to increased heat transfer losses, and for higher speeds due to increased friction. As expected, the efficiency drops to zero as the load is reduced. However, the drop occurs more slowly than in conventional engines, because the equivalence ratio can be reduced as the load is reduced, resulting in lower throttling losses.

The predicted engine map is similar in shape to engine maps for recent gasoline engines (see, for example, [12]). However, engine maps are most often drawn with efficiency as a function of speed and power, so the maps presented in this paper have to be transformed before a direct comparison is possible. Current gasoline engine maps show that efficiency drops with increasing speed at low torque conditions,

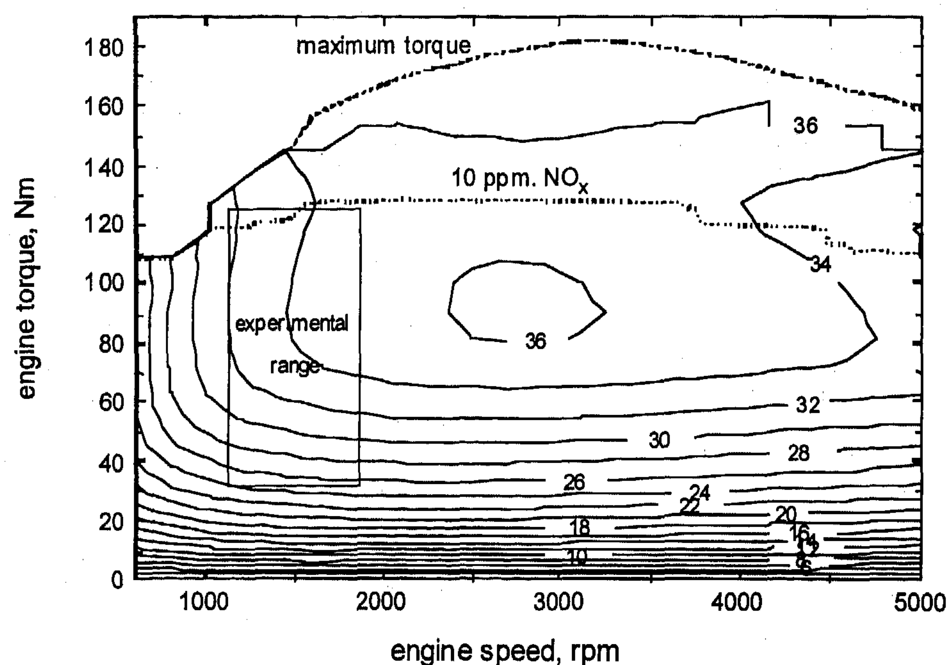

Figure 3. Contour lines of constant brake thermal efficiency (in percent) as a function of engine speed and engine torque. The dotted line corresponds to the conditions at which the engine generates 10 ppm of NO_x; the dashed line indicates the maximum engine torque that can be obtained within the constraints of maximum equivalence ratio (0.5) and inlet pressure (2 bar); and the square indicates the approximate area in which the experimental data were taken.

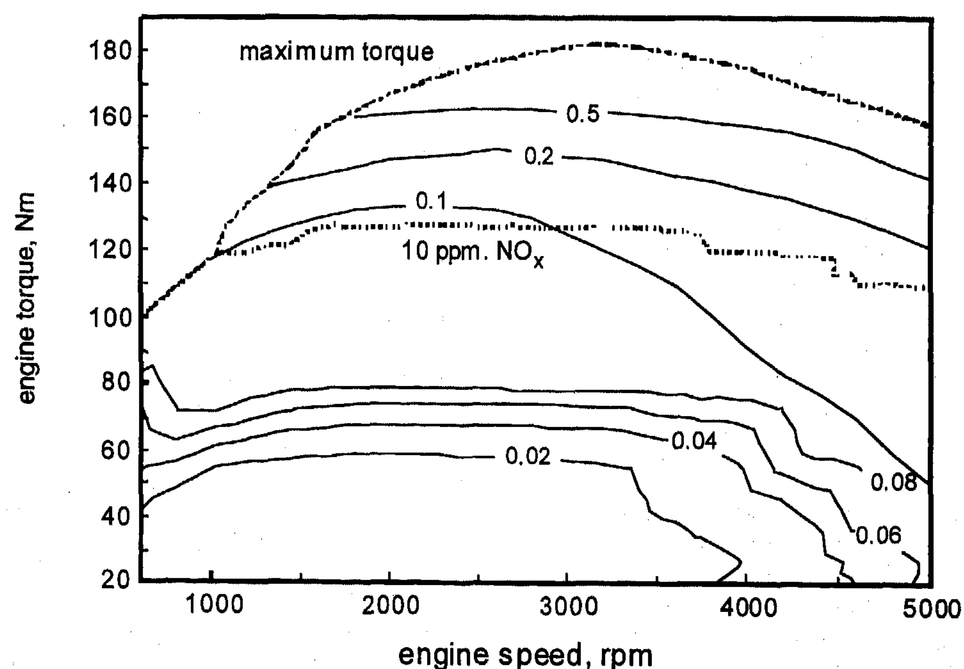

Figure 4. Contour lines of NOx emissions in g/kWh as a function of engine speed and torque. The figure includes a dotted line for the 10 ppm NO_x limit, and a dashed line for the maximum engine torque that can be obtained within the constraints of maximum equivalence ratio (0.5) and inlet pressure (2 bar).

while Figure 3 shows that efficiency is almost independent of speed at these conditions (lower right corner of the map). These differences may be due to lower heat transfer and pumping losses in the lean-burn engine compared to the gasoline engine.

Figure 4 shows contours of NO_x emissions in g/kWh as a function of engine speed and torque. Emissions are less than 0.1 g/kWh for most of the map, with higher emissions obtained at high speed and high torque. The line of 0.1 g/kWh roughly corresponds to the limit of 10 ppm at intermediate speeds. Emission levels are near zero (<0.02 g/kWh) over the low load range, which is the range at which the engine is operated most of the time during city and highway driving in conventional and parallel hybrid cars (see Figure 8). Emissions increase slowly as the torque increases, until the restriction of 10 ppm is approached. When this restriction is approached, the operating conditions in the engine are adjusted so that the 10 ppm line is pushed as high as possible by increasing the manifold pressure without further increases in equivalence ratio, at the cost of some losses in efficiency. This explains the great distance between the 0.08 and the 0.1 g/kWh curves shown in the figure. Emission levels shown in the figure are expected to be valid over the lifetime of the engine, since no catalytic converter, which may deteriorate with time, is used to control emissions.

Intake pressure and equivalence ratio are selected by the optimizer to obtain the optimum brake thermal efficiency at every operating point. At low loads, the equivalence ratio is as low as 0.25 and the intake pressure is 0.5 bar. The equivalence ratio is reduced to keep a relatively high manifold pressure, therefore reducing pumping losses. Full information about the control strategy, including maps of equivalence ratio and intake pressure as a function of engine torque and speed, can be obtained from a previous publication [13].

VEHICLE ANALYSIS

The engine efficiency and NO_x maps presented in the previous section are now used in predicting vehicle fuel economy and emissions for a conventional and parallel and series hybrid vehicles. Vehicle power train components are also selected to meet minimum performance requirements (acceleration, hill climb and range). This is accomplished by incorporating the engine maps into an existing vehicle simulation code [5].

The main characteristics of the three vehicles are listed in Table 2. All the vehicles have good aerodynamics and low rolling friction, and use a cryogenic liquid hydrogen storage. The conventional and the parallel hybrid cars use a 5-speed transmission, and the series hybrid uses a single-speed transmission. Transmission efficiency is considered independent of driving conditions. All the vehicles are required to meet the following minimum performance specifications: acceleration from 0 to 97 km/h (0-60 mph) in no more than 10 seconds; climbing a slope of at least 6% at a constant 97 km/h (60 mph) speed with a 272 kg payload; and minimum range of 483 km (300 miles).

Both hybrid vehicles use a flywheel for energy storage. A flywheel is selected because it has the potential of providing a high efficiency and power output. A detailed model of a flywheel has been developed. This model includes a performance map of efficiency as a function of state of charge and power output, as well as a correlation of stand-by losses as a function of state of charge.

A brief description of the operating strategies for the parallel and series vehicles is as follows: The parallel hybrid vehicle operates very similarly to a conventional car, except that a flywheel and a traction motor are used for complementing the power of the engine during sudden accelerations, and for regenerative braking. The use of the flywheel for power peaking allows a reduction in the size of the engine, which may therefore operate more efficiently than the engine used in the conventional car at the low-power conditions that constitute most of the urban and highway driving cycles. The engine is sized to provide the required performance during long hill climbs, for which the flywheel cannot provide the required energy. A low-capacity, low-power flywheel is enough for this application. The control strategy used for the flywheel consists of keeping it near 50% state of charge. In this way, the flywheel is always ready to provide energy for a sudden acceleration, and to absorb energy during regenerative braking. It is noted that there are many possible parallel hybrid control strategies. The 50% state of charge for the flywheel is chosen as a simple strategy that accomplishes both engine downsizing and regenerative braking. It is likely that better parallel strategies may exist.

The series hybrid vehicle operates with an engine in an on-off mode, with no mechanical link between the engine and the wheels. An electric motor provides all tractive power. When the engine is running, it drives a generator that supplies electricity to both the electric motor and an energy storage system. A flywheel is used for energy storage. When the storage system is fully charged, the engine is turned off, and the storage system provides all the energy required for traction and accessories. Series hybrid vehicles have high fuel economy because the engine is operated at a high efficiency condition without ever idling. Spark ignition engines can be run unthrottled thus avoiding pumping

Table 2. Main parameters for hydrogen-fueled conventional, parallel hybrid and series hybrid vehicles.

Vehicle parameter	conventional	parallel	series hybrid
frontal area, m^2	2.04	2.04	2.04
aerodynamic drag coefficient	0.24	0.24	0.24
coefficient of rolling friction	0.007	0.007	0.007
transmission efficiency	0.94	0.94	0.95
transmission gears	5	5	1
accessory load, W	1000	1000	1000
engine idling speed, rpm	600	600	-
launch engine RPM, maximum effort acceleration	3600	3600	-
regenerative braking	no	yes	yes
fraction of available energy recovered by regen. braking, %	-	70	70
maximum one-way flywheel efficiency, %	-	96	96
generator type	-	permanent magnet	permanent magnet
motor type	-	AC induction	AC induction
energy storage device	-	flywheel	flywheel
hydrogen storage	liquid	liquid	liquid

Table 3. Results of the analysis for the conventional, parallel hybrid and series hybrid hydrogen-fueled vehicles.

Vehicle parameter	conventional	parallel hybrid	series hybrid
test weight, (empty weight + 136 kg)	1136	1127	1238
number of engine cylinders	4	3	3
engine displacement, liters	1.97	1.479	1.479
hydrogen tank storage capacity, kg	7.2	5.7	4.8

losses. Engines in series hybrids operate most of the time at a low power, high efficiency condition, at constant speed and load. When additional power is required during long hill climbs, the engine can be operated at a high power level, possibly at a lower efficiency. The flywheel provides the power for sudden accelerations, and the engine is sized for providing the required performance for long hill climbs. On-off engine operation results in decreased engine efficiency, due to the repeated engine cold starts. This reduction in efficiency is taken into account in this analysis by introducing an energy penalty (10 Wh) every time the engine is restarted. This is done to account for increased friction due to engine cold operation. Emissions are not expected to increase considerably due to on-off engine operation because no catalytic converter is used to control emissions.

The results of the analysis are listed in Table 3. Empty weight is set to 1000 kg for the conventional car, which is used as base case. This low weight is chosen because research programs such as PNGV (Partnership for a New Generation of Vehicles) are likely to result in weight reductions for future cars.

Weight for the other two vehicles is calculated by replacing components, and adding or subtracting the weight of the components. A 30% structural penalty is added to the difference in power train weight, to take into account the need for a heavier structure that results from a heavier power train. The parallel hybrid car has almost the same weight as the conventional car. The weight of the added components (flywheel and motor) is compensated by the reductions in weight that result by downsizing the engine, transmission and hydrogen tank. The series hybrid vehicle weighs about 100 kg more than the other two vehicles, primarily due to its need for a flywheel with greater energy storage capacity.

The conventional vehicle requires a 4-cylinder engine to provide the required acceleration performance. This engine is therefore oversized for providing the required hill climbing performance (12.8% instead of 6%). The hybrid vehicles only require a 3-cylinder engine, since the flywheel can be used for providing the power for maximum effort acceleration. Engines for the hybrid vehicles are sized for the hill climb requirement. However, the previously imposed restriction of keeping the cylinder size and geometry constant in the analysis results in an oversized engine for the parallel hybrid. It would be necessary to reduce the size of the individual cylinders to exactly obtain the specified hill climb performance. The mass of hydrogen in the tank (and therefore the mass and volume of the hydrogen tank) is adjusted to meet the desired range. The internal tank volume for the conventional car is about 100 liters (27 gal) [14]. The parallel hybrid only requires a 20 kW, 0.2 kWh flywheel for power augmentation, compared to 100 kW and 1 kWh for the series hybrid.

Fuel economy is listed in the table in gasoline-equivalent units. Fuel economy for the series hybrid is highest because the engine always operates at peak efficiency (36%). The difference in fuel economy between the parallel hybrid and the conventional car is due in part to the higher average engine efficiency that results from downsizing the engine, and in part due to the regenerative braking that can be done in the hybrid.

While all vehicles have a high fuel economy, the fuel economy of the series hybrid vehicle is lower than the 33.5 km/l (79 mpg) predicted for a hydrogen series hybrid vehicle in a previous work by the authors [5]. The results are different because the engine model used in this analysis is based on experimental data for a particular engine (Onan), while the previous work indicates improvements that are likely to be obtained in a future optimized hydrogen engine.

The most desirable feature of the vehicles analyzed in this paper is their low emissions. Emissions are measured only during the urban cycle for EPA certification. Therefore only these values are reported in Table 3. The conventional car has the lowest emission levels. Emissions for the conventional car are projected to be a factor of 60 lower than the CARB ULEV requirements, and therefore a factor of 6 lower than EZEV. The reason for the emissions to be so low is that the engine is operated most of the time at low torque, generating much less than the 10 ppm maximum allowable NO_x (Figure 8). Emissions out of the parallel hybrid vehicle are slightly higher than the conventional car, because the downsized engine has to operate at a higher load. The series hybrid vehicle operates at peak efficiency, which occurs near the limit of 10 ppm of NO_x. Emissions out of the series hybrid engine are therefore higher than for the other two vehicles, exactly at the EZEV limits. Emissions out of the series hybrid could be reduced by changing the engine operating conditions, at the cost of a slight loss in efficiency, to allow for a margin of error during the certification process.

Two important facts should be emphasized about the emissions generated by these vehicles. First, no catalytic converter is required, and therefore emissions do not increase during the life of the car due to catalytic converter or emissions control system failure. Second, emissions are intrinsically low. No matter how aggressive a driver may drive, emissions are always under 10 ppm NO_x, eliminating high off-cycle emissions that are common in gasoline cars.

Figures 5, 6, 7 and 8 are used to illustrate some of the results. Figure 5 shows flywheel state of charge for the series hybrid and the parallel hybrid vehicles along the

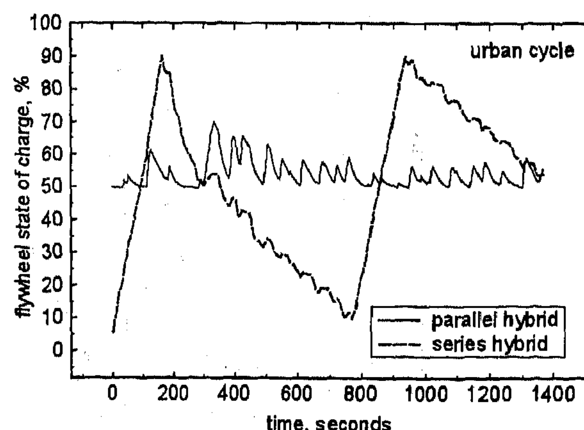

Figure 5. Flywheel state of charge for the series hybrid and the parallel hybrid vehicles along the urban driving cycle. For the series hybrid, the engine runs at constant power until it fully charges the flywheel. For the parallel hybrid, the flywheel is kept at about 50% state of charge, ready to store energy during regenerative braking, or provide energy for a sudden acceleration.

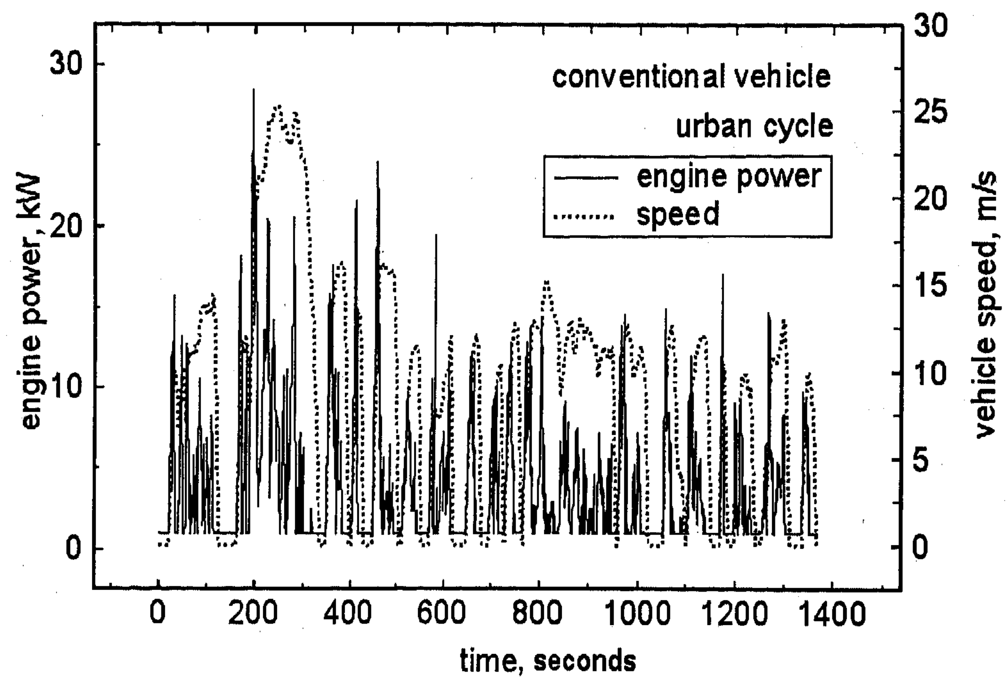

Figure 6. Engine power for the conventional vehicle during the urban cycle. The driving cycle speed is indicated by a dotted line.

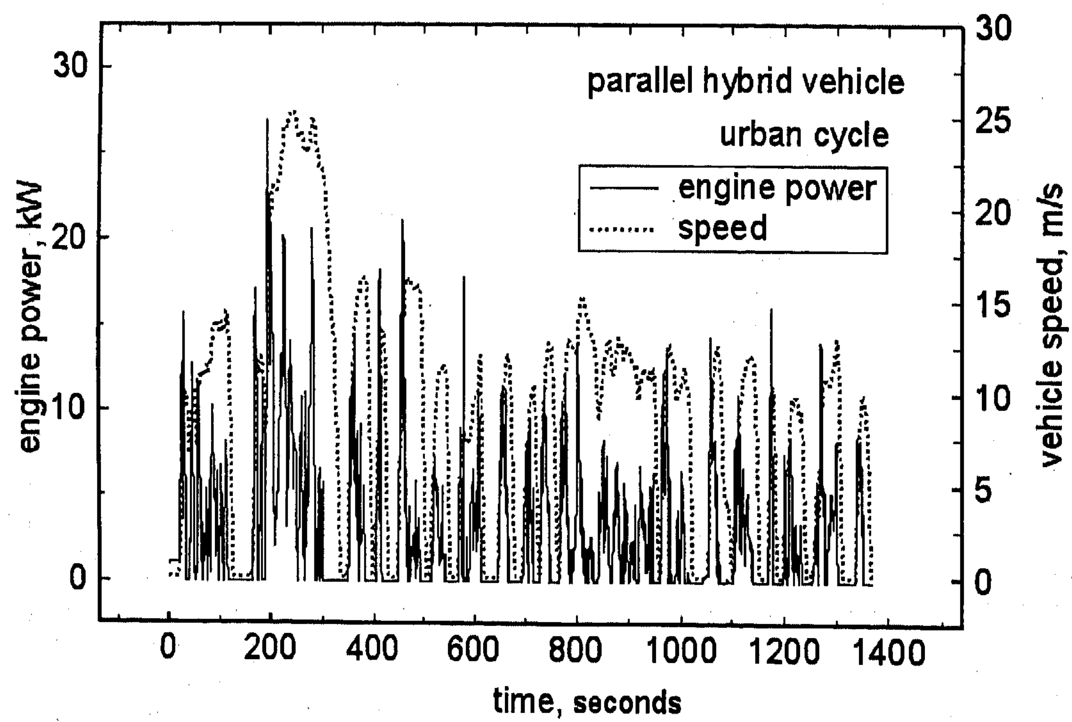

Figure 7. Engine power output for the parallel hybrid vehicle. The driving cycle speed is indicated by a dotted line.

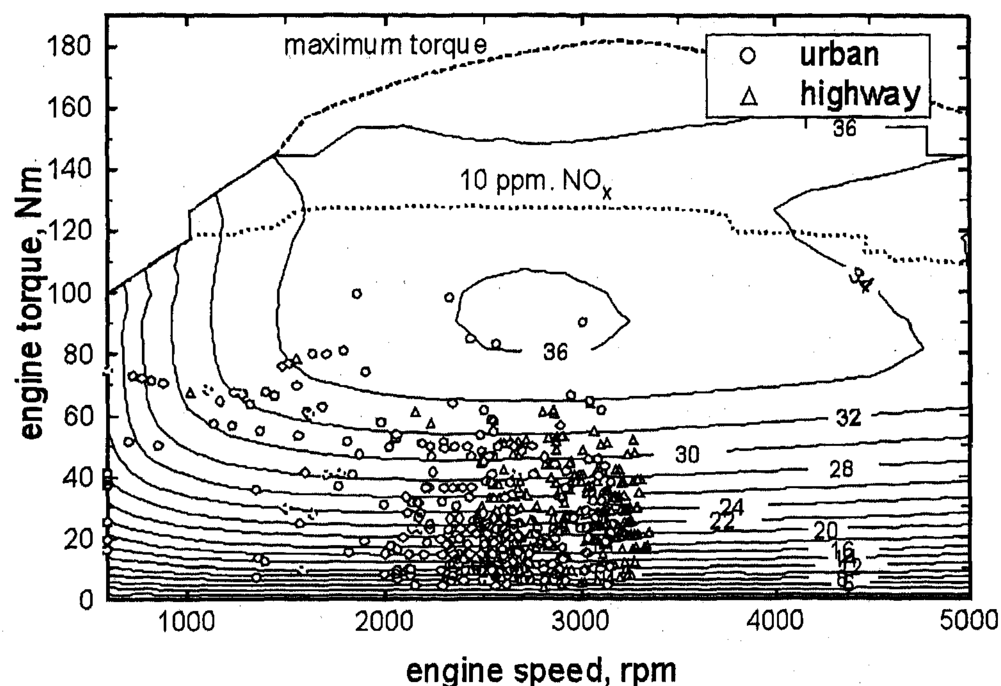

Figure 8. A representative set of engine operating points for the conventional car, for both the urban and highway cycles, superimposed on the engine efficiency map (repeated from Figure 3).

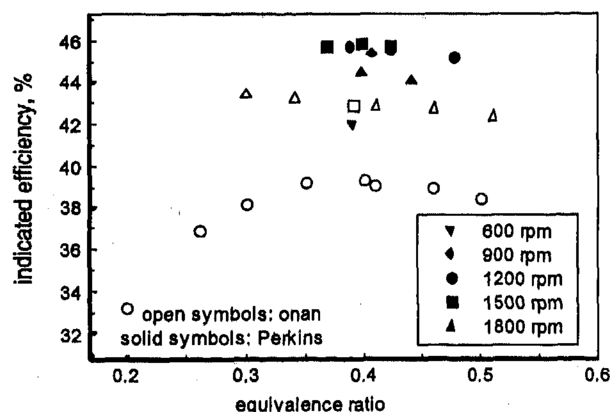

Figure 9. Indicated efficiency as a function of equivalence ratio and engine speed for the Perkins engine (solid symbols) and the Onan engine (open symbols, repeated from Figure 1 for comparison).

urban driving cycle. For the series hybrid, the engine runs at constant power until it fully charges the flywheel, which takes about 180 seconds. The flywheel then provides all the energy requirements, discharging in about 600 seconds. The engine is then turned on again to repeat the cycle. For the parallel hybrid, the flywheel is kept at about 50% state of charge, ready to store energy during regenerative braking, or provide energy for a sudden acceleration. The flywheel state of charge increases due to regenerative braking, and drops when power is extracted from the flywheel. Flywheel stand-by losses are projected to be of the order of 80 W and also tend to reduce the state of charge.

Figure 6 shows engine power for the conventional vehicle during the urban driving cycle. The driving cycle speed is indicated by a dotted line. Minimum engine power output is 1000 W, due to the need to provide for accessories. Figure 7 shows the nearly identical engine power output for the parallel hybrid vehicle. Power out of the two engines is very similar, except that peak power out of the parallel hybrid is reduced by 1 to 3 kW due to the power provided by the flywheel. Another difference between the output powers is that minimum power out of the parallel hybrid engine is zero, since the flywheel can now provide the accessory loads.

Figure 8 shows a representative set of engine operating points for the conventional car, for both the urban and highway cycles, superimposed on the engine efficiency map (repeated from Figure 3). The

points indicate that the engine operates at low torque during most of the time, therefore generating very low emissions. Efficiency could be improved by relaxing the 10 ppm NO_x emission limit, and this limit could be relaxed while still achieving EZEV levels. However, a vehicle that can emit more than 10 ppm of NO_x would not be intrinsically an EZEV, and would generate high NO_x if driven aggressively at high torque.

EXPERIMENTAL HYDROGEN ENGINE EVALUATION UPDATE

An experimental evaluation of a new hydrogen engine (Perkins) has been recently done [4]. The main characteristics of this engine are listed in Table 4. The cylinder is bigger than for the Onan engine (834 cm^3 compared to 493 cm^3), therefore reducing heat transfer losses. Preliminary results are shown in Figure 9, which gives indicated efficiency as a function of equivalence ratio and engine speed for the Perkins engine and the Onan engine (repeated from Figure 1 for comparison). The indicated efficiency for the Perkins engine is higher than for the Onan engine, and it is very insensitive to equivalence ratio and engine speed. Future runs will attempt to increase the engine efficiency by optimizing the turbulence within the cylinder to minimize heat transfer and timing losses.

Table 4. Perkins engine characteristics and experimental conditions.

Experimental range for engine speed, rpm	600-1800
Experimental range for volumetric efficiency, %	90-110

CONCLUSIONS

This paper presents the development and validation of a time-dependent engine model, and its application to conventional and hybrid vehicles. The engine model is applied to a hydrogen engine which has been experimentally tested. The model predicts accurately engine efficiency and NO_x emissions over the full range of experimental operating conditions. The validated model is then used to generate engine performance and emission maps for supercharged engine operation. The performance maps are then incorporated into a vehicle evaluation code to obtain performance and emissions for hydrogen-fueled conventional, parallel and series hybrid vehicles. All vehicles are specified to meet minimum acceleration, hill climb and range requirements that make them comparable to current automobiles. Analysis of these vehicles yields the following results:

1. Emissions out of the conventional car are projected to be a factor of 60 lower than the CARB ULEV requirements, and therefore a factor of 6 lower than EZEV. The engine control strategy presented in this paper guarantees that the conventional vehicle achieves EZEV emissions levels regardless of how the car is driven. The conventional vehicle also has a high fuel economy.

2. The parallel hybrid vehicle uses a downsized engine and a small flywheel for power augmentation and regenerative braking. Emissions are also well within EZEV range. Fuel economy falls between the conventional and the series hybrid cars.

3. The series hybrid vehicle has the highest fuel economy. Emissions are higher than for conventional cars, at the EZEV limits. Emissions in a series hybrid vehicle are intrinsically independent of driver's input.

These results indicate that lean-burn hydrogen spark-ignited engines are an alternative to providing EZEV emissions, while at the same time providing a range, acceleration and hill climbing performance comparable to conventional cars. These vehicles are intrinsically EZEV, since emissions are not controlled with a catalytic converter that may degrade, and are also independent of the driving habits of the driver.

Parametric Design of the Drive Train of an Electrically Peaking Hybrid (ELPH) Vehicle

Yimin Gao[1], Khwaja M. Rahman, and Mehrdad Ehsani
Texas A&M Univ.

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

The operation of an electrically peaking hybrid vehicle (ELPH) can be divided into two basic modes. • Constant or cruising speed mode in which a small internal combustion engine (ICE) is used to power the vehicle. • Peak power mode in which the combination of an electric motor and ICE is used to supply peak power for acceleration and limited-duration steep hill climbing of the vehicle.

A method, by which the engine size and the speed reduction ratio from the engine to drivewheels can be developed based on the cruising mode, is presented in this paper. The electric motor power rating and the motor gear ratio to the drive wheels can then be determined, based on the acceleration and gradeability. The results show that a simple single-gear transmission would be a good selection for overall performance.

INTRODUCTION

Petroleum fueled, internal combustion engine powered vehicles are the most popular means of transportation, because of their high energy density and relatively high power density. However, in recent years, increasing concern over air pollution, caused by tailpipe emissions of the petroleum-based vehicles, and the dwindling petroleum resources have caused the automotive engineers and automakers to re-evaluate the designs of the conventional internal combustion engine powered vehicles. The conventional automotive drive train suffers from a number of disadvantages :

1. The inherently mismatched speed-torque characteristic of the engine and the vehicle necessitates a complicated transmission, with its associated losses and inflexibility.

2. In order to have ample power for acceleration and gradeability with a limited number of transmission gears, the engine must be oversized to roughly ten times that required for cruising at *100 Km/h* on a level road and three or four times that required for maintaining *100Km/h* on a *6%* grade.[1]

3. Today's internal combustion engines show a significant difference in specific fuel consumption between partial load and the optimal operating point, which is close to full load as shown in *Fig. 1*. An oversized engine moves the cruising operating point away from the optimal operation point. Consequently, ICE vehicles have low efficiency [2].

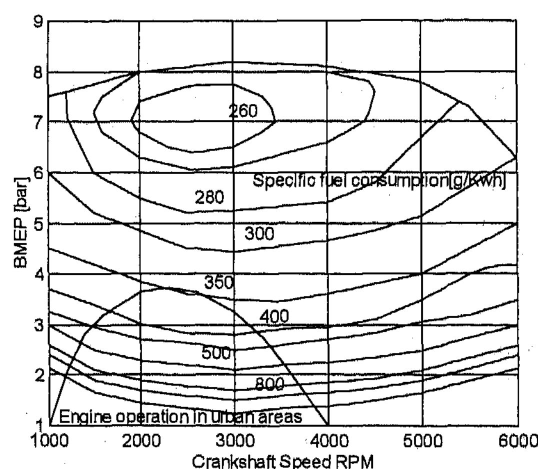

Fig. 1. Typical SI-engine SFC Map with Actual Operation Point[2]

The electric motor, in addition to its clean, quiet and efficient operation, has inherent flexibility in its speed-torque control. *Fig. 2* shows a typical torque-speed characteristics of the electric motor with power electronic drive. The motor can operate anywhere within this torque-speed boundary. This

[1] Visiting scholar from Jilin University of Technology, China

allows the motor to meet the vehicle torque-speed requirements at all times, without a variable gear transmission. However, pure electric vehicles (Ev's) suffer from other disadvantages[9].

1. The heavy and bulky battery pack, with its relatively small energy storage, makes the EV limited in range, and load carrying capacity.

2. Long charging time limits the EV's practicality.

Therefore, commercial success of the EV depends strongly on the development of advanced batteries. However, progress in batteries over the past several decades has not been adequate.

The hybrid configurations, in which two power sources are applied to propel the vehicle, show significant promise[7,8]. The hybrid electric-internal combustion engine drive train, if properly configured, can combine many of the advantages of both EV and ICE vehicles [9].

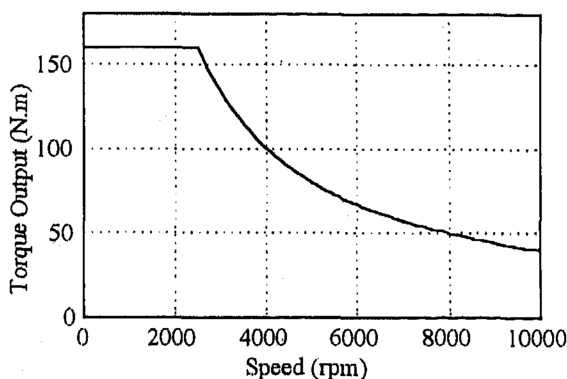

Fig. 2. The Speed-torque Characteristic of Electric Motor

ELECTRICALLY PEAKING HYBRID CONFIGURATION

The operation of passenger vehicles can be divided into two basic modes: constant speed (cruising), and acceleration (peak power). In cruising mode, relatively low power is required from the drive train. However, large amount of energy is consumed in a long trip. In acceleration mode, high peak power is required but not much energy is consumed, due to its brief and transient occurrence. Proper parallel combination of ICE, for cruising operation, and electric motor with a small battery pack, for acceleration, can satisfy these requirements in a viable drive train. The motor with a small chemical battery pack optimized for high power would have acceptable power capability and power density for acceleration[3]. A small ICE with a small fuel tank would have the energy density for cruising and recharging the battery for the next acceleration.

A configuration of such an electrically peaking hybrid (ELPH) vehicle is shown in *Fig. 3* in which the base power unit is the engine and peaking power unit (or load leveling device) is the electric motor.

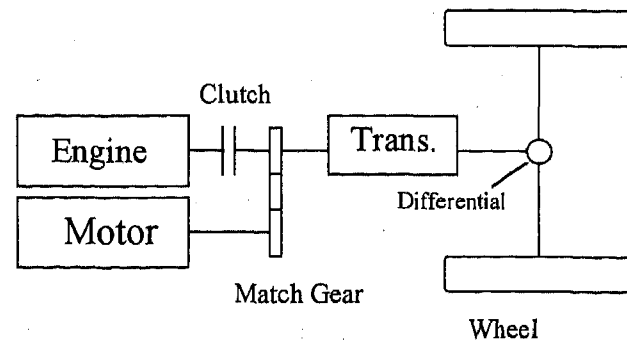

Fig. 3 The Configuration of an Electrically Peaking Hybrid (ELPH) Vehicle

The ELPH configuration, in addition to satisfying the requirements of acceleration and gradeability, has the ability to recover braking energy with the electric motor functioning in regenerating mode. Furthermore, when the vehicle operates with light load, such as at a low constant cruising speed or going down a slight hill, the engine can recharge the battery pack to maintain adequate state-of-charge. More beneficially, this enhances the engine load, for operation close to its optimal point. A well designed ELPH vehicle may never use an external source to charge its battery pack and can achieve an excellent fuel economy.

In this paper, the following specification of the Electrically Peaking Hybrid (ELPH) vehicle prototype, which is being developed at Texas A&M University, will be taken as the example.

Curb weight	*1700 kg,*
Rolling resistance coefficient of tire	*0.013,*
Aero-dynamic drag coefficient	*0.29,*
Front area	*2.13 m^2,*
Wheel radius	*0.2794 m.*

CRUISING MODE

As described above, when the vehicle operates on level ground with a constant cruising speed, the engine alone delivers power to the drivewheels. Consequently, the performance of the vehicle is determined only by the engine power and speed reduction ratio from the engine to the drivewheels.

ENGINE POWER REQUIREMENT- The determination of the engine power plays a very important role in the design of ELPH vehicle. An oversized engine would lose its fuel-saving advantage as in the conventional vehicles. On the other hand, an undersized engine can not deliver enough power to meet the requirements of the vehicle. Therefore, a large battery pack and a large motor would be needed to compensate for the shortage of engine power. Consequently, the ELPH vehicle would suffer from the same problems as an EV.

When the vehicle operates on a level ground with a constant cruising speed, the engine must deliver enough power to overcome the vehicle load power which includes the rolling resistance power and the aero-dynamic drag power. Thus, the required engine power output is

$$Pe = \frac{v}{1000\eta_{et}}\left(mgf + \frac{1}{2}\rho C_D A v^2\right) \qquad (1)$$

where, v = speed of vehicle, *m/s*,

η_{et} = efficiency of the transmission form engine to drivewheels, *0.9*

m = vehicle mass, *Kg*,

f = rolling resistance coefficient,

g = gravity acceleration, *9.81 m/s²*,

C_D = aero-dynamic drag coefficient,

A = front area of the vehicle, m^2,

ρ = air density, *1.228 Kg/m³*.

Fig. 4. shows the vehicle load power as a function of the vehicle speed in cruising mode This figure indicates that not much power is needed to maintain the vehicle operation in cruising mode. About *30 Kw* of power capacity will be plenty to meet the requirement of the vehicle at a speed of *130 Km/h (81.5 mph)*. This *30 Kw* of engine power capacity is quite small in comparison to the average *50* to *70 Kw/1000Kg* specific power of conventional cars More precise selection of the engine power capacity will be made with consideration of recharging of the peaking battery pack

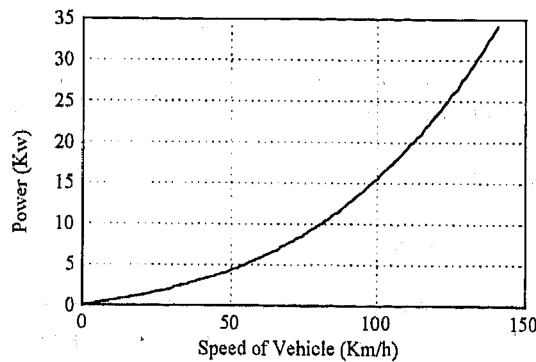

Fig. 4. Required Engine Power Versus Constant Speed on A Level Road

DIFFERENTIAL GEAR RATIO-*Fig. 5.* shows the speed-power characteristics of a typical gasoline SI engine. Equation (2) gives the vehicle speed for a single-gear transmission or a top gear operation of a multi-gear transmission. By equation (2), *Fig. 5* can be transformed into a vehicle speed-power profile, as shown in *Fig. 6*,

$$v = \frac{\pi r N}{30 r_d} \quad (m/s) \qquad (2)$$

where, r_d = differential gear ratio drivewheels,

r = radius of the drivewheel, *m*

N = speed of engine, *rpm*.

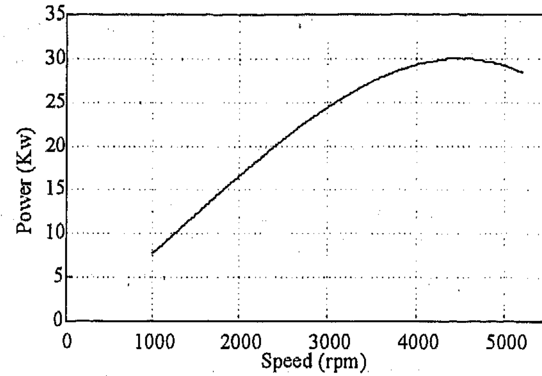

Fig. 5. Typical Characteristics of SI Engine

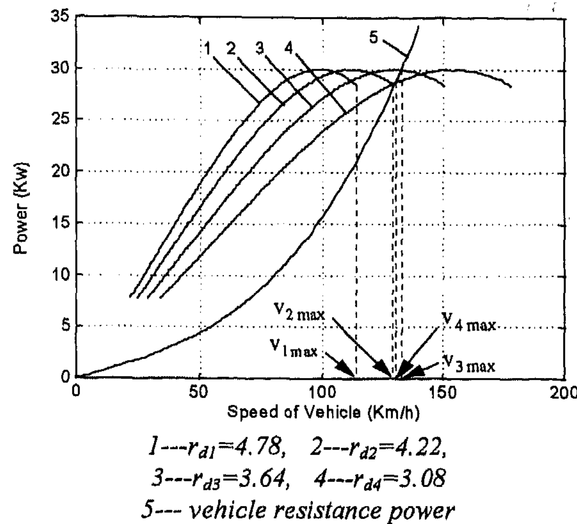


In *Fig. 6.* several engine power curves with different differential gear ratios are shown along with the vehicle resistance power curve. The top speeds of the vehicle with different differential gear ratios are represented by the crossing points of engine power curves with resistance curve (such as v_{2max}, v_{3amx} and v_{4max} corresponding to r_{d2} , r_{d3}, and r_{d4}) or by the maximum rpm of the engine (such as v_{1max} corresponding to r_{d1}). *Fig. 6* indicates that, with r_{d3}, the vehicle has a highest top speed which corresponds to the peak power of the engine. However, with r_{d2}, the vehicle has more remaining power, defined as the difference between the engine power curve and vehicle resistance power curve only a slight top speed reduction. The remaining power can be used for acceleration or grade climbing or battery charging . As shown in *Fig. 6*, with a gear ratio of r_{d2} and at a speed of *100 Km/h*, the engine has about half of its power remaining. A large gear ratio, such as r_{d1}, will allow the vehicle to have more remaining, but the top speed will suffer a significant reduction. In contrast, too small a gear ratio, such as r_{d4}, will allow the vehicle to have a small remaining power. For a small engine with the addition of battery charging load, the differential gear ratio of r_{d2} is a suitable selection.

ACCELERATION MODE

When the vehicle experiences acceleration or steep hill climbing, high traction peak power is needed. This high transient power (peaking power) is supplied by both the engine and the motor working together. In the ELPH vehicle, the contribution of the electric motor drive to the peak power should be dominant. Thus, the acceleration and maximum gradeability of the ELPH drive train is mainly determined by the electric motor drive and battery power rating.

ACCELERATION-The ideal characteristic of a power unit for vehicular application is constant power output over the full speed range[4,5,6,]. A vehicle with this kind of power unit does not require a multi-gear transmission to enhance its acceleration and gradeability performance. A well controlled electric motor has speed-torque characteristics that are close

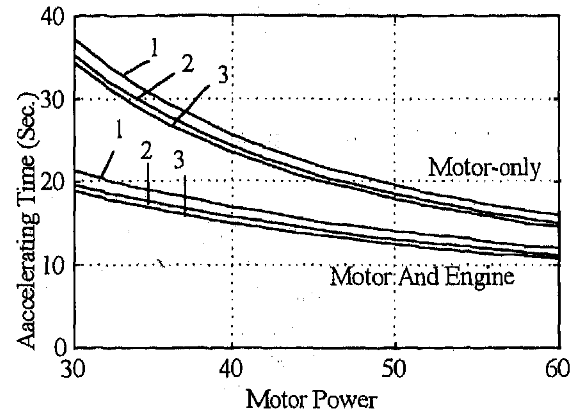
to this ideal, as shown in *Fig. 2*. Here the motor has a constant power output over a large range of speed and a constant torque output over the low speed range. Therefore, the acceleration performance of the ELPH vehicle will be determined by the power rating of the electric motor and is only slightly influenced by the gear number and gear ratios of the transmission.

1---r_{d1}=4.78, 2---r_{d2}=4.22,
3---r_{d3}=3.64, 4---r_{d4}=3.08
5--- vehicle resistance power

Fig. 6. Engine Power Output And Resistance Power Versus Vehicle Speed with Different Differential Gear Ratios

The vehicular acceleration on a level ground can be expressed as:

$$\frac{dv}{dt} = \frac{F_t - F_w - F_f}{\delta m} \quad (m/s^2) \qquad (3)$$



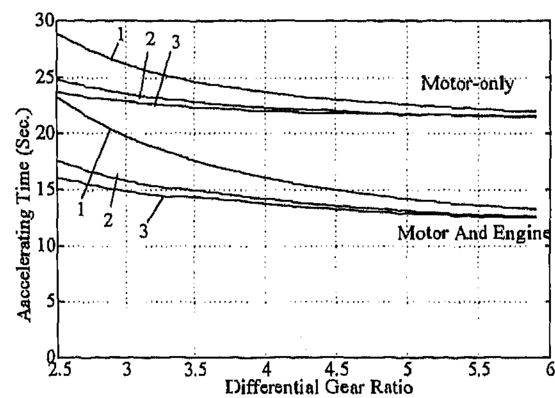
where, $F_t = (T_e + T_m r_m) r_t r_d \eta_t / r$, the thrust force of ground acting on the drivewheels (T_e and T_m are engine torque and motor torque respectively; r_t and r_d are the transmission and differential gear ratios, respectively; r_m is gear ratio from motor to driveshaft.), $F_w = 0.5\rho C_D A v^2$, the aero-dynamic drug, and $F_f = mgf$, the rolling resistance. δ is the rotational inertia coefficient.

The accelerating time from zero to a desired speed , v^*, can be expressed as:

$$t = \int_0^{v^*} \left(\frac{dt}{dv}\right) dv = \int_0^{v^*} \frac{\delta m}{F_t - F_w - F_f} dv \qquad (4)$$

The calculation of the vehicle acceleration time is somewhat difficult due to the speed-torque characteristic of the engine which, generally, can not be expressed by an explicit formula. However, it may be completed by numerical methods with a computer.

Fig. 7 shows a plots of acceleration times from zero to *96 Km/h* vs. electric motor power with different gear ratios from the motor to the driveshaft, r_m . The assumptions are a *30 Kw* engine, motor characteristics as shown in *Fig. 2*, a differential gear ratio of r_d = *4.23* and transmission gear ratio of r_t = *1.0*.



1---r_m=1.5, 2---r_m=1.9, 3---r_m=2.3

Fig. 7. The Accelerating Time Versus Electric Motor Power

As we expected, the gear ratio from the motor to the driveshaft has a small influence on the acceleration time and, the electric motor power plays a dominant role in the acceleration of the vehicle.

Using a computer program, the acceleration time of the vehicle with a multi-gear transmission can also be calculated, as shown in *Fig. 8*. The results indicate that the number of gears in the transmission has a small influence on the acceleration of the vehicle when the differential gear ratio is greater than *4*. This result is desirable because a single-gear transmission can greatly simplify the drive train and the control system.

1- gear transmission, gear ratio, 1
2--2-gear transmission , gear ratios , 1.6,1
3--3-gear transmission , gear ratios, 2.54, 1.6 and 1
Engine power = 30 Kw,
Electric motor power = 42 Kw
Gear ratio from motor to driveshaft, r_m=1.7

Fig. 8. Accelerating Time with Different Number of Gears and Different Differential Gear Ratios

GRADEABILITY-The gradeability of the vehicle is determined by the maximum thrust forces acting on the drivewheels. The gradeability of a vehicle can be expressed by

$$\sin\alpha = \frac{F_t - F_w - F_f}{mg} \quad (5)$$

where α is the road angle in degrees.

Due to the small aero-dynamic drag at low speeds, the gradeability of the vehicle is mostly determined by the maximum torque of the motor and the engine as well as the gear ratios of the transmission. *Fig. 9* shows the gradeability of the vehicle with a three-gear transmission in which the parameters used are the same as in *Fig. 8*. *Fig. 9* indicates that the gradeability will be greatly enhanced by using a multi-gear transmission. However, in real applications, the vehicle would seldom use the first or second gear for climbing a grade, because, normally, such large grades are seldom encountered in highway and urban driving. This also means that a single-gear transmission would serve the gradeability well.

Fig. 10 shows gradeability versus different power outputs with a single-gear transmission in which the parameters are the same as in *Fig. 8*. Actually, the gradeability can be enhanced, without a need for increasing the gear ratio or applying a multi-gear transmission, by decreasing the base speed of the electric motor. This is accomplished in the low speed, constant torque region of the motor operation

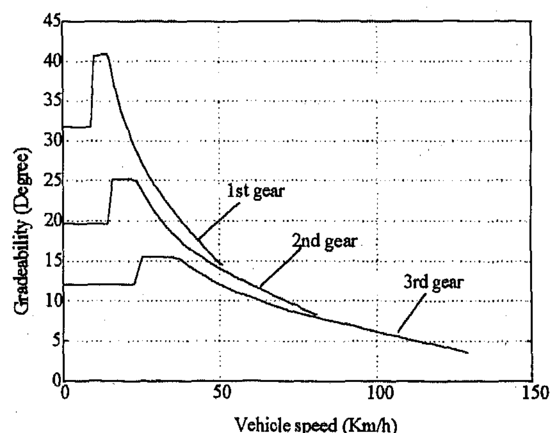


Fig. 9. Gradeability with A Multi-gear Transmission

CONCLUSION

The ELPH vehicle can combine many advantages of conventional and electric vehicles. A well designed ELPH vehicle would have a comparable performance to the conventional vehicle and excellent fuel economy and emission characteristics.

Using the method presented in this paper, the power capacity of a small internal combustion engine and a single speed reduction gear can be used to achieve a satisfactory performance and a excellent fuel economy at cruising speed. Properly selected electric motor power and speed reduction gear can eliminate application of the complicated multi-gear transmission with satisfactory acceleration and hill climbing performance.

Theoretical Consideration of Relation of Rear-Wheel Skid to Steering Inputs

Hideki Sakai
Toyota Motor Corp.

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

This paper examines the steering inputs that cause rear-wheel skid. First, we compare the front and rear side force at maximum lateral acceleration and thus distinguish rear-wheel skid from front-wheel skid. Next, we examine the affect of forward velocity on rear-wheel skid, and show that rear-wheel skid cannot occur below a given forward velocity. We use this velocity as an index of rear-wheel skid tendency and formulate it. This formula shows that the difference between front and rear axle trajectories strongly affects rear-wheel skid.

INTRODUCTION

This paper investigates the kind of steering inputs that make vehicles skid on their rear wheels, extending the Force and Moment method[1] to the frequency domain.

As shown in Figure 1, the stability factors of almost all passenger cars are always positive even at maximum lateral acceleration. In other words, they tend to front-wheel skid in steady-state turning (i.e. understeer) at all times. However, these vehicles also often tend to rear-wheel skid with rapid steering inputs.

From the Force and Moment method, in front-wheel skid, the front axle generates its maximum side force at the maximum lateral acceleration, while the rear axle does not. This paper applies this concept to behavior with sinusoidal steering inputs in order to investigate rear-wheel skids with rapid steering inputs.

VEHICLE BEHAVIOR WITH SINUSOIDAL STEERING INPUTS

MODEL - Figure 2(A) shows the vehicle model[1][2]. Transforming Fig. 2(A) into Fig. 2(B) as described in the particle system, we investigate vehicle behavior. Using Fig. 2(B), we will focus on the difference between the particles lateral motion in the discussion section. The motion equations of this vehicle model are in the form

$$m\,u\left(\frac{d\beta}{dt}+r\right)=F_f+F_r \tag{1}$$

$$I_d\, m\, l_f\, l_r\,\frac{dr}{dt}=l_f\,F_f-l_r\,F_r \tag{2}$$

$$F_i=CF_i\;F_{zi} \tag{3}$$

Figure 3 shows the tire model[2]. We assume dynamic properties of the tires based on Reference 3.

The motion equations of the tire model are in the form

$$CF_i=C_i\left[1-\frac{4}{27}\left(\frac{C_i}{\mu_i}\right)^2\alpha_{\text{ground }i}{}^2\right]\alpha_{\text{ground }i} \tag{4}$$

$$\alpha_{\text{ground }i}=\alpha_i-\frac{v_{\text{ground }i}}{u} \tag{5}$$

$$v_{\text{ground},i}=\frac{d}{dt}\,y_{\text{tire }i} \tag{6}$$

$$y_{\text{tire }i}=\frac{\frac{1}{2}F_i}{k_{\text{tire}i}}=\frac{CF_i}{ck_{\text{tire}i}} \tag{7}$$

$$\alpha_f=\beta+\frac{l_f\,r}{u}-\delta \tag{8}$$

$$\alpha_r=\beta-\frac{l_r\,r}{u} \tag{9}$$

$$ck_{\text{tire}i} = \frac{k_{\text{tire}i}}{\frac{1}{2}F_{zi}} \qquad (10)$$

where $\alpha_{groundi}$ is the slip angle at the contact region of the tire, $y_{groundi}$ is lateral deformation of the tire, and k_{tirei} is tire lateral stiffness. In addition, we term C_i *effective cornering coefficient* and μ_i *effective friction coefficient.*

The front wheels skid when $CF_f = \mu_f$ and conversely the rear-wheel skid when $CF_r = \mu_r$. Thus the comparison of μ_i implies the skid tendency in steady state turning as follows[1]:

1) If $\mu_r > \mu_f$, the vehicle tends to front-wheel skid because the lateral acceleration of the vehicle cannot exceed μ_f, which is maximum lateral acceleration.

2) If $\mu_f > \mu_r$, the vehicle tends to rear-wheel skid.

This paper assumes $\mu_r > \mu_f$ and $C_r > C_f$; this condition represents almost all current passenger cars (Appendix A).

INPUT - This paper adopts a sinusoidal steering input at various frequencies as the input into the vehicle model. This steering angle is set to encourage the maximum lateral acceleration. This steering angle is expressed by

$$\delta = \delta_0(\omega) \sin \omega t \qquad (11)$$

where $\delta_0(\omega)$ is the steering angle that promotes the maximum lateral acceleration at ω.

OUTPUT - The tire model has nonlinearity, and consequently the vehicle response contains harmonics. Hence, we extract the fundamental component from the output of the calculation using a Fourier series.

DEFINITION OF SKIDDING IN THE FREQUENCY DOMAIN - We can extend the definition of skidding defined in the Force and Moment Method to the frequency domain as follows:

1) If $CF_f = \mu_f$, the front wheel skids.

2) If $CF_r = \mu_r$, the rear wheel skids.

RESULTS - Figure 4(A) shows calculations of the side forces coefficients and maximum lateral acceleration ($A_{max}(\omega)$) for both axles. These calculations were made to detect the optimum $\delta_0(\omega)$ through many trials.

In Fig. 4(A), we can divide the frequency band as follows:

1)Frequency where $CF_f = \mu^*_f$, namely, the front wheel skids.

2)Frequency where $CF_r = \mu^*_r$, namely, the rear wheel skids.

At the rear-wheel skid frequencies, the rear particle moves in the lateral direction more than the front particle, as shown in Fig. 4(B). In particular, when I_d=1, the ratio of the lateral displacement of the rear particle to that of the front exceeds μ^*_r/μ^*_f (>1) at these frequencies.

In addition, μ^*_i in Fig. 4(A) disagrees with μ_i in Fig. 3; this phenomenon is caused by one of the propertie of the filter, which will be described in the discussion section.

SLALOM DIAGRAM - Figure 5 is transformed from Fig. 4(A). We call this figure the *slalom diagram.* The slalom diagram enables us to understand the skid tendency. $A_i(\omega)$ is the "extended" maximum lateral acceleration at the center of gravity assuming that the other axle of axle i does not reach effective friction coefficient; $A_i(\omega)$ is defined by

$$A_i(\omega) = \frac{\mu^*_i}{|CF_i(\omega)|}|A_{\max}(\omega)| \qquad (12).$$

The larger one of $A_i(\omega)$ cannot be realized and the smaller one equals $A_{max}(\omega)$. This figure shows the skid tendency as follows:

1) If $A_r(\omega)>A_f(\omega)$, the front wheel skids.

2) If $A_f(\omega)>A_r(\omega)$, the rear wheel skids.

This agrees with the definition of front/rear-wheel skid tendency in the frequency domain.

To clarify this point, we will focus on the response, for instance, at about 1.1 Hz. As shown in Fig. 4, $CF_r(\omega)$ corresponds to μ_r^* at about this frequency. By substituting $CF_r(\omega)=\mu_r^*$ into EQ (12), EQ (12) becomes $A_r(\omega)=A_{max}(\omega)$. On the other hand, since $CF_f(\omega) < \mu_f^*$, $A_f(\omega)>A_{max}(\omega)$ from EQ (12). Since $A_f(\omega)>A_r(\omega)$ (=$A_{max}(\omega)$), the vehicle tends to rear-wheel skid at this frequency. The slalom diagram thus shows $A_{max}(\omega)$ and skid tendency.

LINEAR CALCULATION FOR SLALOM DIAGRAM

This section describes a linear calculation method for the slalom diagram. The reasons for the linearization are as follows:

1) In the simulation method in the previous chapter, we need much time for many calculations to detect the optimum steering angle that promotes maximum lateral acceleration at each frequency.

2) This numerical simulation is unsuitable for theoretical interpretations of $A_i(\omega)$ because $A_i(\omega)$ is not formulated in the simulation.

Motion Equations - Since we adopt sinusoidal inputs, we can describe the motion equation using the $j\omega$ operator form. Linearizing CF_i (APPENDIX B), we can reduce EQS (1) through (9) to

$$m\,u\,(\beta j\,\omega + r) = CF_f\,F_{zf} + CF_r\,F_{zr} \qquad (13)$$

$$I_d\,l_f\,l_r\,m\,r\,j\,\omega = l_f\,CF_f\,F_{zf} - l_r\,CF_r\,F_{zr} \qquad (14)$$

$$CF_f = -\left(1 - \frac{l^*_{df}}{u} j\,\omega\right) C^*_f\,\alpha_f \qquad (15)$$

$$CF_r = -\left(1 - \frac{l^*_{dr}}{u} j\,\omega\right) C^*_r\,\alpha_r \qquad (16)$$

$$\alpha_f = \beta + \frac{l_f\,r}{u} - \delta \qquad (17)$$

$$\alpha_r = \beta - \frac{l_r r}{u} \quad (18)$$

where

$$\frac{C^*_i}{C_i} = \frac{3}{4} \quad (19)$$

$$\frac{l^*_{di}}{l_{di}} = \frac{1}{\sqrt{3}} \quad (20)$$

$$l_{di} = \frac{C^*_i}{ck_{tirei}} \quad (21).$$

In these equations, l^*_{di} is the tire relaxation length. We treat this length as negative time-constant of a first-order-lead-system based on the "Complex Cornering Stiffness" concept[4][5]. Solving EQS (13) through (21), we obtain

$$\frac{A_f(\omega)}{g} = \left| \frac{\frac{(j\omega)^2}{\omega_s^2} + \frac{2\zeta_s j\omega}{\omega_s} + 1}{\frac{(j\omega)^2}{\omega_{skid}^2} + \frac{2\zeta_{skid} j\omega}{\omega_{skid}} + 1} \right| \mu^*_f \quad (22)$$

$$\frac{A_r(\omega)}{g} = \left| \frac{\frac{(j\omega)^2}{\omega_s^2} + \frac{2\zeta_s j\omega}{\omega_s} + 1}{T_{skid}\, j\omega + 1} \right| \mu^*_r \quad (23)$$

$$\frac{1}{\omega_{skid}^2} = \frac{I_d}{C^*_r}\frac{l}{g} - cic_r \frac{l^*_{dr}}{l}\left(\frac{l}{u}\right)^2$$

$$\frac{2\zeta_{skid}}{\omega_{skid}} = \left(cic_r - \frac{l^*_{dr}}{l}\right)\frac{l}{u}$$

$$\frac{1}{\omega_s^2} = \frac{I_d}{C^*_r}\frac{l_r}{g} - \frac{l_r}{l}\frac{l^*_{dr}}{l}\left(\frac{l}{u}\right)^2$$

$$\frac{2\zeta_s}{\omega_s} = \left(\frac{l_r}{l} - \frac{l^*_{dr}}{l}\right)\frac{l}{u}$$

$$T_{skid} = (I_d - 1)\frac{l_r}{u}$$

$$cic_r = \frac{I_d\, l_f + l_r}{l}$$

(Appendix C).

Figure 6 shows the calculation results of EQS (22) and (23). The comparison between the results of the linear calculation and those of the numerical simulation shows that we can use this linearized model for slalom diagram prediction.

INDEX FOR REAR-WHEEL SKID

This section proposes and formulates an index for rear-wheel skid to steering inputs.

INDEX - Figure 7 shows the rear-wheel skid tendency at various speeds. This figure illustrates that rear-wheel skid never occurs below a given speed for sinusoidal steering. We call this speed the *skid critical speed* (V_{skid}). V_{skid} is adopted as the index of rear- wheel skid in this paper. V_{skid} is described in the form

$$V_{skid}^2 = F_s V_{tt}^2$$

(when I_d=1 and l^*_{dr}=0) (24)

$$V_{skid}^2 = \frac{C^*_r}{C_r}\left(1 - \frac{l^*_{dr}}{l}\right)^2 \left[F_s + 2\frac{R^4}{\left(1 - \frac{l^*_{dr}}{l}\right)^2}\frac{l^*_{dr}}{l}\right] V_{tt}^2$$

(when I_d=1) (25)

$$V_{skid}^2 = \frac{C^*_r}{C_r}\frac{R^2}{I_d}\left[\frac{cic_r^2}{R^2} - (I_d - 1)^2\left(\frac{l_r}{l}\right)^2\right] F_s V_{tt}^2$$

(when l^*_{dr}=0) (26)

$$V_{skid}^2 = \frac{C^*_r}{C_r}\left[1 + \frac{l_r - l_f}{l}(1 - I_d) + 2\left(\frac{R^4}{F_s} - 1\right)\frac{l^*_{dr}}{l}\right] F_s V_{tt}^2$$

when $I_d \doteqdot 1$ and $l^*_{dr}/L \ll 1$) (27)

where

$$V_{tt}^2 = C_r \frac{l}{2} g \quad (28)$$

$$F_s = \left(1 + \sqrt{1 - \frac{1}{R^2}}\right) R^2 \quad (29)$$

$$R = \frac{\mu^*_r}{\mu^*_f} \quad (30)$$

(Appendix D), where

$$\mu^*_i = \frac{9}{8}\mu_i \quad (31)$$

(Appendix B)

$$cic_r = \frac{I_d\, l_f + l_r}{l} \quad (32)$$

$$I_d = \frac{I_Z}{m\, l_f\, l_r} \quad (33).$$

In EQ (24), we define the first term as *statics factor* (F_s) and the second as *track-on-track speed* (V_{tt}). F_s is similar to the "yawing moment coefficient," which is defined by the force and moment method[1]. That is, F_s and the yawing moment coefficient indicate the effect of maximum side forces on rear-wheel skid in statics. Thus F_s is closely related to the yawing moment coefficient. On the other hand, V_{tt} implies the effect of attitude angle on rear-wheel skid in dynamics. This is examined in detail in the discussion. In addition, we call *R friction balance ratio*.

SENSITIVITY OF V_{skid} - Figure 8 shows the sensitivity of V_{skid} to different parameters. We define this sensitivity as

$$sensitivity = \frac{\partial V_{skid}}{\partial x}\frac{x}{V_{skid}} \quad (34)$$

where x is the vehicle parameters in EQ (27).

EXPERIMENTS FOR VERIFICATION

Figure 9 compares the rear-wheel skid region of the linear calculations and that of the actual vehicle experiments. Since they agree closely, we can infer that the above studies are valid.

DISCUSSION

FRICTION BALANCE RATIO - Friction balance ratio (R) belongs to statics as well as "yawing moment coefficient[1]." Figure 8 shows that R enhances V_{skid}, which corresponds to the force and moment method[1]. However, the increase of R, i.e., the increase of F_s, decreases $A_{max}(\omega)$ in steady state turning ($=A_{max}(0)$) when the tires are not changed, as shown in Fig. 10.

Now R affects V_{skid} due to the statics factor (F_s). It follows from EQ (34) that the sensitivity of V_{skid} to F_s is approximately 1/2 because V_{skid} is roughly proportional to the square root of F_s. In particular, when I_d=1 and l^*_{dr}=0, this sensitivity is exactly 1/2 because V_{skid} is exactly proportional to the square root of F_s, as shown in EQ (34).

TRACK-ON-TRACK SPEED - Suppose $C^*_r=C_r$, I_d=1, l^*_{dr}=0 and R ->1; then V_{skid} approaches V_{tt} and ω_p (Appendix D) approaches 0 Hz, which is steady-state turning. Hence, we can examine rear-wheel skid during steady-state turning at V_{tt}.

Figure 11 illustrates V_{tt}; at V_{tt}, the track of the rear axle, on which one of particles lies, follows that of the front axle, on which the other lies. Thus, V_{tt} represents the attitude angle properties. Inward attitude increases the lateral displacement of the rear particle during a sinusoidal input, as shown in Fig. 4(B), and consequently generates the rear-wheel skid tendency. Thus, the attitude angle strongly affects the rear-wheel skid due to steering inputs.

DYNAMIC INDEX TO PLANE MOTION - This section discusses the affect of I_d on V_{skid}. This affect depends on the longitudinal distribution of mass (l_r/l). Namely, with decreasing I_d, V_{skid} increases when the front end is heavy (l_r>1/2) but decreases when the rear end is heavy. This is illustrated in Fig.12, which shows the attitude angles during steady-state turning at the speed at which the trajectories of two particles correspond. We define this speed as the *characteristic speed of particle model* (V_{par}). V_{par} can be expressed as

$$V_{par}^2 = \left[1+\frac{l_r - l_f}{l}\left(1-\sqrt{I_d}\right)\right] V_{tt}^2 \quad (35).$$

V_{par} is the general case of V_{tt}. That is, V_{par} corresponds to V_{tt} when I_d=1 and l^*_{dr}=0. Hence, we can deduce that V_{skid} increases with increasing V_{par} as well as increasing V_{tt}.

To verify this point, we will examine the V_{skid} formula that contains V_{par}. By substituting l^*_{dr}=0 into EQ (27), it becomes

$$V_{skid}^2 = \left[1+\frac{l_r - l_f}{l}\left(1-I_d\right)\right] F_s V_{tt}^2 \quad (27').$$

If we make EQ (35) a Taylor's expansion around I_d=1, we obtain

$$V_{par}^2 = \left[1+\frac{1}{2}\frac{l_r - l_f}{l}\left(1-I_d\right)\right] V_{tt}^2 \quad (35').$$

We eliminate

$$\frac{l_r - l_f}{l}\left(1-I_d\right)$$

from EQ (27') and EQ (35'), and we thus obtain

$$V_{skid}^2 = \left[1+2\left(\frac{V_{par}^2}{V_{tt}^2} - 1\right)\right] F_s V_{tt}^2 \quad (36).$$

Therefore, the effect of I_d on V_{skid}^2 is exactly twice as large as the effect of I_d on V_{tt}^2.

EFFECT OF ACTIVE REAR STEERING - The previous section noted that an outward attitude increases V_{skid}. It is well known that an inward attitude is corrected by active rear steering (ARS)[7][8]. Table 1 shows the effect of ARS on V_{skid}. If we can set the control gain to G*, V_{skid} increases to infinity. Thus, ARS can reduce the rear-wheel skid tendency due to steering inputs.

REAR SUSPENSION PROPERTIES - V_{skid} increases with increasing C^*_r and decreasing l^*_{dr} as shown in Fig. 8. C^*_r and

l^*_{dr} can be controlled not only by tire characteristics but also by rear suspension properties[4][5]. This is summarized in Table 2.

EFFECT OF FRONT AXLE ON V_{skid} - The effective cornering coefficient of the front axle (C^*_f) is quite independent of the forms of $A_f(\omega)$ and $A_r(\omega)$ as shown in Fig. 16 for the following reason. We obtained EQS (18) through (21) assuming that

$$\alpha_f = \alpha_{max\,f} \sin \omega t$$

(Appendix B).

Hence the side force is given by

$$CF_f = C^*_f \, \alpha_{max\,f} \sin \omega t.$$

Hence

$$CF_f = \mu^*_f \sin \omega t \quad (37).$$

Thus, the input of this linear calculation is equivalent to a sinusoidal maximum side force. Consequently, C^*_f is automatically eliminated(Fig.13).

RELATIONSHIP BETWEEN SLALOM DIAGRAM AND FORCE AND MOMENT METHOD - The difference between $A_f(\omega)$-$A_r(\omega)$ is equivalent to the *"yawing moment coefficient"* (C_n), which is defined by the Force and Moment Method[1], at maximum lateral acceleration. We can describe the difference with the form

$$A_f(\omega) - A_r(\omega) = \frac{l_f F_f(\omega) - l_r F_r(\omega)}{l_f l_r m g} \quad (38).$$

The yawing moment coefficient is defined by the form

$$C_N = \frac{l_f F_f(0) - l_r F_r(0)}{l m g} \quad (39).$$

Hence

$$C_N = \frac{l_f l_r}{l}\left[A_f(0) - A_r(0)\right] \quad (40).$$

holds. Therefore, the slalom diagram is an extension of the Force and Moment Method to the frequency domain.

EFFECT OF STEERING INPUTS ON REAR-WHEEL SKID - Rear-wheel skid as a function of steering inputs fundamentally differs from rear-wheel skid with a fixed steering angle. From EQ (28), we find that C^*_r strongly affects rear-wheel skid. In other words, the relation of rear-wheel skid to steering inputs depends on only α_r. However, rear-wheel skid tendency with a fixed steering angle depends on α_r - α_f [6]. Therefore, the two kinds of skid are different.

SUMMARY

The results of this paper are summarized as follows.

1) We extended the definition of front/rear-wheel skids during steady state turning to the frequency domain. Moreover, we found that vehicles, which tend to front-wheel skid in steady-state turning, tend to rear-wheel skid with sinusoidal steering inputs. This is because the rear wheels move in the lateral direction more than the front wheels do.

2) We proposed the *slalom diagram*, a "force and moment diagram [1]" that is extended to the frequency domain. Using this diagram, we can predict rear-wheel skid tendency as a function of steering inputs.

3) We proposed *skid critical speed* (V_{skid}) as an index of rear-wheel skid; below V_{skid}, rear-wheel skid is never caused by sinusoidal steering inputs. Furthermore we established a formula for this index.

4) Interpreting the formula of V_{skid}, we found that the rear-wheel skid tendency is strongly affected by the attitude angle during steady-state turning as well as the friction balance between the front and rear axles. Therefore, we can reduce the rear-wheel skid tendency by increasing wheel base and cornering coefficient as well as by active rear steering.

NOMENCLATURE

cic_i : coefficient of instantaneous center of plane motion to the side force of axle i

ck_{tirei} : coefficient of tire lateral stiffness

f : frequency

g : gravity
h : height of center of mass
j : unit of imaginary number
k_i : tire lateral stiffness
k_{susi} : suspension lateral stiffness
l : wheelbase
l_f : length from C.G. to front axle
l_r : length from C.G. to rear axle
l_{di} : relaxation length
l^*_{di} : linearized relaxation length
m : vehicle mass
r : yaw velocity
ck_{tirei} : coefficient of tire lateral stiffness
r_{chi} : roll center height
t : time
u : forward velocity
$v_{groundi}$: lateral velocity of tire contact area
$y_{groundi}$: lateral deformation at tire contact area
$A_i(\omega)$: side force coefficient representing maximum lateral acceleration when the limit of the other axle force is neglected
$A_{max}(\omega)$: maximum lateral acceleration at ω
C_i :effective cornering coefficient (equivalent cornering stiffness / normal load)
C^*_i : cornering coefficient of linearized effective axle characteristics
CF_i :side force coefficient (F_i/F_{zi})
F_i :side force
F_{zi} : normal force
F_s : statics factor
G^* :control gain of active rear steer
I_z : yaw moment of inertia
I_d :dynamic index of lateral motion ($I_d=I_z/(m\, l_f\, l_r)$)
R :friction balance ratio (μ^*_r / μ^*_f)
V_{skid} : critical speed of rear-wheel skid
V_{tt} :track-on-track speed
V_{par} : speed where trajectories of two particles correspond during steady-state turning
X,Y : components in Earth-fixed axes
α_i : slip angle
$\alpha_{ground\,i}$: slip angle of tire contact area
β : side slip angle at C.G.
δ : steer angle
δ_r : controlled steer angle of rear wheel
μ_i : effective friction ratio of axle i
μ^*_i : friction ratio of linearized effective axle characteristics
ω : angular frequency
ω_p : frequency where skid function is maximized

Suffix
i :i=f or r
f : front
r : rear
L : left
R : right

APPENDIX - A
TIRE CHARACTERISTICS

Comparing the two curves in Fig. 3, we can gain the following insights into vehicle behavior.

1) The slopes of the two curves determine the stability factor[9]. Namely, if the rear slope is larger than the front slope at a given side force coefficient, i.e. lateral acceleration, then the vehicle tends to understeer at this lateral acceleration[6]. Conversely, if the rear slope is smaller than the front slope, the vehicle tends to oversteer.

2) The two μ_i values determine the skid tendency during steady-state turning[1]. Namely, if $\mu_r < \mu_f$, the vehicle tends to rear-wheel skid. Conversely, if $\mu_r > \mu_f$, the vehicle tends to front-wheel skid.

Table A1 illustrates various vehicle behaviors when the steering wheels are fixed.

From Fig. 1, we can see that Case 1 in table A1 represents almost all current passenger vehicles. Thus, this paper focuses on Case1 rear-wheel skid to steering inputs.

APPENDIX B
LINEARIZATION FOR EFFECTIVE AXLE CHARACTERISTICS

We linearize the tire model, which is effective axle characteristics[6], using the harmonic balance method. Figure B1 outlines this procedure.

Namely, we assume the slip angles are

$$\alpha_i = \alpha_{max\,i} \sin \omega t = \frac{3}{2}\frac{\mu_i}{C_i} \sin \omega t \qquad \text{(B1)}.$$

We will discuss the validity of this assumption in Appendix E.

Further, we solve EQS (4) through (8). Since EQ (4) is a nonlinear function, the side force CF_i contains higher harmonics. Hence

$$CF_i = e_1 \sin \omega t + e_2 \sin 2\,\omega t + e_3 \sin 3\,\omega t + \cdots \qquad \text{(B2)}$$

where e_i is a complex number. Since e_1 is the response to this input frequency, we focus on only e_1. Hence,

$$CF_i \equiv e_1 \sin \omega t \qquad \text{(B3)}.$$

Substituting EQS (4) through (8) and (B1) into (B2), we obtain

$$e_1 = \frac{9}{8}\frac{1}{1+\left(\frac{l^*_{di}}{u}j\omega\right)^2}\left(1-\frac{l^*_{di}}{u}j\omega\right) \qquad \text{(B4)}$$

where

$$l^*_{di} = \frac{\sqrt{3}}{4}\frac{C_i}{ck_{tirei}} \quad \text{(B5)}$$

where l^*_{di} is relaxation length. It should be noted that not only C^*_i but also l^*_{di} include the properties of the tire, steering system, and suspension(Table 2).

Rearranging EQ (B4), we obtain the frequency response function of CF_i to α_i in the form

$$\frac{CF_i}{\alpha_i} = \frac{1}{1+\frac{l^*_{di}}{u}j\omega}C^*_i \quad \text{(B6)}$$

where

$$C^*_i = \frac{3}{4}C_i \quad \text{(B7).}$$

Since

$$\alpha_i = \frac{3}{2}\frac{\mu_i}{C_i}\sin\omega t \quad \text{(B1),}$$

thus

$$0 \le |CF_i| \le \mu^*_i \quad \text{(B8)}$$

where

$$\mu^*_i = \frac{9}{8}\mu_i \quad \text{(B9).}$$

Then we approximate EQ (B6) using the complex cornering stiffness concept[4][5] to simplify the motion equations. Namely, complex cornering stiffness can approximate $A_f(\omega)$ into a quadratic of ω with high accuracy, while the exact form of $A_f(\omega)$ is quartic.

Assume

$$\left|\frac{l^*_{di}}{u}j\omega\right| << 1 \quad \text{(B10)}$$

and

$$\left|1+\frac{l^*_{di}}{u}j\omega\right| \approx 1 \quad \text{(B11).}$$

We can thus make EQ (B6) a Maclaurin's expansion for l^*_{di} and obtain

$$\frac{CF_i}{\alpha_i} = \left(1-\frac{l^*_{di}}{u}j\omega\right)C^*_i \quad \text{(B12).}$$

Using the above functions, we can estimate the slalom diagram with a linear calculation.

APPENDIX C
CALCULATION OF $A_f(\omega)$

Using EQS (13) through (21) and (B10) through (B12), we can obtain vehicle response in the form[4][5]

$$\frac{r(\omega)}{\delta(\omega)} = G^*_r \frac{\left(T^*_{r0}+T^*_r\right)j\omega + 1}{\frac{1}{{\omega^*_n}^2}(j\omega)^2 + 2\frac{\zeta^*}{\omega^*_n}j\omega + 1} \quad \text{(C1)}$$

$$\frac{\beta(\omega)}{\delta(\omega)} = G^*_\beta \frac{\left(T^*_{\beta 0}+T^*_r\right)j\omega + 1}{\frac{1}{{\omega^*_n}^2}(j\omega)^2 + 2\frac{\zeta^*}{\omega^*_n}j\omega + 1} \quad \text{(C2)}$$

$${\omega^*_n}^2 = D^*_\omega {\omega^*_{n0}}^2 \quad \text{(C3)}$$

$$\zeta^*\omega^*_n = D^*_\zeta D^*_\omega \zeta^*_0\ \omega^*_{n0} \quad \text{(C4)}$$

$$D^*_\omega = \frac{1}{1+\frac{1}{I_d}\left\{\frac{g}{u}\left[cic_f C^*_f T^*_f + cic_r C^*_r T^*_r\right] + C^*_f C^*_r \frac{g^2 T^*_f T^*_r}{u^2}\right\}} \quad \text{(C5)}$$

$$D^*_\zeta = 1 + \frac{-\left(1-\frac{l_r}{l_f}\frac{C^*_f\, l\, g}{u^2}\right)C^*_f\frac{u\,T^*_f}{l} + \left(1+\frac{l_f}{l_r}\frac{C^*_r\, l\, g}{u^2}\right)C^*_r\frac{u\,T^*_r}{l}}{cic_f\, C^*_f + cic_r\, C^*_r} \quad \text{(C6)}$$

$${\omega^*_{n0}}^2 = \frac{C^*_f C^*_r}{I_d}\left(1 + A^* u^2\right)\frac{g^2}{u^2} \quad \text{(C7)}$$

$$\zeta^*_0\ \omega^*_{n0} = \frac{1}{2}\left[cic_f\, C^*_f + cic_r C^*_r\right]\frac{g}{u} \quad \text{(C8)}$$

$$T^*_{r0} = \frac{u}{C^*_r\, g} \quad \text{(C9)}$$

$$T^*_{\beta 0} = \frac{I_d}{\frac{1}{1+A^* u^2}\left(1-\frac{u^2}{C^*_r\, g\, l_r}\right)}\frac{u}{C^*_r\, g} \quad \text{(C10)}$$

$$cic_f = \frac{l_f + I_d\ l_r}{l}$$

$$cic_r = \frac{I_d\ l_f + l_r}{l}$$

$$G^*_\beta = \frac{1}{1 + A^* u^2}\left(1 - \frac{u^2}{C^*_r\ g\ l_r}\right)\frac{l_r}{l} \quad \text{(C11)}$$

$$G^*_r = \frac{1}{1 + A^* u^2}\ \frac{u}{l} \quad \text{(C12)}$$

$$A^* = \left(\frac{1}{C^*_f} - \frac{1}{C^*_r}\right)\frac{1}{l\ g} \quad \text{(C13)}$$

$$T^*_i = -\frac{l^*_i}{u} \quad \text{(C14).}$$

Using EQS (C1) through (C13), we can obtain frequency response function of $[u(\beta j\omega + r)/g]$ to CF_f and CF_r as

$$\frac{\left[\dfrac{u\left(\beta j\omega + r\right)}{g}\right]}{CF_f(\omega)} = \frac{\dfrac{u}{g}\left(\dfrac{\beta}{\delta}j\omega + \dfrac{r}{\delta}\right)}{-C^*_f\left(1 - \dfrac{l^*_{df}}{u}j\omega\right)\left(\dfrac{\beta}{\delta} + \dfrac{l_f\dfrac{r}{\delta}}{u} - \dfrac{\delta}{\delta}\right)}$$

$$= \frac{\dfrac{(j\omega)^2}{\omega_s^2} + \dfrac{2\ \zeta_s\ j\omega}{\omega_s} + 1}{\dfrac{(j\omega)^2}{\omega_{skid}^2} + \dfrac{2\ \zeta_{skid}\ j\omega}{\omega_{skid}} + 1} \quad \text{(C15)}$$

and

$$\frac{\left[\dfrac{u\left(\beta j\omega + r\right)}{g}\right]}{CF_r(\omega)} = \frac{\dfrac{u}{g}\left(\dfrac{\beta}{\delta}j\omega + \dfrac{r}{\delta}\right)}{-C^*_r\left(1 - \dfrac{l^*_{dr}}{u}j\omega\right)\left(\dfrac{\beta}{\delta} - \dfrac{l_r\dfrac{r}{\delta}}{u}\right)}$$

$$= \frac{\dfrac{(j\omega)^2}{\omega_s^2} + \dfrac{2\ \zeta_s\ j\omega}{\omega_s} + 1}{T_{skid}\ j\omega + 1} \quad \text{(C16).}$$

Recalling the definition of $A_i(\omega)$,

$$A_i(\omega) = \frac{\mu^*_i}{\left|CF_i(\omega)\right|}\left|A_{max}(\omega)\right| \quad \text{(C17).}$$

Hence

$$A_i(\omega) = \left|\frac{A_{max}(\omega)}{CF_i(\omega)}\right|\mu^*_i \quad \text{(C18).}$$

Performing the linear calculation, we obtain

$$\frac{A_{max}(\omega)}{CF_i(\omega)} = \frac{u\left(\beta\ \omega j + r\right)}{CF_i(\omega)}$$

$$= \frac{\left[\dfrac{u\left(\beta\ \omega j + r\right)}{g}\right]}{CF_i(\omega)}g \quad \text{(C19).}$$

Therefore

$$A_i(\omega) = \left|\frac{\left[\dfrac{u\left(\beta\ \omega j + r\right)}{g}\right]}{CF_i(\omega)}\right|\mu^*_i\ g \quad \text{(C20).}$$

Substituting EQS (C15) and (C16) into EQ (C20), we can obtain EQS (22) and (23) respectively.

APPENDIX D
CALCULATION OF V_{skid}

First, we define the *skid function* as

$$S(\omega) = \frac{CF_f(\omega)}{CF_r(\omega)} \quad \text{(D1)}$$

$$= R\ \frac{A_f(\omega)}{A_r(\omega)}$$

$$=\left|\frac{T_{\text{skid}}\ j\omega+1}{\frac{(j\omega)^2}{\omega_{\text{skid}}{}^2}+\frac{2\ \zeta_{\text{skid}}\ j\omega}{\omega_{\text{skid}}}+1}\right| \quad \text{(D2)},$$

where

$$R=\frac{\mu^*_{\mathrm{r}}}{\mu^*_{\mathrm{f}}} \quad \text{(D3)}.$$

The skid function is shown in Fig. D1. Secondly, we define ω_p as the solution of

$$\left.\frac{\mathrm{d}\,S(\omega)}{\mathrm{d}\omega}\right|_{\omega=\omega_p}=0 \quad \text{(D4)}.$$

At ω_p, the value of the skid function is maximized. Further, at V_{skid}, the maximum value of the skid function must equal R. Thus the equation

$$S(\omega_p)=R \quad \text{(D5)}$$

holds at V_{skid}. Hence we substitute $u=V_{skid}$ into EQ (D5) and then solve this equation for V_{skid} on the asumtion that $T_{skid}=0$, yielding

$$V_{\text{skid}}{}^2=\frac{C^*_{\mathrm{r}}}{C_{\mathrm{r}}}\frac{R^2}{I_{\mathrm{d}}}\left(\Delta_1+\Delta_2\sqrt{1-\frac{1}{R^2}}\right)V_{\mathrm{tt}}{}^2 \quad \text{(D6)}$$

where

$$\Delta_1=\left(cic_{\mathrm{r}}-\frac{l^*_{\mathrm{dr}}}{l}\right)^2-\left[(I_{\mathrm{d}}-1)^2\left(\frac{l_{\mathrm{r}}}{l}\right)^2-2cic_{\mathrm{r}}\frac{l^*_{\mathrm{dr}}}{l}\right]R^2 \quad \text{(D7)}$$

$$\Delta_2=\left(cic_{\mathrm{r}}-\frac{l^*_{\mathrm{dr}}}{l}\right)^2-(I_{\mathrm{d}}-1)^2\left(\frac{l_{\mathrm{r}}}{l}\right)^2R^2 \quad \text{(D8)}$$

$$V_{\mathrm{tt}}{}^2=\frac{C^*_{\mathrm{r}}}{C_{\mathrm{r}}}\ \frac{l}{2}\ C_{\mathrm{r}}\ g \quad \text{(D9)}.$$

Assuming $I_d \doteqdot 1$ and $l^*_{dr}/l \doteqdot 0$, we can make EQ (D6) a Taylor expansion for $I_d=1$ or $l^*_{dr}=0$ and then obtain EQS (24) through (27).

APPENDIX E
ACCURACY OF LINEAR CALCULATION

We assumed

$$\alpha_i=\alpha_{\max i}\ \sin\omega t$$

in EQ (B1). However, there is no assurance that this slip angle promotes A_r, which is the maximum value of the rear side force at each frequency. Considering this assumption, this section discusses the accuracy of this linearized calculation.

Suppose A_r is generated at

$$\alpha_i=\alpha_{\max i}\ (1\text{-}\Delta)\sin\omega t \quad \text{(E1)}$$

where $0 \leqq \Delta \ll 1$. Further, assume $l^*_{dr}=0$, $l_f=l_r=l/2$, and $I_d=1$ for convenience. Replacing EQ (B1) with EQ (E1), we obtain

$$C^*_i(\Delta)=\frac{3}{4}\ C_i\ \left(1+\frac{3}{2}\Delta+\Delta^2\right) \quad \text{(E2)}$$

$$\mu^*_i(\Delta)=\frac{9}{8}\ \mu_i\ \left(1-\frac{1}{3}\Delta-\Delta^2\right) \quad \text{(E3)}$$

using Maclaurin's expansions for Δ.
Thus C^*_r increases and μ^*_r decreases with increasing Δ.
Next, we assume

$$\omega^2=C^*_{\mathrm{r}}\frac{g}{l} \quad \text{(E4)}$$

and

$$u^2=C^*_{\mathrm{r}}\ l\ g \quad \text{(E5)}$$

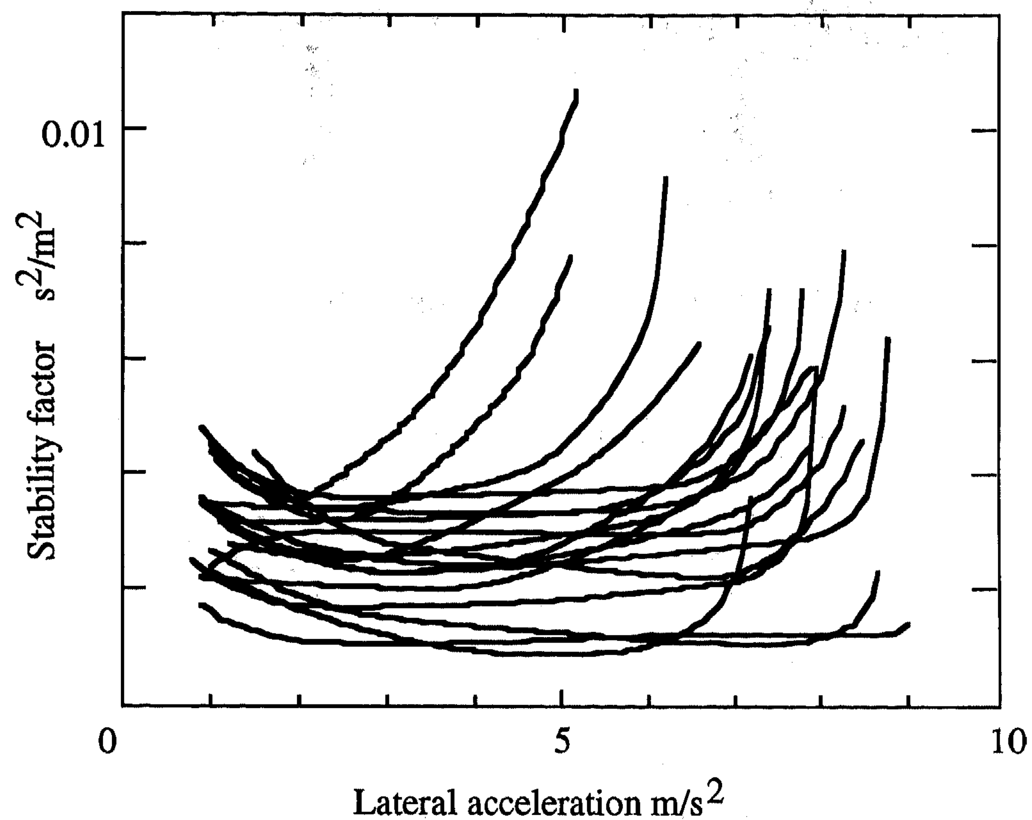
as typical conditions to promote rear-wheel skid, i.e., this frequency is the undamped natural frequency of the skid function and this velocity is the square root of twice the track-on-track speed. Hence, this frequency is most likely to produce rear-wheel skid and this speed is even higher than V_{skid}. Substituting EQS (E2) through (E5) into (23), we make EQ (23) a Maclaurin's expansion for Δ and obtain

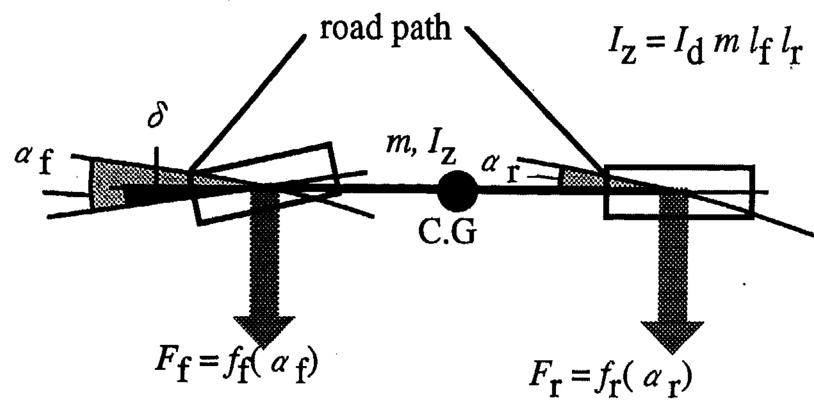
$$\left|A_{\mathrm{r}}(\Delta)\right|=\sqrt{\frac{\mu^*_{\mathrm{r}}}{2}}\sqrt{1-\frac{26}{9}\Delta^2} \quad \text{(E6)}.$$

Thus, $\Delta=0$ maximizes $A_r(\omega)$, and the assumption of EQ (B1) is valid in rear-wheel skid frequencies. This shows the high accuracy of the rear-wheel skid estimation as long as EQ (4) is used for the effective axle characteristics.

Next, we will discuss the accuracy of front-wheel skid estimation. At a front-wheel skid frequency, $A_{max}(\omega)$ is determined by the limit of the front side force, and so the rear maximum side force does not increase. Hence, the rear slip angle is lower than α_{maxr}, and the actual C^*_r will be larger than $(3/4)C_r$, which is used in this linear calculation, as shown in EQ (E2). The estimation values of $A_f(\omega)$ and $A_r(\omega)$ using $(3/4)C_r$ as C^*_r will be lower than the exact values at the front-wheel skid frequency, which does not assure accurate estimation of front-wheel skid.

Therefore, this linear calculation is valid for rear-wheel skid prediction, which includes V_{skid} estimation.





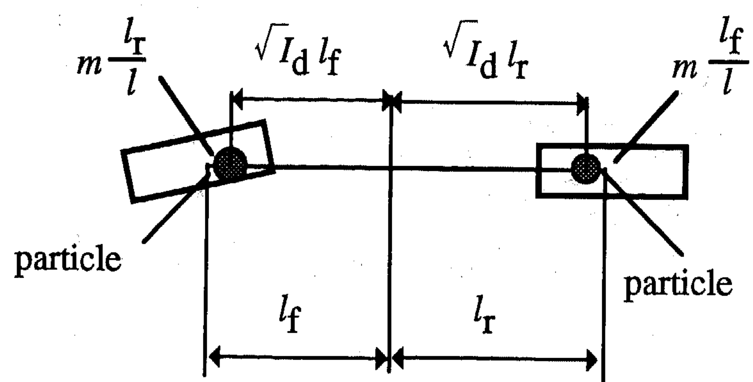


Figure 1 Measuring result of stability factor. These tests were conducted in constant radius (30 R) turning from approximately 1 m/s^2 up to the maximum lateral acceleration. From this figure, we can see that almost all current passenger cars tend to understeer at any lateral acceleration. Therefore these cars tend to front-wheel skid.

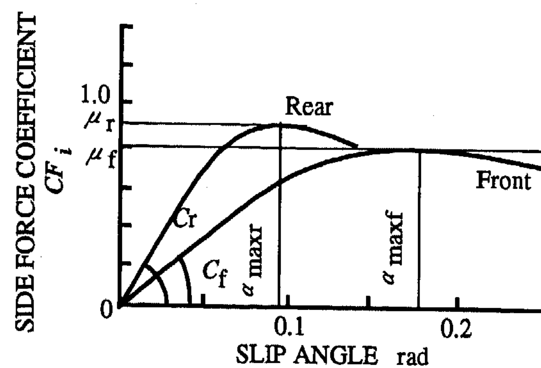
(B) Description in system of particles

Figure 2 Equivalent Vehicle Model. This paper also describe an equivalent vehicle model in a system of particles to focus on the difference between the two particles in motion.



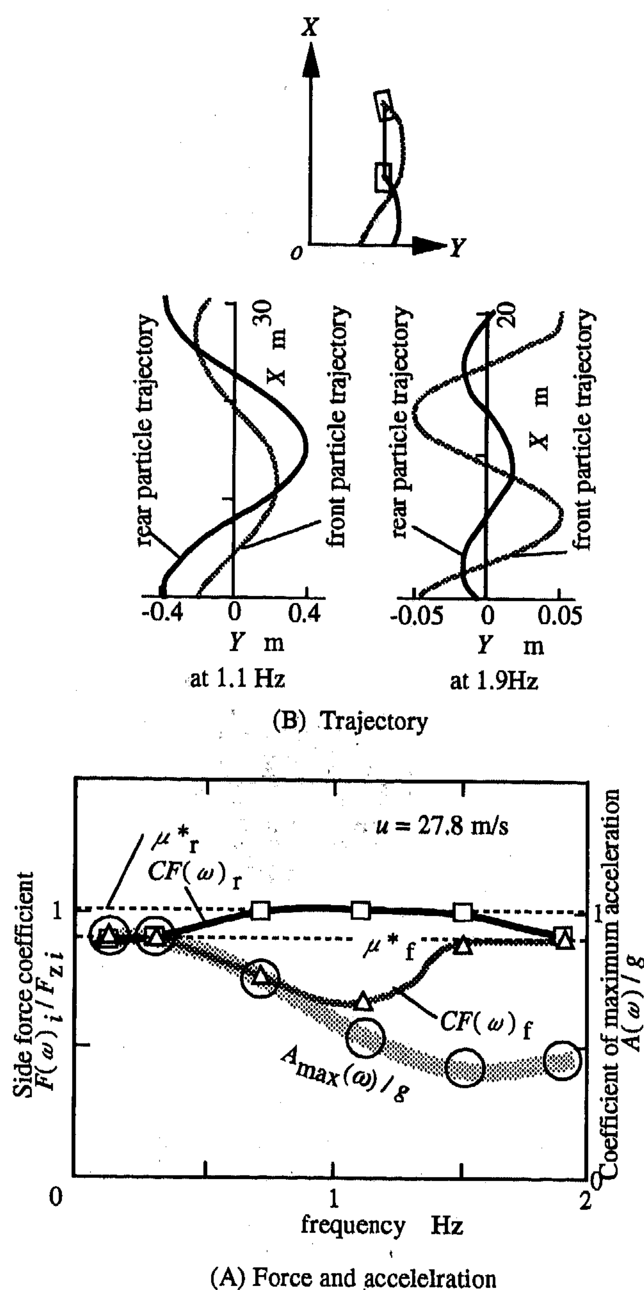


Figure 3: Effective axle characteristics in steady state. This figure shows the tire model in steady-state turning. Focusing on oridinary vehicles, which tend to understeer at any acceleration as shown in Fig. 1, we assume $C_r > C_f$ and $\mu_r > \mu_f$. In addition, we assume a time lag in the transient state based on Ref[3].

(A) Force and accelelration

Figure 4 Simulation result of response to sinusoidal steering input. At 0.1, 0.3 and 1.9 Hz, since the front axle produces its maximum force, the vehicle tends to front-wheel skid. While at 0.7 and 1.1Hz, the rear axle yields its maximum force, so the vehicle tends to rear-wheel skid. The reason is illustrated by the particle trajectories. Namely, rear-wheel skids occur when the rear particle moves in the lateral direction more than the front particle.

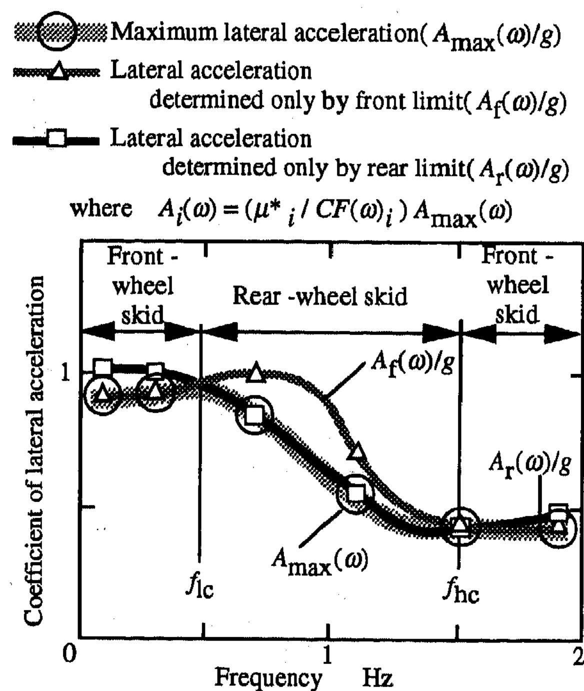

Figure 5 Slalom Diagram. We transform figure 4(A) to simply illustrate skid tendency and maximum lateral acceleration.

Linearized calculation

Coefficient of extended maximum lateral acceleration as determined by front limit $(A_f(\omega)/g)$ only

Coefficient of extended maximum lateral acceleration as determined by rear limit $(A_r(\omega)/g)$ only

Simulation

△ Coefficient of extended maximum lateral acceleration as determined by front limit $(A_f(\omega)/g)$ only

□ Coefficient of extended maximum lateral acceleration as determined by rear limit $(A_r(\omega)/g)$ only

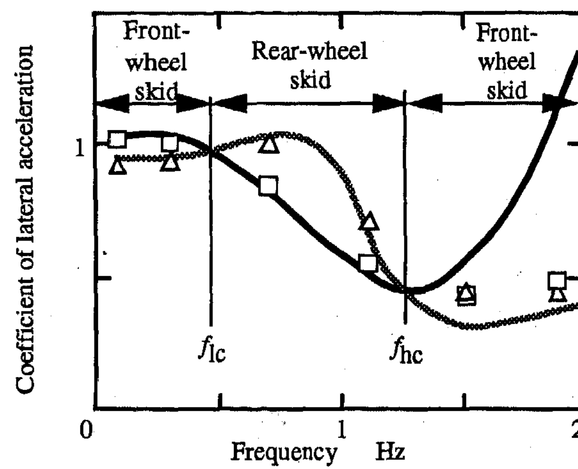

Figure 6 Accuracy of linearized calculation. The numerical simulation takes much time to detect the optimum steer angle for promoting maximum lateral acceleration. Since this linearized calculation does not require much time and agrees with the numerical simulation, we can use the linearized simulation hereafter in this paper.

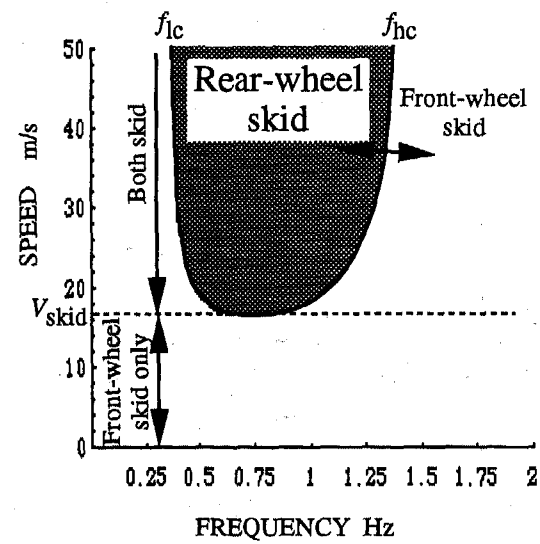

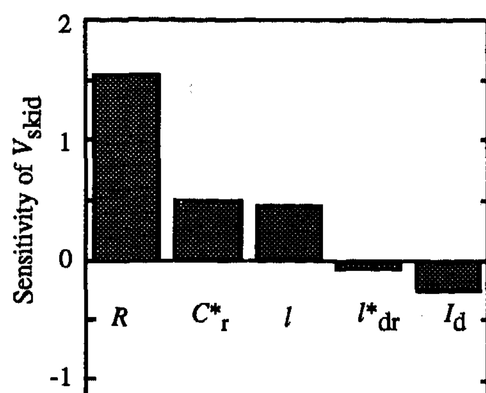

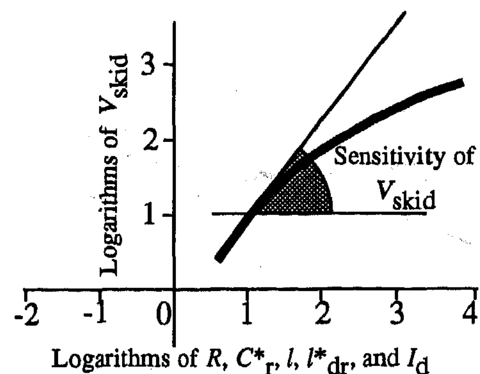

Figure 7 Effect of speed on rear-wheel skid tendency. V_{skid} denotes the critical speed in the rear-wheel skid zone. V_{skid} is adopted as an index of rear skid tendency.

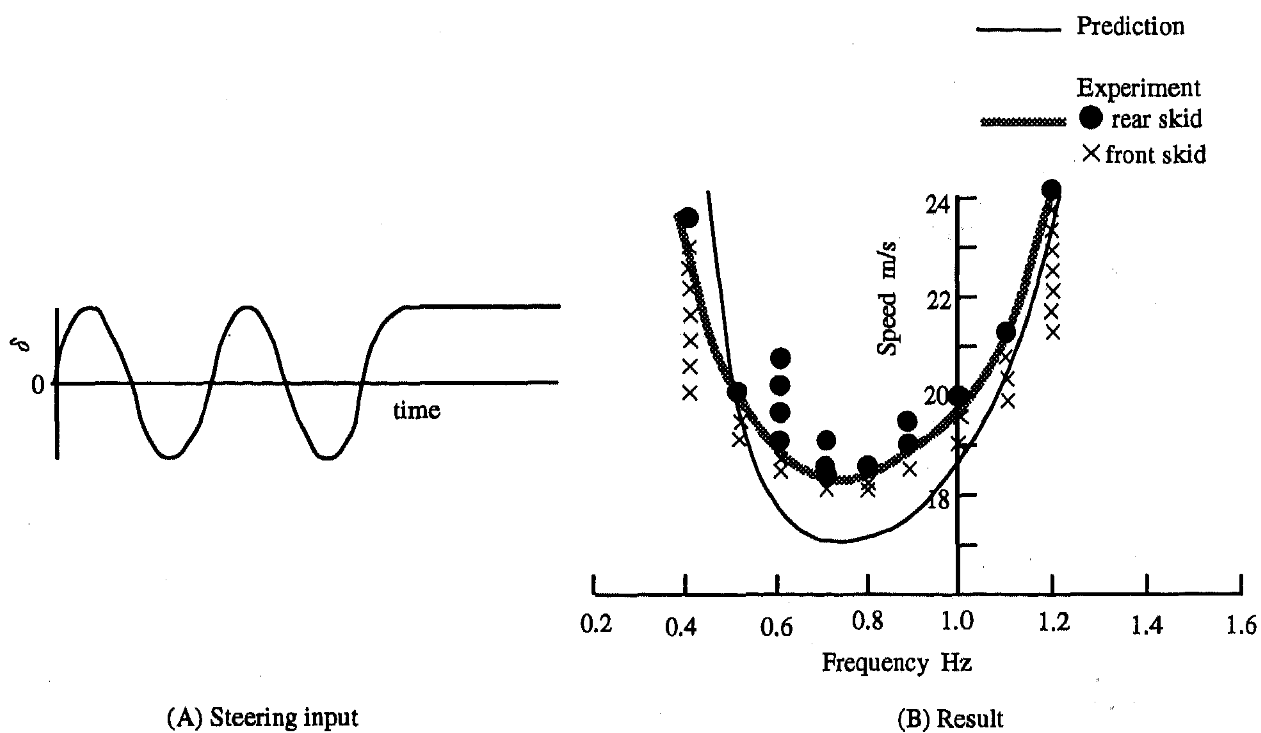

(A) Sensitivity of parameters

(B) Explanation of parameters

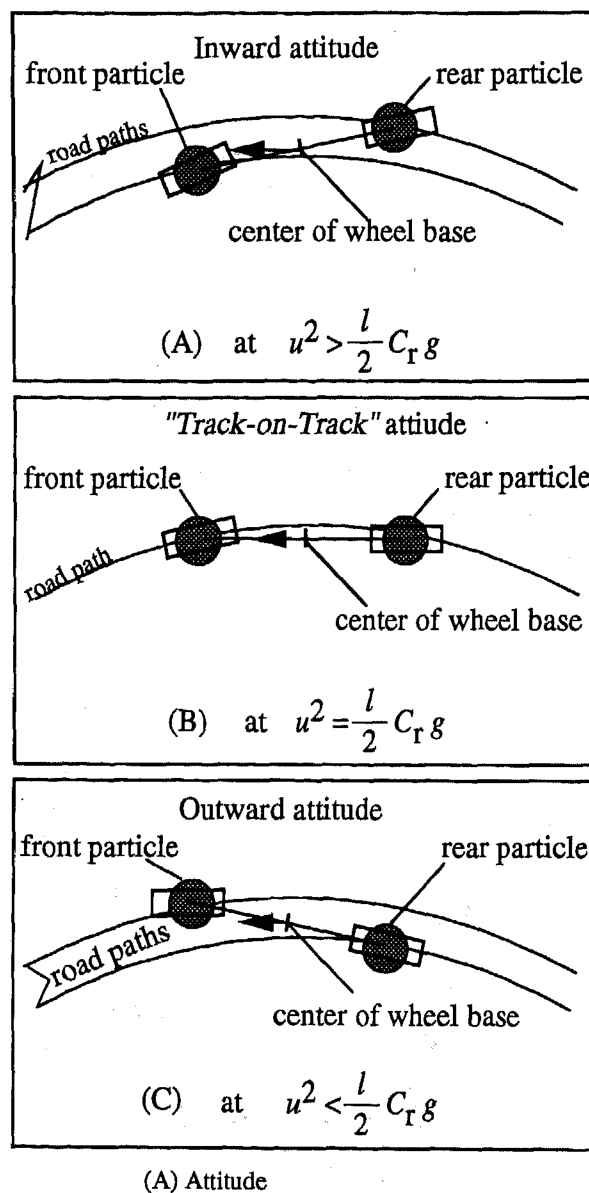

Figure 8. Sensitivity of V_{skid}. This figure shows that an increase of the ratio of friction balance (R) enhances V_{skid}, as is well known. Hence, we deduce that this sensitivity result is correct. Further, an increse of C_r and l and decrease of l^*_{dr} and I_d also enhance V_{skid}.

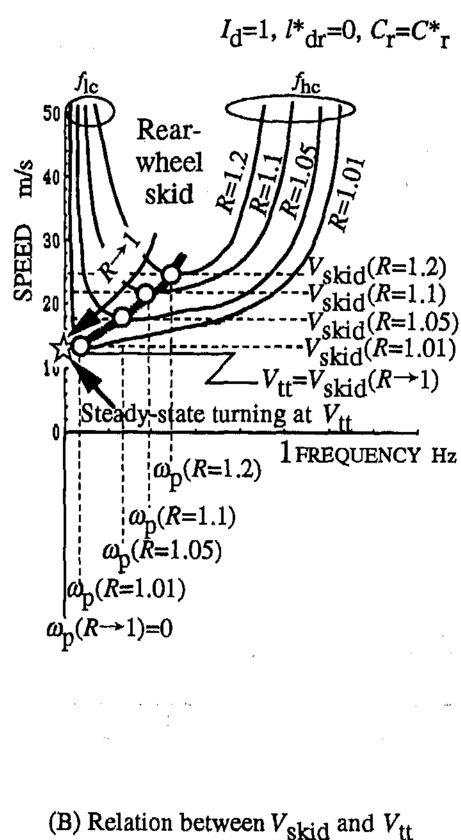

(A) Steering input

(B) Result

Figure 9 Verification experiment. These results generally agree with those expected.

(A) Attitude

(B) Relation between V_{skid} and V_{tt}

Figure 11 Track-on-Track speed. At *track-on-track speed,* the front and rear tracks correspond during steady state turning. This speed is V_{skid} under the assumption of I_d=1, l^*_{dr}=0, C_r=C^*_r and $R\to 1$. As shown in Fig. 11(B), we can examine rear-wheel skid with the steady-state turning at V_{tt}. Over this speed, the rear particle trajectory goes beyond the front as well as vehicle behavior in rear-wheel skid as shown in figure 5. In addition, the particles lie just on the respective axles because I_d=1.

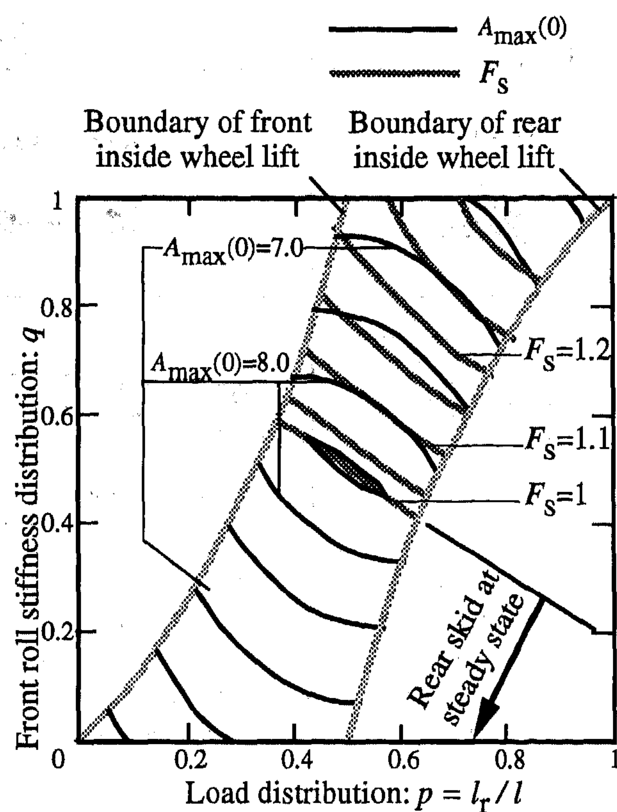

Figure 10 effect of roll moment distribution on friction ratio and maximum lateral acceleration. Increase of F_s can reduce rear skid tendency. Further, an increase of p and q is able to increase F_s. Hence front-end heavy and front heavy distribution of the roll moment can decrease rear skid tendency. This fact is well known empirically. However, this also reduces maximum lateral acceleration during steady-state turning.

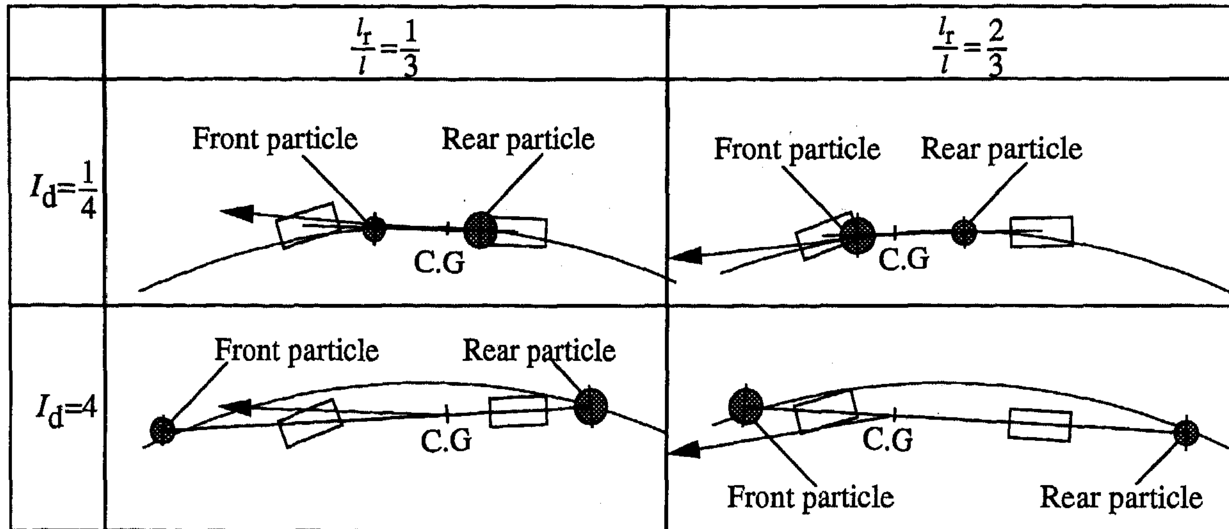

Figure 12 Affect of yawing moment(I_d) on particle trajectories. This figure shows the attitude angles at the speed (V_{par}) where both trajectories of the front and rear particles correspond. V_{par} is the expansion of track-on-track speed (V_{tt}) into genaral cases, where I_d dose not equal 1. Hence we can replace V_{tt} by V_{par} in the discussion of V_{skid}. Suppose a rear-end-heavy vehicle. A larger I_d makes inward attitude at V_{par}. In other words, this implies $V_{par}>V_{tt}$ when $I_d>1$. Therefore a larger I_d increases V_{skid}. Conversely, for front-end-heavy vehicles, a smaller I_d enhances V_{skid}.

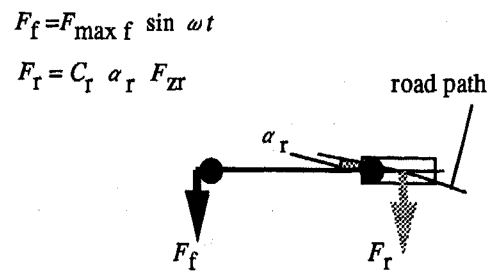

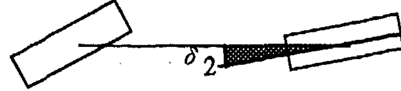

Figure 13: Vehicle model for front force input;. This model equals the equivalent vehicle model provided we choose a steer angle that promotes maximum front side force.

Table 1 Effect of Active Rear Steer (ARS) on V_{skid}. Since ARS affects attitude angle, ARS enhances V_{skid}. In particular, control for β=0 and dβ / dt =0 makes V_{skid} infinity.

Control law	V_{skid} when $I_d=1$	G for $V_{skid}=\infty$
$\delta_2 = G\delta$	$\dfrac{1-\dfrac{G}{R^2}}{\left(1-\dfrac{C_r^*}{C_f^*}G\right)^2(1-G)}\left[R^2-\dfrac{C_r^*}{C_f^*}G+\sqrt{\left(1-\dfrac{1}{R^2}\right)\left(\dfrac{C_r^*}{C_f^*}\dfrac{G}{R}\right)^2-R^2}\right]V_{tt}^2$	$\dfrac{C_1}{C_2}$
$\delta_2 = G\dfrac{r}{u}$	$\left[\left(1+\dfrac{G}{l}\right)^2-\dfrac{1}{R^2}\dfrac{G}{l}\right]F_s V_{tt}^2$	impossible

Analysis of Energy Consumption for Various Power Assisted Steering Systems

Geoffrey P. Dyer
A.E. Bishop & Associates Pty. Ltd.

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

The energy consumption of conventional open-centre hydraulic power steering was mapped to pinpoint areas of potential for improvement. Using this data, equivalent maps were generated for existing, and potential, competing systems. These maps were used to identify likely future trends in this area.

The results immediately illustrate the gross inefficiency of the conventional system due to high parasitic losses and indicate not only that systems that operate purely "on-demand", such as electric power steering (EPS), are likely to be the optimum solution at least as far as energy consumption is concerned but also that interim solutions such as electro-hydraulic power steering (EHPS) can make significant contributions.

INTRODUCTION

Power assisted steering is penetrating ever further across (and down) the automobile market. Even cars with engine capacities as low as 700 to 800 cc are sold with power steering now, a situation which was unheard of less than 10 years ago! With the rising concern for the level of energy consumption by automobiles and also the consequent level of production of greenhouse gases, it has become necessary/desirable to analyse the energy consumption of the conventional open-centre hydraulic power steering system in order to establish its significance with respect to the total vehicle consumption and identify the most effective areas to target for improvement. With several existing and potential alternatives to this system available, it is also useful to compare these systems by using steering history data to simulate their respective energy maps.

There are a multitude of parameters that affect the energy consumption of open-centre power steering systems. They include:

a) Oil supply flow rate (to steering gear)
b) Losses in the flow control valve
c) Flow losses in the hydraulic lines
d) Flow losses in the power steering valve
e) Friction and viscous losses in the pump
f) Weight on the front wheels of the vehicle
g) Front end geometry of the vehicle
h) Boost characteristic of the power steering valve
i) Pump speed vs. time history
j) Assistance pressure vs. time history

Parameters **a** to **e** are controlled by the system design and can vary greatly from vehicle to vehicle. They have, potentially, a large effect on overall energy consumption. Parameters **f** to **h** are governed by the vehicle specification and their effect can only be gauged by comparison testing of vehicles of disparate weight and configuration. Parameters **i** and **j** are the result of a combination of driver behaviour and demands of road conditions and affect the energy picture through their effect on parameters **a** to **e**. From the recording of the steering history of a vehicle, we can calculate the variations in these parameters and establish their influence on the end result.

In order to generate representative maps of energy consumption, two vehicles were selected for energy mapping: Vehicle A, a large rear wheel drive family sedan, of Australian manufacture and with a mass of 1500 kg and Vehicle B, a small/medium sized front wheel drive family sedan, of European manufacture and of 1100 kg mass. These were chosen so as to establish the possible differences in system requirements caused by their widely conflicting specifications. Overall average fuel consumption for these cars was found to be 16 l/100 km and 10 l/100 km, respectively, when used mainly for suburban commuting with the occasional country trip. In order to obtain a complete picture of steering requirements, data was collected for a wide variety of driving conditions (not standardised drive cycles as in fuel consumption testing) and also for a variety of drivers. Track testing was also carried out to establish the steering performance envelope for extreme manoeuvres such as emergency lane change and dry parking.

Using the steering histories from these two vehicles, maps of energy consumption were generated and analysed for its significance relative to the total energy consumption of the vehicle and the relative contributions of the different components of the system. Also generated were maps of energy consumption for alternative systems and these were compared with the open-centre system.

OVERVIEW OF SYSTEMS

Currently, there are four main categories of system which would be considered contenders for power assistance of automotive steering:

- Conventional open-centre
- Open-centre with constant speed drive for the pump
- Closed centre
- Electric power steering

The fairest means of comparing these systems is to reference the amount of energy supplied by the base power source (in most cases the engine crankshaft) and, therefore, the efficiency of the means used to drive the system must be taken into account.

CONVENTIONAL OPEN CENTRE (OC) - A pump of fixed displacement is driven, mechanically and at a fixed ratio, from the engine crankshaft. Pump flow is, therefore, proportional to engine speed. In order to maintain constant control valve characteristics, a flow control valve (FCV) is used to maintain constant flow through the valve by bypassing the excess flow around the steering gear, usually internally in the pump.

The main contributors to the low efficiency of the conventional system are the parasitic losses associated with the continuous supply of oil to the power steering valve as well as the non constant speed of the pump drive (being proportional to engine speed). Not only does the pump have to work continuously against the back pressure of the system (due to FCV, power steering valve and feed and return lines) but it can also be pumping oil at up to 5 to 6 times the rated flow of the FCV against the same pressure. This latter situation is a consequence of the pump being engine driven at a fixed ratio.

In this case, the efficiency of the mechanical (usually belt) drive to the pump must be applied.

OPEN-CENTRE CONSTANT SPEED DRIVE FOR PUMP (OCCS) - The pump for an open-centre system is driven, mechanically or electrically, at a constant speed. This negates the need for a flow control valve in the pump as there is no excess flow to bypass the steering gear.

This system still has parasitic losses due to the continuous flow of oil through the power steering valve but the system back pressure would be reduced by the absence of a FCV and, also, there would be no excess flow for the pump to supply.

There are three likely scenarios for driving this system:

An Electric Motor (EHPS) - this involves the efficiency of the belt drive to the alternator as well as that of the alternator/motor/battery package.

A Constant Speed Accessory Drive - a CVT driving all accessories at constant speed. The efficiency of both the transmission and the belt drive would apply.

Engine Maintained at (or Near) Constant Speed - a CVT main transmission maintains the engine at relatively constant speeds with varying throttle openings. The pump would then run at (or near) constant speed with only the efficiency of the belt drive to take into account.

CLOSED CENTRE (CC) - An accumulator is used to store oil at high pressure for use "on demand", ie. flow only occurs when the steering is actually displaced. Recharge of the accumulator is achieved by a pump, intermittently driven electrically or mechanically, as required by the stored pressure.

Whilst this is an "on demand" system having no parasitic losses, all flow required by the steering is supplied by dropping full accumulator pressure, via the steering ram, to atmosphere. Hence, energy is lost when the steering pressure requirement does not equate to full accumulator pressure.

The accumulator is charged by a pump which is driven intermittently, based on the demands of the stored pressure. Again, this pump can be driven mechanically or electrically with similar considerations for efficiency to those stated above.

ELECTRIC POWER STEERING (EPS) - The steering is directly powered by electric motor, usually via a gearbox, and controlled electronically. A torque transducer replaces the sensing function of the valve in the hydraulic system.

This system is close to a true "on demand" system, only supplying energy to the steering as and when it is required and only supplying as much as is required. The efficiency of the system is then only affected by the efficiency of the energy conversion mechanisms: the power supply to the motor; the motor and the gearbox.

DATA ACQUISITION

Analysis of the energy consumption required the following in-vehicle data to be recorded on the cars:

- Vehicle speed.
- Pump driving torque.
- Pump speed.
- Differential boost pressure.
- Rack travel.
- Oil temperature.
- Fuel flow.

All of these parameters could be recorded directly, via transducers, or from signals already available on the vehicle. However, because of the difficulty of running a torque transducer on the input-shaft of the pump in the aggressive environment of the engine bay, it was decided to calibrate the pump for input torque versus output pressure (just down stream of the FCV) and pump speed. This was carried out on a test rig, in the laboratory, and an algorithm developed empirically to allow the calculation of pump torque from these two variables. One benefit of recording the time/pressure/pump speed histories is that the energy loss results can be recalculated for varying system back pressures.

Hence, the actual parameters, measured and recorded in the vehicle, were:

- Vehicle speed.
- Engine speed.
- Pump speed.
- Oil temperature.
- Differential pressure.
- Pump output pressure.
- Rack position.
- Fuel flow.

The data acquisition system sampled all the variables at 5000Hz. At each sample point, the software would take the first 50 data points (0.01 s), average them, calculate all the required parameters and store the results. These sample points were collected every 0.09 to 0.2 s, depending on the time to calculate the stored information.

DATA PROCESSING

From the measured inputs, the following parameters directly relating to the performance of the system on the vehicle, were calculated:

- Energy absorbed by the pump.
- Work done on the rack.
- Efficiency of the system.
- Distance traveled by the vehicle.
- Energy absorbed by the pump/km traveled.
- Work done on the rack/km traveled.
- Average vehicle speed.
- Maximum OC power absorbed by the pump during test.

Additional parameters were calculated, relating to the equivalent consumption for alternative systems:

- Energy used if the system was CC.
- Volume of fluid used if the system was CC.
- Volume of fluid used/km if system was CC.
- Energy used if the system was OCCS.
- Maximum rack power during the test.
- Maximum OC power absorbed by the pump during the test.
- Maximum OCCS power during the test.

These calculations did not take into account the efficiencies of the component parts of each system.

At the end of each test, a file was generated to store the summary of the parameters for the whole test.

VEHICLE TESTING

A wide variety of routes were used for the mapping exercise for Vehicles A an B so as to give a reasonably balanced picture for vehicle use in a metropolitan environment. Types of route used included:

- Local suburban (trip distances less than 8 km.).
- Local suburban (trip distances between 8 and 25 km.).
- Local city suburbs to outer suburbs (trip distances approx. 40 km).
- Local suburbs to inner city in rush hour.
- Low speed manoeuvring.
- Freeway.
- Country roads (trip distances up to 500 km).
- Around country towns.
- Twisty country roads.

As well as energy mapping, testing was carried out to define the steering performance requirement envelope for each vehicle. This was carried out on a test track and included emergency avoidance manoeuvres (lane change) and "dry parking" (winding the steering from lock to lock with the service brake applied).

Lastly, Vehicle B was laboratory tested for fuel consumption on a rolling road dynamometer, to Australian standard highway and urban drive cycles, both with and without the power steering pump connected. This was deemed necessary when road testing for changes in fuel consumption proved to be inconclusive.

CALIBRATION OF PUMP INPUT TORQUE

Figure 1 shows the relationship between input torque and outlet pressure for the pump on Vehicle A and is reasonably representative of that for Vehicle B. It shows a basically linear relation between torque and pressure and, thus, is largely independent of pump speed. The only case when this does not hold true is that of the "on- centre" condition, ie. when the steering has little or no torque applied to it. As illustrated in Figure 2, although the on-centre outlet pressure stays reasonably constant, the torque rises linearly with speed. This is attributed to viscous losses in the pump and bearings as well as a slight rise in internal supply pressure to the FCV at higher pump speeds. It is applied as a speed correction factor to the

empirical equation for torque vs pressure and is only significant when output pressures are low.

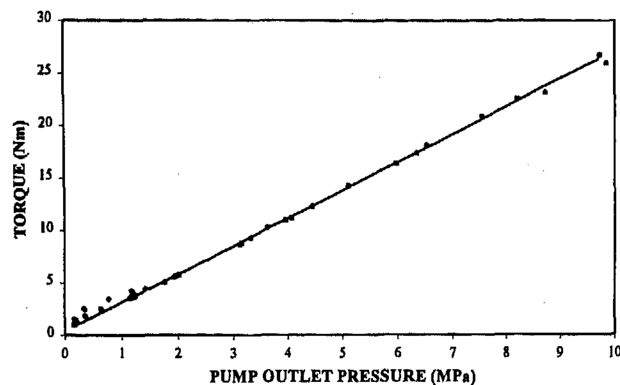

Fig. 1 Pump Drive Torque vs Outlet Pressure.

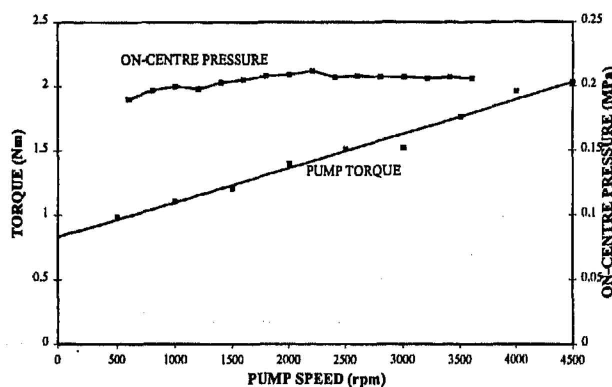

Fig. 2 Torque and Pump Pressure vs Pump Speed: On Centre Pressure

Hence, the equation for the pump input torque was developed as:

T = Pc.Pv + Sc.RPM + C
Where:
T = Pump Input Torque (Nm)
Pv = Pump Pressure (MPa)
RPM = Pump Speed (rpm)
Pc = Pressure Constant (0.02559 for vehicle A)
Sc = Pump Speed Constant (0.0003 for vehicle A)
C = Torque Constant (0.4134 for vehicle A)

The above algorithm was generated with rig testing carried out at 50 - 60°C and, as such, would only hold true for those temperatures. However, changes in temperature (Vehicle A would run with oil at approximately 90°C and Vehicle B 55°C) will have two effects: both viscous losses in pipes and viscous losses in the pump bearings will increase with lower temperatures. Whilst the losses in the piping can be considered significant, they are catered for in the above algorithm for pump torque. The variation in internal losses in the pump were considered to be of less significance and were not considered in this analysis.

DISCUSSION OF RESULTS FOR OC SYSTEM

Figure 3 shows the collective results for the efficiency of the OC system (work done by rack ÷ input energy to pump x 100%) for each test run with respect to average speed. Apart from the obviously low overall result, the interesting trend to notice is that the efficiency increases quite markedly at lower average speeds. Maximum efficiency was approximately 6% and the minimum efficiency less than 0.01%. This phenomenon can be explained by inspection of the steering usage relative to average journey speed.

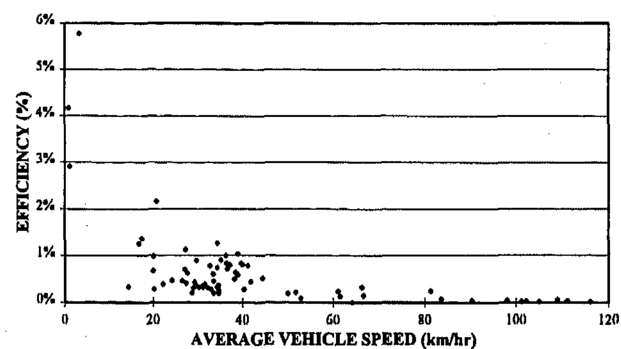

Fig. 3 Efficiency of OC System vs. Average Speed.

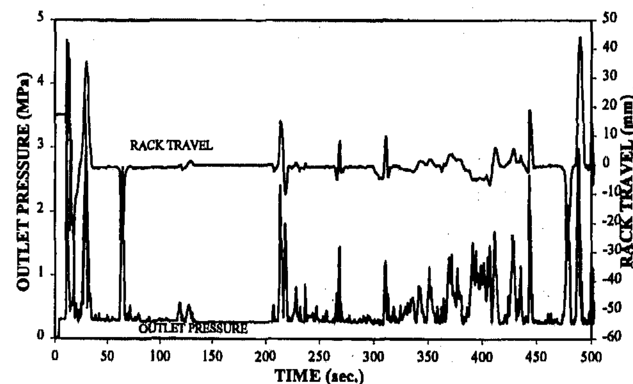

Fig. 4 Rack Travel and Pump Pressure History for a Typical, Suburban Route.

Figure 4 is the steering history for a typical, short, suburban drive in the Sydney area. The distance represented is 5 km and overall average speed was 34.8 km/h. Of immediate interest is how little work the steering is actually required to do. Apart from the gross steering movements at the start and end of the run (exit car park and entry into driveway) and during turns at intersections, the steering spends a very large percentage of the time at (or near) on-centre even though this route includes very little straight road. Also noticeable is the

significant "waiting time", from 134 secs to 206 secs, where the vehicle was stationary at traffic lights. This amounts to 14% of the total journey time and is relatively low when compared to average figures for waiting time in town driving.

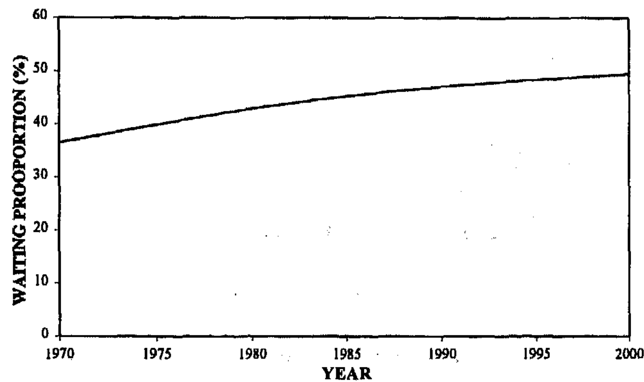

Fig. 5 Development of Proportion of Waiting Times for Urban and City Traffic[1]

Figure 5 represents the development of waiting times, ie. that proportion of time which the vehicle remains stationary, with no steering input and engine at idle, for urban and city traffic from 1970 and projected forward to the year 2000 (reference 1). From this data, waiting times of nearly 50% would be expected in the urban environment The pump on vehicle A, at idle (pump speed 760rpm), absorbs 90W, although this can easily be doubled by resting a hand on the steering wheel during the waiting period. This means that the waiting time is a significant factor in the energy consumption of the steering in town driving and, since this is a large component of the usage of the average vehicle, it is also significant in the overall picture. But this factor would not account for the increase in efficiency at lower speeds. Indeed, it would tend to point toward the opposite effect.

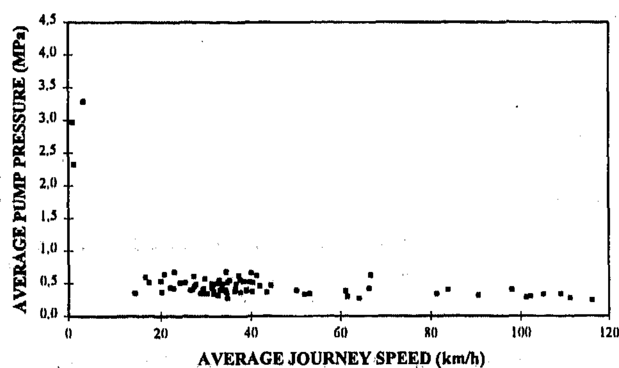

Fig. 6 Average Pump Pressure vs. Average Journey Speed: Vehicle A.

To explain this, we have to look at the trends in steering history for different average journey speeds.

In Figure 6, it will be noted that the average pump outlet pressure falls very quickly with increasing speed from just over 3 MPa at 3 km/h (car park manoeuvring) to of the order of 0.5 MPa at 20 km/h. From here, the pressure drifts down toward the on-centre pressure of 0.2 MPa because, as the speed increases, the steering is required to carry out less work. Hence, the parasitic losses of the on-centre regime become more dominant.

Figure 7, for Vehicle B, illustrates very much the same trends except that the pressures are generally 0.2 - 0.3 MPa higher throughout the range of speeds. This is a direct result of the piping arrangements for this vehicle which had an on-centre pressure of approximately 0.5 MPa as opposed to 0.2 MPa for Vehicle A with similar flow rates. The fact that on-centre losses are dominant means that the back pressure, generated by the piping as well as the power steering valve housing and the power steering valve, are features to focus on with regard to optimising the system for energy consumption.

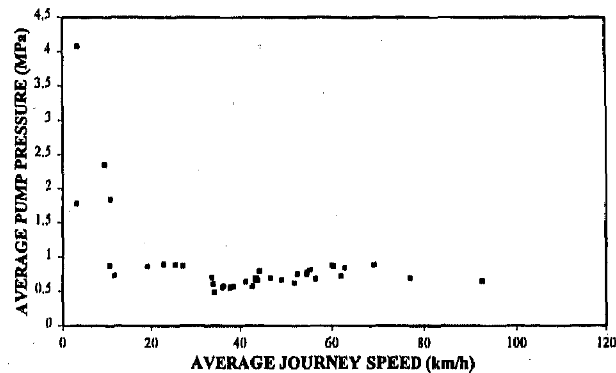

Fig. 7 Average Pump Pressure vs. Average Journey Speed: Vehicle B.

Confirmation of the importance of the on-centre losses can also be found by looking at the percentile bands

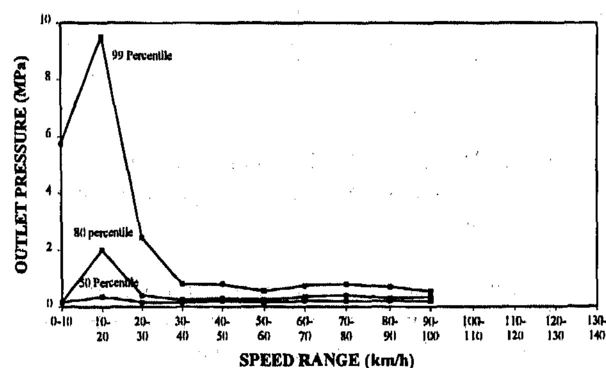

Fig. 8 Percentile Bands of Pump Pressure vs. Speed Range: Inner City in Peak Hour.

of pump pressure with respect to speed. Figures 8, 9 and 10 detail the percentile bands of pump pressure for three widely differing routes and types of driving.

One can immediately identify the different steering demands of these routes: city driving with high waiting times and low speed manoeuvring; free moving suburban driving with many intersections and roundabouts and fast, country driving with long, flowing curves which demand reasonable steering pressure but little in the way of rack travel. Given these differences, it is interesting to note that, for the vast majority of the speed ranges, the pressure is at (or near) the on-centre pressure for 80% of the time on all three routes.

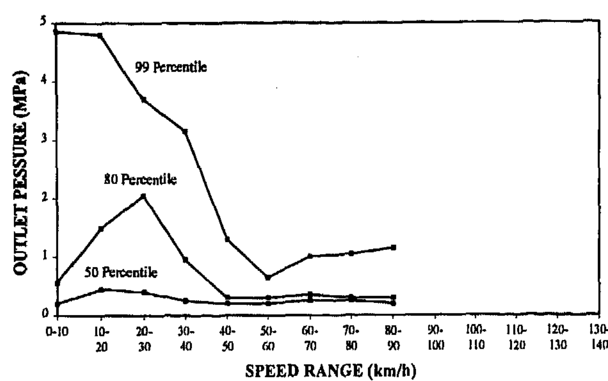

Fig. 9 Percentile Bands of Pump Pressure vs.Speed Range: Suburban Back Streets in Light Traffic.

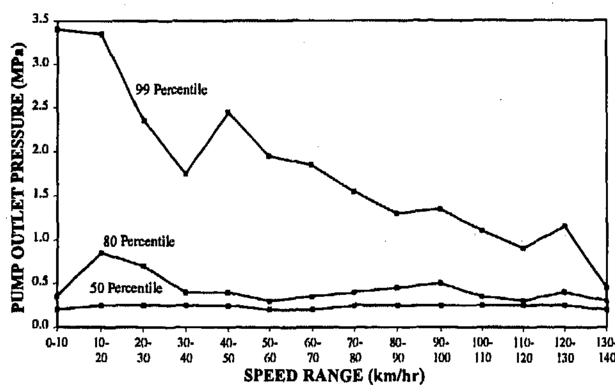

Fig. 10 Percentile Bands of Pump Pressure vs.Speed Range: Fast, Country, Single Carriageway Roads.

If we now look at the percentile bands for rack deviation from centre for the same three routes (Figures 11, 12 and 13), it is evident that, in all cases above approximately 40 km/h, the rack deviates more than 5mm extremely infrequently. This means that, at higher speeds, the amount of work done by the rack is low. At lower speeds, the work rate is dependant on the driving conditions: city driving requiring more rack work at low speeds (10 - 20 km/h); suburban driving requiring more rack work at moderate speeds (10 - 40 km/h) due to the number of intersections and roundabouts to be negotiated.

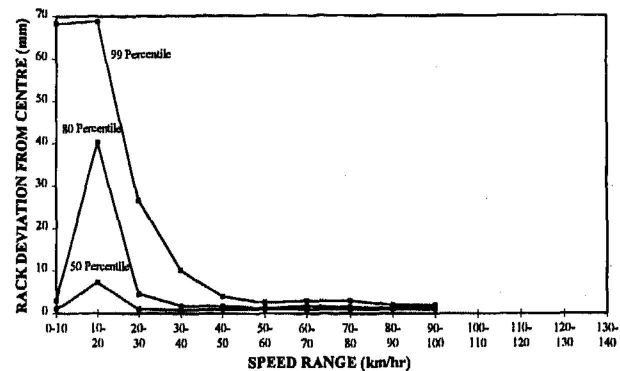

Fig. 11 Percentile Bands for Rack Deviation From Centre: Inner City in Peak Hour.

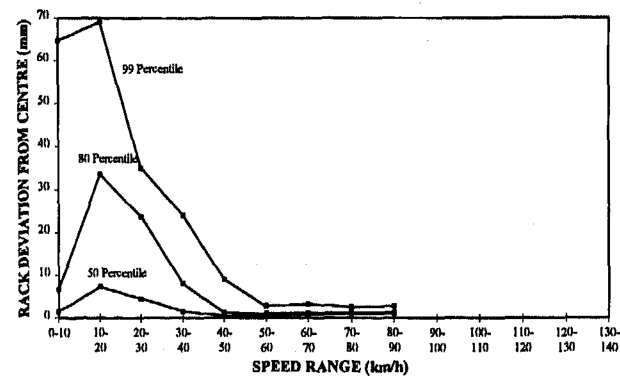

Fig. 12 Percentile Bands for Rack Deviation From Centre: Suburban Back Streets in Light Traffic.

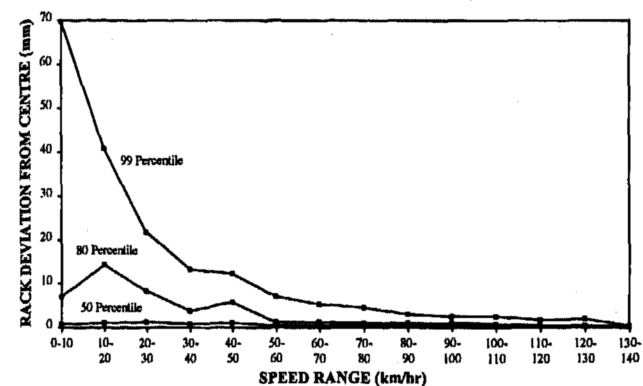

Fig. 13 Percentile Bands of Rack Deviation From Centre: Fast, Country, Single Carriageway Roads

THE OVERALL PICTURE - The average pump speed varies approximately linearly with average vehicle speed (see Figure 14) except at low speeds when gear changes have an effect. On Vehicle A at 100 km/h, the pump speed is approximately 2500 rpm and the input power is 400W when on-centre (see Figure 15). This translates into an energy consumption of 14.4 kJ/km with zero output force at the rack.

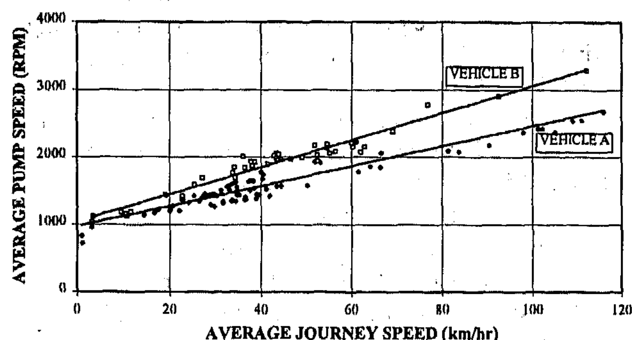

Fig. 14 Pump Speed vs. Average Journey Speed

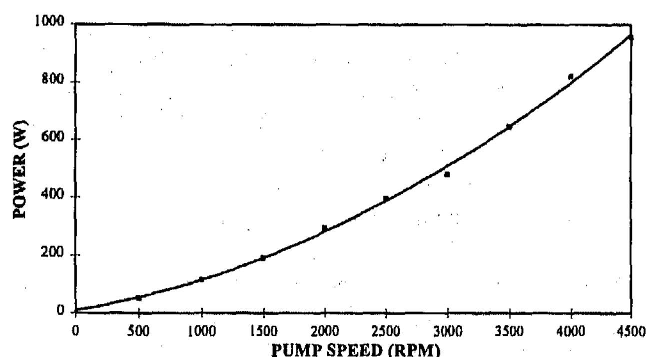

Fig. 15 Input Power vs. Pump Speed: On Centre

Referring back to Figures 6 and 7, the average pump pressure at 120 km/h is very close to that for the vehicle stationary and at idle rising slowly as the speed reduces to 20 km/h. Below 20 km/h, the pressure can rise dramatically due to the amount of gross steering movement which can be made at these speeds. As an approximation, the average pump pressure varies as follows:

Ave. Pump Pressure a (Ave. Vehicle Speed)$^{-1/2}$

Figure 16 shows the energy consumption per kilometre for Vehicle A as a function of average vehicle speed. There is a strong correlation with speed, the energy consumption/km varying approximately with the inverse of the average speed.

Vehicle B displays the same relationship between speed and consumption (see Figure 17) except that the consumption at any given speed is higher than that for vehicle A. This can directly be attributed to the higher on-centre back pressure that this vehicle displays.

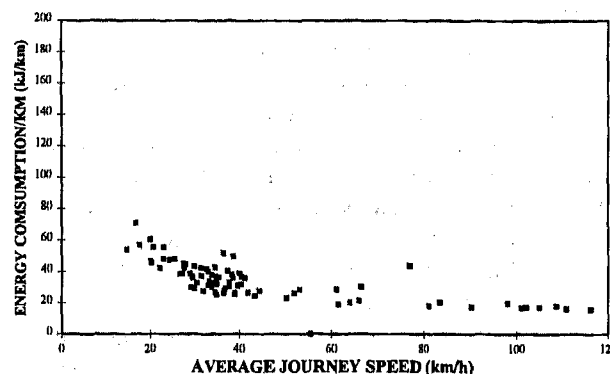

Fig. 16 Energy Consumption / km vs Average Journey Speed: Vehicle A.

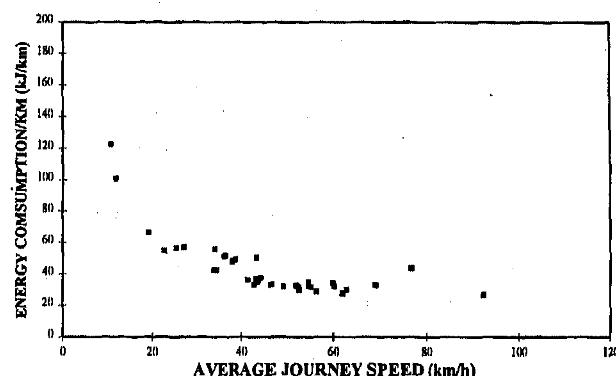

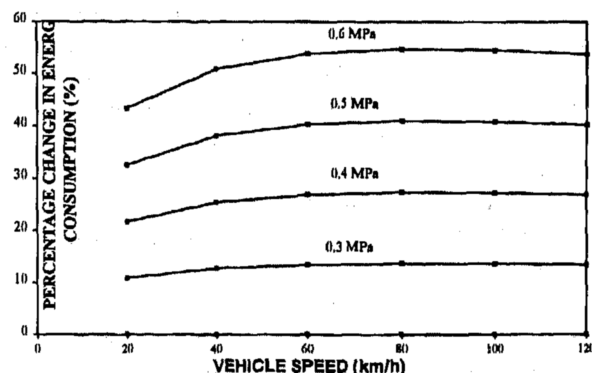

Figure 17 Energy Consumption/km vs Average Journey Speed: Vehicle B.

Having established the importance of the on-centre regime, the effect of the on-centre back pressure should be investigated.

.Fig. 18 Change in On-Centre Energy Consumption vs. Back Pressure.

Figure 18 shows the change in energy consumption, to be expected by changing this parameter, calculated using the empirical formula for pump torque developed earlier.

The level of change is reasonably constant except that it falls away at speeds below 20 km/h, due to the increased demand for rack work increasing the input power requirement whilst the absolute on-centre losses actually decrease at these speeds. Vehicle B runs with a back pressure of between 0.4 and 0.5 MPa. From Figure 18, one would expect an increase in consumption, over that of Vehicle A, of approximately 30% at 100 km/h which is confirmed by experimental data.

How does this affect the fuel consumption of the host vehicle? Overall energy consumption for Vehicle A's steering was 23.28kJ/km and that for Vehicle B was 31.12.kJ/km and overall average speeds were 55.6km/h and 47.1km/h, respectively. The efficiency of the drive to the pump from the crankshaft would be approximately 0.9, so crankshaft energy output would be 25.87 and 34.58 kJ/km, respectively. Modern automobile engines, at the duty levels represented here, are approximately 25% efficient in terms of output at the crankshaft relative to fuel input. Hence, the steering requirement for energy from fuel would be 103.48kJ/km and 138.32kJ/km or 0.32 l/100 km and 0.43l/100 km (using a calorific value of 32.25MJ/l for petrol).

Laboratory testing for fuel consumption on Vehicle B gave raw results (in l/100km) of:

	HWY	URBAN
Pump Connected	7.66	10.38
Pump Disconnected	7.52	10.09
Difference	0.14	0.29

Obviously, on the rolling road, no steering inputs could be made. This was accounted for by using the difference in results for energy consumption/km and on-centre losses at the equivalent average pump speeds to generate a correction factor. The modified differences in consumption then became: 0.23l/100 km (HWY) and 0.46 l/100 km (URBAN) which, given the mix of urban and highway usage represented by the mapping exercise, is in close agreement with the above results for the test vehicles.

Track testing of the two vehicles produced the following results for maximum system performance requirement:

Vehicle:	A	B
Maximum Rack Speed (m/s)	0.15	0.15
Maximum Rack Accel. (m/s^2)	0.90	0.92
Maximum Rack Force (kN)	6.0	7.1
Maximum Rack Power (W)	800	700

It is interesting to note how similar the requirements are, given the widely differing specifications of the two vehicles. The energy maps are also very similar except for the extra back pressure for Vehicle B which is the sole reason that its steering system absorbs more energy than that of Vehicle A.

The OC system, then, is grossly inefficient, having an overall efficiency of the order of 0.03%. This is due to the large parasitic losses associated with the constant supply of oil to the power steering and the pump being driven at varying speeds above that required to supply the rated flow of oil.

The question to ask now is: "How does this fit in to the picture of the automobile as a whole?". Currently, overall driveline efficiencies (fuel in to tractive effort out) are in the region of 8 - 10%, fuel consumption for a medium sized sedan is 8 - 10l/100 km and fuel is relatively inexpensive, especially with respect to the overall costs of running a vehicle. In the life of the vehicle (160,000km), 690l of fuel will be used to power the steering which, currently in Australia, costs approximately A$500 or A$50 - 80 per year. Of growing concern is the 1660kg of CO_2 produced by burning this fuel. The steering currently accounts for approximately 4% of the fuel consumption of the vehicle but efforts are being made to improve the overall efficiency of the vehicle (the US Government PNGV target is 2.94l/100 km for a medium sized sedan) which will increase the significance of the steering contribution. Indeed, with the apparently constant absolute energy requirement, regardless of vehicle size, the application of power steering to smaller vehicles means that the significance of this energy consumption increases quite markedly and this, along with packaging problems, may have already caused manufacturers to look to alternative systems.

Very little can be done to improve the efficiency of the OC system apart from paying attention to the back pressure generated by the system as a whole.

ALTERNATIVE SYSTEMS

OCCS SYSTEM - Mechanical Drive - A transmission to convert crankshaft output to constant speed would have an efficiency of approximately 0.9 and, with the belt drive (also 0.9), would have an overall drive efficiency of 0.81.

Losses would be reduced by reducing on-centre losses (by lowering pump internal back pressure - no FCV) and no extra losses due to the speed of the pump at higher road speeds.

Electric Motor Drive (EHPS) - With the use of an electric motor, the efficiency of the whole electricity supply system comes into play. Assuming the accessory drive efficiency is 0.9, the alternator average efficiency is approximately 0.4 and the electric motor efficiency is approximately 0.6, the total system efficiency is 0.22.

(Alternator and motor efficiencies are estimates based on information from reference (2)) This would seriously disadvantage this system if it is designed to supply the same flow rate as the OC system which is set to account for the highest rack speeds. These speeds are rarely seen in general driving and, since the speed of the electric motor can be controlled electronically, the EHPS system is normally designed around a lower flow rate (typically ¼ of the conventional figure) and the motor accelerated when rack speed demands extra flow. This has compounding benefits: the system would be expected to run at marginally lower back pressures and, for the vast majority of the time, the pump will require only 25% of the power at equivalent steering pressures. This is not now a true constant speed system.

CC SYSTEM - For this system, the amount of energy input required is calculated by multiplying the volume of oil required to move the rack by the accumulator pressure and applying the efficiencies of the component parts of the system. The parts, common to both electrically and mechanically driven systems are: accumulator (0.9)and pump (0.9). Energy is saved in this system because it is a true "on demand" system. In theory, when the rack is stationary and only required to supply a force, the system will not be using any energy due to there being no active flow from the accumulator. This situation doesn't take into account the problem of leakage of fluid from the accumulator, through the valving.

In calculating the CC energy consumption for vehicle A, the mean accumulator pressure was assumed to be 13MPa which would require a rack piston area of $682mm^2$ to achieve the 8.86kN maximum rack load at the standard relief pressure (10MPa and $886mm^2$ piston area). The highest fluid volume requirement occurs during maneouvring in a narrow roadway. The volume required for a five point turn (carried out in 30sec.) was 415ml. This means that the accumulator should be of the order of 500ml capacity and the pump should have a delivery rate of approximately 1.0l/min. Any leakage will have the effect of adding a parasitic loss to the system since the stored energy, in the form of pressure, is continually being vented to atmosphere. Since the leakage rate would be reasonably constant, the additional burden on energy consumption (kJ/km) would be inversely proportional to the vehicle average speed.

Leakage rates will be determined by the design of the control valving and are difficult to estimate. For the purposes of our comparison, here, a leakage rate of 0.2l/min was selected as representing a severe leakage problem and this represents a parasitic loss off 43.3W or 53.5W at the input to the pump.

Mechanical Drive - Here the efficiency of the drive to the pump (possibly integrated into the engine camshaft) would be approximately 0.9 and total efficiency of 0.73 would be applied.

Electric Drive - The efficiency of the electric motor system, as before, would be 0.22 and the total efficiency would be 0.175.

EPS SYSTEM - Whilst this is an "on demand" system, an electric motor draws a current even if it is only supplying a torque at zero rotational speed. Hence, the efficiency of the system is more difficult to calculate because the efficiency of the motor is dependant on its speed.

Motor torque requirement is calculated from the rack force and the mechanical advantage (from maximum rack speed (0.15m/s) and maximum motor speed (assumed 4000 rpm giving a ratio of 26,667 rads/m). Motor torque has a relationship with current which is independant of speed (reference 2) and this is used to calculate the instantaneous current requirement. However, in order to control the motor current, the voltage applied has to be varied due to the back EMF generated being proportional to motor speed. Hence, when calculating the energy requirement, both motor speed and torque have to be considered. For the purposes of this analysis, a conventional 12V brush DC motor of 1000W capacity was selected as the basis of these calculations. This is not necessarily the most suitable equipment but could be presented as a "worst case" scenario.

In addition to the motor characteristics, we have to apply the efficiency of the rest of the electrical system as well as that of the gearbox/steering gear system. When motoring (eg. dry parking) the figures would be: accessories drive (0.9); alternator (0.4); gearbox (at best 0.9) and steering gear (say 0.9). The total for this would be 0.29. Battery efficiency (approximately 0.7) would only enter the equation infrequently, such as when parking.

Higher voltage systems would be of definite advantage in the electrical efficiency area by reducing current, and, hence, resistance losses in the motor windings.

COMPARISONS

From figure 19, it can be seen that the OCCS mechanical system consumes between 15% and 50% of the energy consumed by the OC system. At very low speeds (driving in car parks), this rises to nearly 100%. This is because the OC system is running at the same speed as the OCCS at these vehicle speeds.

Figure 20 demonstrates the same comparison for the EHPS system. It is immediately apparent why these systems are designed with reduced flow. With the conventional flow rate (same as the OC system), the energy consumption is higher than that of the OC system up to 60 - 70km/h. This is due to the lack of efficiency of the electrical energy conversion.

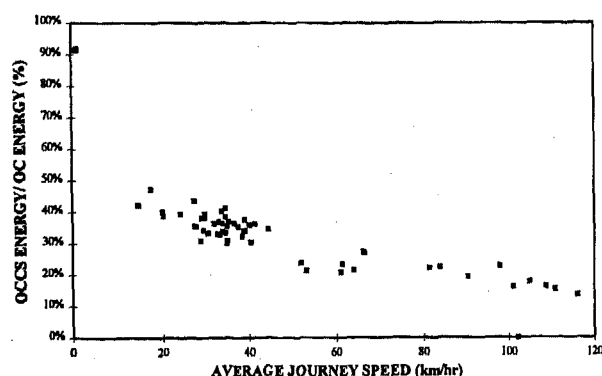

Figure 19 Comparison of Energy Consumption: OC to OCCS Mechanical Drive.

The reduced flow system, on the other hand, provides significant savings of between 50% and 90% over the OC system.

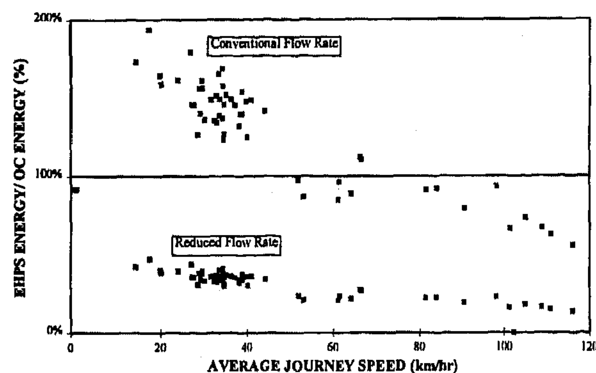

Figure 20 Comparison of Energy Consumption: OC to EHPS

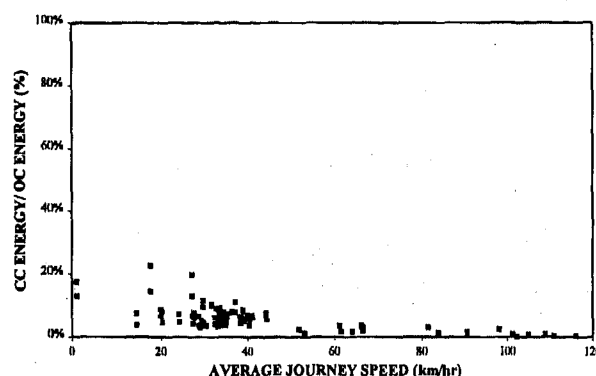

Figure 21 Comparison of Energy Consumption: OC to CC Mechanical Drive.

The energy consumption of the mechanically driven CC system is between 1% and 19% of that of the OC system if one assumes zero leakage. Adding the 0.2l/min leakage rate (see figure 21) raises the upper limit to approximately 23% but has very little effect on the relative consumption at higher average speeds.

With electric drive for the pump, the CC consumption (without leakage) rises to levels similar to that for the EHPS reduced flow system, although the CC system has an advantage at higher average speeds. The rise, again, is due to the inefficiency of the vehicle electric system. With accumulator leakage (figure 22) the maximum is raised to over 60% of that of the OC system.

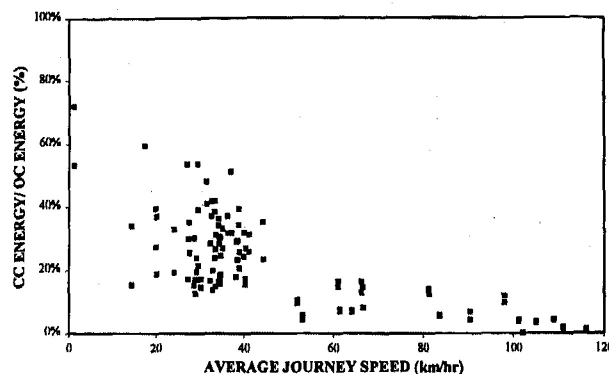

Figure 22 Comparison of Energy Consumption: OC to CC Electrical Drive.

Finally, figure 23 illustrates the energy consumption trends for the EPS system. Generally, consumption is of the same order as that of the CC mechanical with the CC system having an advantage at higher average speeds. This advantage at higher vehicle speeds is due to the fact that rack motion decreases with increasing speed (see figures 11,12 and 13) and the CC energy consumption is directly proportional to rack travel (ignoring leakage) whereas the EPS system can be drawing current even when the rack is stationary.

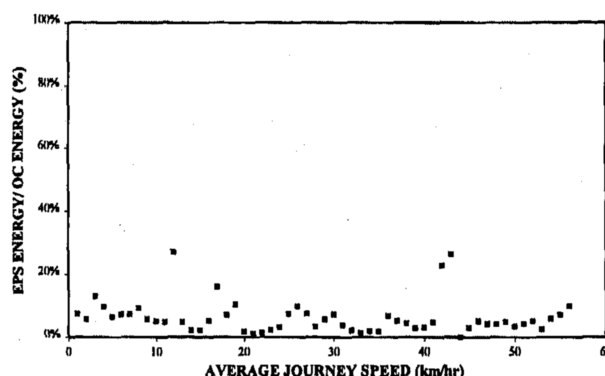

Figure 23 Comparison of Total System Energy OC vs. EPS.

CONCLUSIONS

The most energy efficient systems are the two "on demand" systems: CC mechanical and EPS, both systems exhibiting similar levels of energy consumption of less than 20% of that of the OC system. Even an accumulator leakage rate of 0.2l/min does not severely disable the CC system. However, future trends in powering the automobile would be likely to include an IC engine which is not required to run continuously (eg. hybrid vehicles) and these would probably require electric drive to accessories such as steering. This would tend to devalue the benefits of the CC system as the electrically driven version suffers a consumption penalty of approximately 2.5:1 over its mechanically driven brethren. Therefore, the EPS system would be most applicable in this scenario.

In terms of the current vehicle specifications, significant energy advantages can be gained from the use of the EHPS system, providing the "reduced flow" scenario, described above is utilised.

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

The technology thrust to develop an effective electromagnetic actuator for application in an active suspension system has precipitated a fresh look at the active control schemes in an effort to reduce the required force levels of the actuator. The resulting "near constant force" control algorithm is described and its ability to greatly reduce vehicle sprung mass motion is documented through simulation and single wheel station laboratory test stand results. The vehicle power and energy requirements associated with this unwanted vehicle vertical are analyzed and comparisons between the corresponding passive and active systems are presented. The success of the active system leads naturally to the conclusion that a passive suspension equipped vehicle will become power limited at a much lower speed than will this active system when traversing severe cross-country terrain.

INTRODUCTION

The possibility of utilizing an electromagnetic (EM) actuator in a high-wheel travel active suspension system has recently gained considerable interest in both the commercial and the military sector [1-2]. The bus developers are interested in the potential benefits of active suspension for ride comfort and vehicle roll control as well as for the accompanying height and attitude control. Height and attitude control can be used to greatly simplify potential solutions to the handicap access requirements the bus manufactures must meet. The interest in an EM actuator based system is predicated on the availability of an energy efficient, and appropriately packaged system, that if exists would eliminate the need for a complex hydraulic system.

A passive suspension system is simply a traditional suspension system composed of springs, dampers (i.e. shock absorbers), and various structural linkages [3]. The springs and dampers of a passive system are appropriately tuned for the expected input frequencies, to attenuate the terrain input (as seen by the tires). The purpose of the shock absorbers (or dampers) is to dissipate the energy that is input into the chassis by the ground through the suspension system. The more energy that is allowed to be input to the chassis, the more energy that the shock absorbers must dissipate, and the more energy that the vehicle's power train must provide. A semiactive suspension system is defined here as a passive system which has adaptive damping characteristics. The system has the traditional springs and dampers, but the vehicle motion is constantly monitored, and the damper characteristics are reduced (or set to zero) when the damping forces would increase chassis motion. It has been demonstrated that semiactive suspension systems can moderately increase the ride quality of a vehicle while simultaneously slightly decreasing the energy dissipated by the suspension system [4-5].

An active suspension system represents a distinct departure from traditional suspension system concepts. Springs and dampers are no longer required (though for practical reasons springs are often still included). The suspension forces that are normally provided by the springs and dampers are now provided by some form of actuator (e.g. hydraulic, pneumatic, or EM) based on the output of vehicle motion based control algorithms. The active suspension control research for rough terrain negotiation has primarily focused on more sophisticated approaches to the attenuation of the ground induced inputs [6-7]. The success of active suspension has been quite impressive in the areas of on-road stability and handling and has been demonstrated repeatedly. The cross-country ride problem, however, has not proven as easy to conquer to date.

The military's interest is active suspension systems also begins with significantly improving vehicle ride and stability, but for the military, cross-country ride is the focus of interest. The Army's thrust to remove hydraulics from its ground combat vehicles precipitated its interest in EM actuator based active suspension systems. The technology thrust to develop an electric drive combat vehicle has only served to heighten this interest since adequate electric power would be available on the vehicle and the addition of a hydraulic system for active suspension would only add to the overall vehicle complexity.

The intended application of such a system would be to obtain maximum high-speed cross-country performance desired by military applications. The major barrier to making such an application practical has been the weight and power requirements of an electromagnetic actuator based system. Since the actuator weight for such a system is driven largely by the actuator force requirements and therefor indirectly by its power demands, minimizing the required active suspension power will also greatly reduce the system weight.

An active suspension control algorithm is presented that requires significantly less power (and correspondingly lower forces) than do other algorithms. This "near constant force"

strategy attempts to prevent the excitation of the vehicle's sprung mass rather than to attenuate the motion once it has begun. The resounding success of this algorithm is demonstrated through a series of simulation and laboratory test stand results. The laboratory test stand results include test data obtained from a single wheel station, rotary EM actuator, supporting a sprung mass of 4500 kg as well as test data from a reduced scale, 4 wheel representation of a high mobility off-road vehicle. Simulation results corresponding to the test data are also presented.

The power and energy requirements of this active suspension configuration are actually shown to be significantly lower than those for the comparable passive suspension configured vehicle. In addition the acceleration levels of the sprung mass are also dramatically reduced resulting in the operational maximum cross-country speed being significantly increased over, not only the passive system, but over other proposed active suspension configurations as well.

NEAR CONSTANT FORCE ACTIVE SUSPENSION CONTROL ALGORITHM

The underlying philosophy for the "near constant force" (or NCF) active suspension system algorithm is quite simple. Since the purpose of a suspension system is to isolate the chassis (or sprung mass) from the motion of the wheel (or unsprung mass) which is trying to follow the terrain, a perfect suspension system (in terms of isolation) would always generate only the static force to the chassis. With a constant vertical force on the chassis, the chassis would then be subjected to zero vertical acceleration and therefor a perfect ride. In practice, of course, this is simply not practical since the vehicle must go up and down hills and the suspension travel is limited to a few inches at best.

The idea persists, however, that the best active suspension control algorithm would be the one that would provide the least variation in suspension forces while minimizing the prospect of exceeding suspension travel. Thus was born the NCF control algorithm. The perfect solution of this problem would require prior knowledge of the terrain, but the development of the NCF algorithm was developed without the assumption of this prior knowledge and yet has been shown in the laboratory to perform at an extremely high level of efficiency.

A model of the original laboratory test stand for which the NCF control scheme was developed, is shown in figure 1. This model represents (as does the test stand) one of the fourteen roadwheel stations and one-fourteenth of the hull mass of a main battle tank (the M1 Abrams). The road-wheel is mounted on a trailing arm and the hull mass is constrained so that it can move only in the vertical direction. The suspension vertical force to the hull is actually applied as a torque between the road arm and the hull at the road arm pivot. Since this model is restricted to vertical motion, it can be viewed the same as a 1/4 car model would be for a four wheeled vehicle. Figure 2 presents the predicted motion of this model's hull mass for the standard torsion bar suspension system on the M1 tank to the terrain input shown. This terrain is extremely rough as indicated by its terrain roughness index of 8.9 cm rms. The gradual hills were removed from the terrain prior to the simulation to comply with the travel

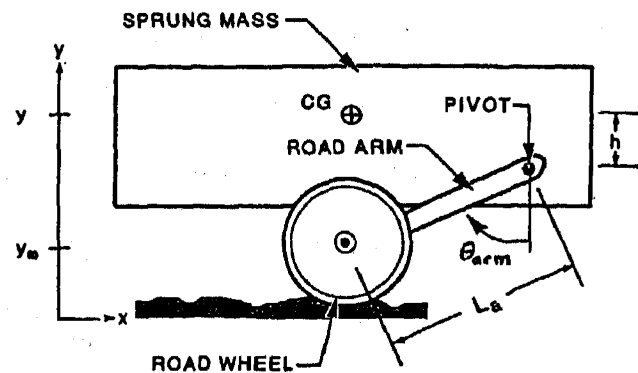

Figure 1 One-dimensional tank suspension model

limits of the laboratory terrain generation hardware. This simulation represented a vehicle velocity of 16 kph and it can be seen from the plots that for this very stiff passive suspension system, the hull tends to follow the terrain.

Any practical active suspension design will include a passive spring to statically support the vehicle and to reduce the overall power requirements of the active system and the EM actuator based system is no different. The demonstration rotary actuator built on a main battle tank scale, incorporated air spring for this purpose. This permitted the spring rate to be kept quite low while still providing the required static force. The first task of the NCF algorithm is to negate the effect of this low rate spring which varies with the arm angle of the trailing arm suspension system. The NCF algorithm was developed based on the premise that it would have available only measurements that could be obtained from the vehicle itself. These could include arm angle and velocity making the cancellation of the spring force a simple matter, and could also include, as needed, chassis (or hull) vertical, pitch, and roll accelerations, velocities, and displacements (or estimations thereof). The resulting actuator

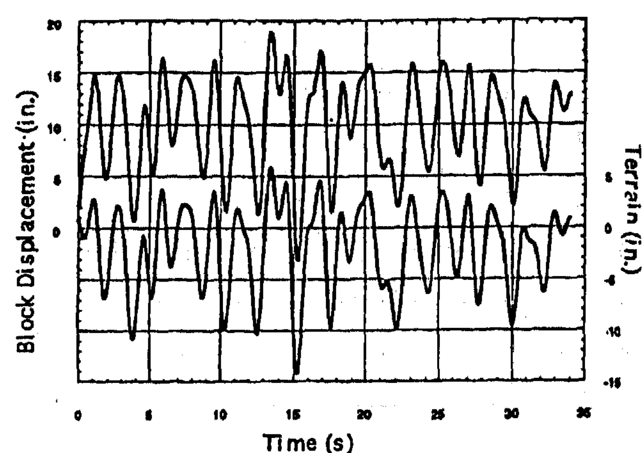

Figure 2 Simulated hull motion at 16 kph for passive M1 torsion bar system

force from the NCF algorithm for a 1/4 car model (i.e. considers chassis vertical motion but not pitch or roll) is given by:

$$F_a = -F_s(\theta_{arm}) - k_1[y - y_{ref}] - k_2 y' - k_3 \theta_{arm} - k_4 \theta'_{arm} \quad (1)$$

where $F_s(\theta_{arm})$ is the force required to offset the air spring's additional force (as indicated, F_s is a function θ_{arm}), y is the vertical displacement of the chassis, θ_{arm} is the angle of the roadarm, y_{ref} is the height of the desired chassis vertical trajectory, and k_1, k_2, k_3, and k_4 are appropriate gains. Of course the displacement of the chassis, y, and of the desired reference trajectory, y_{ref} , are not readily available to the controller and so the gain k_1 is set equal to zero in the NCF algorithm. The term is left in equation (1) to emphasize the fact that it is ideally what is desired to be controlled. However much can be discerned about the nature of the term $[y - y_{ref}]$, from the more easily measured signals y' and θ_{arm} and feedback based on these terms is used instead of on $[y - y_{ref}]$.

Figure 3 shows the hull motion for a 16 kph simulation as did figure 2, but in this case an active suspension system was assumed and the suspension force is determined by the one-dimensional NCF algorithm. Also, as was done for figure 2, the gradual hills had been removed from the terrain. Figure 4 shows the actual results from the laboratory test stand corresponding to the predicted results of figure 3. The comparison is quite comforting and lends credibility to the attempt to greatly decrease hull motion in response to severe cross-country terrains.

The appropriate choice of gains in (1) allows the NCF algorithm to actually respond to hills while effectively filtering out the higher frequency inputs inherent in rough cross-country terrain. Figure 5 presents the simulated hull response to the same terrain used in the previous examples, but where the gradual hills have been left in the terrain. This simulation was performed at a vehicle speed of 64 kph and shows almost a total attenuation of the higher frequency inputs.

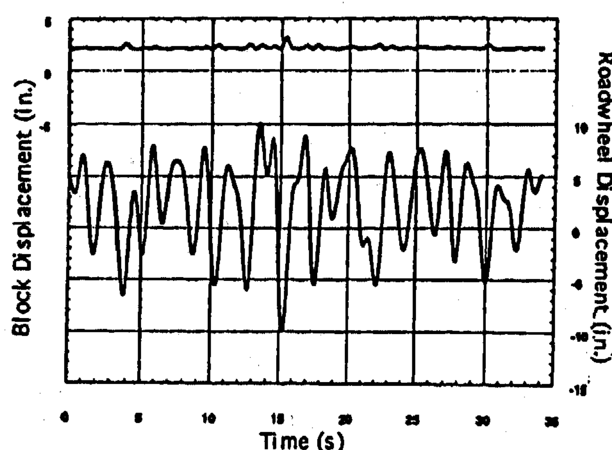

Figure 3 Simulated hull motion at 16 kph for NCF active suspension system

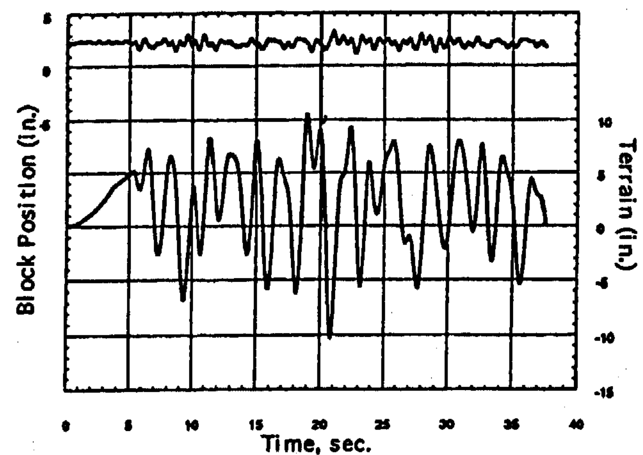

Figure 4 Laboratory test stand hull motion at 16 kph for NCF active suspension system

The version of the NCF algorithm presented in (1) is concerned with minimizing vertical chassis motion only. The extension of the NCF algorithm to a full 3-dimensional vehicle model must also consider the chassis pitch and roll motions in calculations. The NCF actuator force for this full vehicle model can be similarly be written as:

$$F_a = -F_s(\theta_{arm}) - k_1[y - y_{ref}] - k_2 y' - k_3 \theta_{arm} - k_4 \theta'_{arm} - k_5 \theta - k_6 \theta' - k_7 \alpha - k_8 \alpha' \quad (2)$$

where θ and θ' are the chassis pitch angle and pitch rate, α and α' are the roll and roll rate, and the additional k's are appropriate gains as before. This 3-d version of the NCF active algorithm was implemented to control a 30 % scale, 4 wheeled active suspension test rig representing the Army's High Mobility Multi-purpose Wheeled Vehicle (or HMMWV). Preliminary results from this test rig were similar in terms of chassis motion reduction, to those discussed earlier for the single wheel station system.

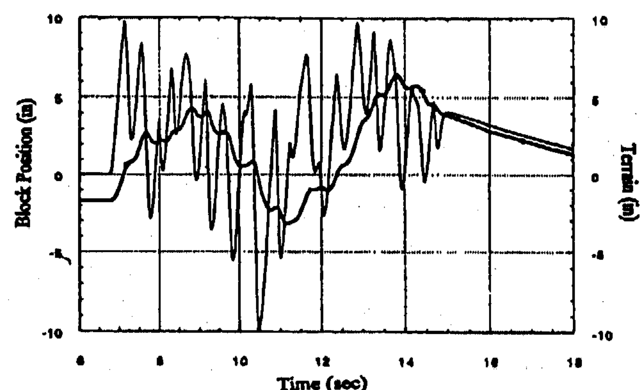

Figure 5 Simulated hull motion at 16 kph for NCF active suspension with hill following employed

POWER COMPARISONS FOR ACTIVE AND PASSIVE SUSPENSION SYSTEMS

It is clear that when the sprung and unsprung masses are moving up and down, that some of the power that was intended to drive the vehicle forward is being expended in the vertical direction. This power is, of course, supplied by the vehicle's engine and is delivered through the inefficiencies of the drive train to provide motion to the vehicle. Power expended in exciting the vehicle vertically is totally wasted, and if it becomes excessive will significantly limit the overall performance of the vehicle. It will be demonstrated that this is in fact the case for the passive suspension system on the M1 when trying to negotiate very rough terrain.

The unsprung mass (roadwheel or tire) is intended to follow the terrain and thus must be continuously accelerated in the vertical direction when traversing rough terrain. The unsprung mass, however, is usually less than 10 % of the sprung mass and thus is a rather minor drain on the system power than is the sprung mass at the same excitation levels. The active suspension system cannot, therefor, effectively reduce the unsprung mass motion of the power required of the engine to produce that motion.

The sprung mass on the other hand has no requirement to follow the high frequency component of the terrain input, and in fact, the suspension systems very purpose is to keep it from doing so. Unfortunately, the passive system, as was demonstrated in figure 2, is not very effective at accomplishing this. In the passive system the power that is input into the unwanted vertical (as well as pitch and roll) motions is ultimately dissipated by the shock absorbers and lost. In order to compare the vertical motion power between the active and passive suspension systems, vertical sprung mass power was computed as:

$$\text{Power} = F\,v = F\,a\,v \qquad (3)$$

where F is force, v is velocity, m is mass, and a is acceleration. The resulting comparisons that are shown below are for a single wheel station as represented in figure 1, where the sprung mass represents $1/14^{th}$ of an M1's sprung weight (the M1 has 14 road-wheels).

Figures 6 and 7 depict the power required to accelerate the sprung masses for the passive and NCF active suspension systems at 4.47 m/s and 17.8 m/s. The simulated results are over the same severe cross-country terrain that was used in the previous examples. The passive system employed the standard M1 torsion bar and rotary damper whereas the active system was modelled with the electromechanical suspension active suspension system described in [1] and utilizing the NCF control algorithms described above. At the lower speed, figure 6 shows that the rms and peak powers associated with both systems is quite small. At 17.8 m/s, however, the difference in power between the two systems is dramatic as demonstrated in figure 7. The passive system requires 540 kW peak and 71 kW rms power just to accelerate the sprung mass of a single wheel station along its vertical trajectory. Projecting this rms power over the 14 road-wheels of the M1 would result in a total sprung mass acceleration rms power of 994 kW, or almost 90 % of the M1 engines rated gross power. It is realized that not all the M1 wheel stations are identical (only 6 of the 14 have dampers) and vertical motion of the sprung mass is somewhat abated over the length of the vehicle, but this power figure does not include contributions from the hull pitch and roll motions either.

It should be noted that the passive M1 could not attain nearly this speed (i.e. 17.8 m/s) across this terrain even if the vehicle and crew could stand the accelerations generated by such a run. The vehicle is in fact power limited long before this speed even though this is approximately the level surface top speed of the M1.

Figure 8 portrays the peak and rms power levels for this same pair of suspension systems as a function of vehicle speed. The terrain is the same cross-country terrain that was used previously and the plots were generated from simulation results using the same single wheel station model. The item of major interest here is the extreme divergence in power requirements at higher vehicle speeds between the passive and the NCF algorithm based active suspension system. Thus high speed travel on such a

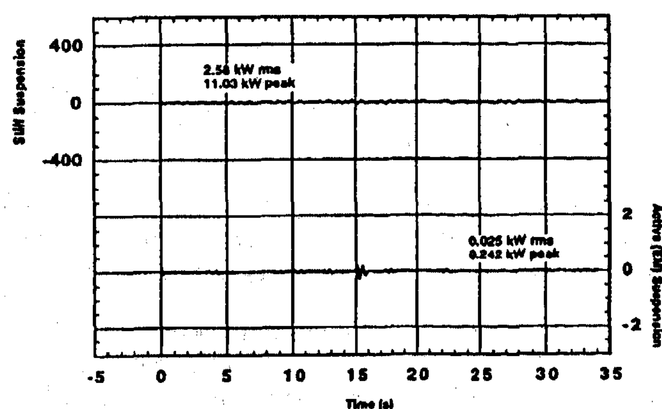

Figure 6 Sprung mass vertical power requirements for active and passive systems at 16 kph

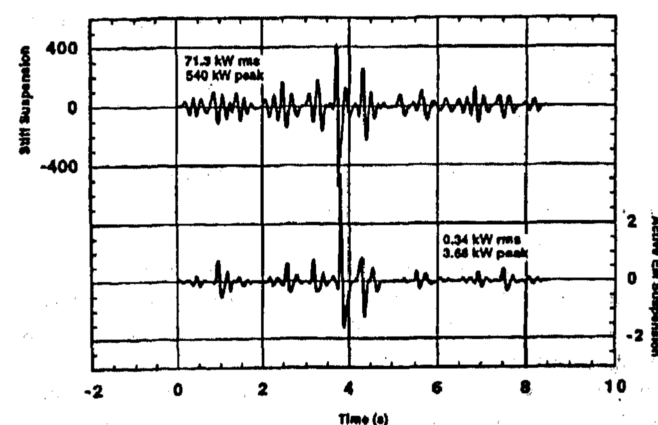

Figure 7 Sprung mass vertical power requirements for active and passive systems at 64 kph

terrain simply cannot be accomplished by this passive suspension system (or probably any other practical passive system). It will require instead, not only an active suspension system, but an active system that significantly reduces unwanted vehicle hull motions.

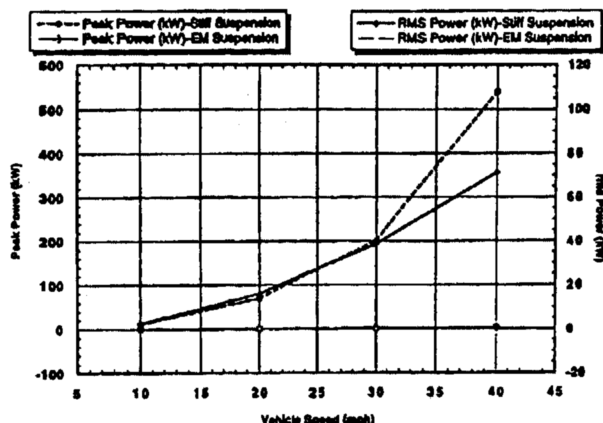

Figure 8 Power consumption between active and passive systems as a function of vehicle speed

ENERGY USAGE

When considering energy consumption of the passive and active suspension systems, the vehicle drive train and active suspension power delivery system efficiencies must be considered. At the 17.8 m/s speed, the passive system required 994 kW rms of power to provide the sprung mass vertical acceleration of the total vehicle. Since the power to accomplish this motion must be provided through the vehicle's drive train, the associated additional power losses can also be attributed to the excessive vehicle motion. If it is assumed that the vehicle automatic transmission and differential each operate at 90 % efficiency, these losses are approximately 233 kW.

These power train losses would represent the total power lost if the energy imparted to the sprung mass were completely recoverable, however this is not the case. Separate simulations show that an individual M1 shock absorber can dissipate as much as 95 to 100 kW of power when the vehicle is driven at 17.8 m/s over this same terrain. It should be noted that there are six shock absorbers on the M1 (on the front two and the rear wheel stations on each side) but the other wheel stations also have some inherent damping associated with them also.

The rms power required for the active system to accelerate the sprung mass was shown to be only 5 kW. This power can be applied by one of two paths to the sprung mass. As in the passive case, the power can be delivered through the vehicle drive train with the partially misdirected goal of vehicle forward motion in mind. Alternatively, the power to accelerate the sprung mass can be delivered directly through the active suspension system actuators. If in this latter case, one assumes that the active suspension power conversion device (for either mechanical to hydraulic or mechanical to electrical) and the suspension force actuator are both 90 % efficient, then the overall efficiency of the power delivery process is 81 % regardless of whether it is delivered through the vehicle drive train or through the active suspension system. Thus the total power required from the engine to provide the sprung mass motion for the NCF active system is only 6 kW even if none of the sprung mass motion energy is recoverable.

The power losses attributable to the unsprung mass vertical motions have not been considered here but they are not avoidable since the wheels must be made to follow the ground in order to be able to provide the necessary hull (or chassis) support. Ground contact is also required, of course, to permit adequate vehicle stability and handling. In either case, the wheel motions of both the active and the passive systems should be quite comparable making the power lost do to unwanted sprung mass motion the major power differential between the two systems.

CONCLUSIONS

The attempt to negotiate severe cross-country terrain at high speeds with conventional suspension equipped vehicles has been shown, to not only impart excessive motion to the vehicle hull or chassis, but to also require such high levels of available engine power that the higher speeds are simply not possible. The "near constant force" (or NCF) active control algorithm has been defined, and when coupled with an EM suspension system has been shown to reduce the sprung mass motion power by a factor of about 200. The NCF approach to active suspension control requires much lower actuator force levels than do previous active control schemes, thus making the prospects of a competitively sized EM actuator quite plausible.

Semiactive Suspension: A Mobility Case Study

Nancy L. Saxon and William R. Meldrum, Jr.
U.S. Army Tank-Automotive and Armaments Command

ABSTRACT

The U.S. Army has initiated a program to assess the performance potential of a semiactive advanced suspension system for its combat vehicles. The program utilizes the Bradley Fighting Vehicle as a test bed for a semiactive external in-arm hydropneumatic suspension. The system hardware includes the suspension and associated plumbing, computer controller, and dynamic track tensioner. This paper describes the comparable benefits of the semiactive suspension over the passive suspension through both laboratory testing and simulation results. Transmissibility analysis of the laboratory data document far less hull motion in the semiactive case. Simulated vehicle mobility again shows less vehicle motion and superior ride quality using the semiactive suspension.

INTRODUCTION

The superior mobility of a military vehicle provides the combat crew with a tactical advantage through increased cross country speed. The suspension system plays a pivotal role in evaluating a vehicle's mobility. The primary function of a vehicle's suspension is to cushion the vehicle body and its contents from terrain induced vibrations to permit higher vehicle speeds. Secondary, and no less important, the crew must have a measure of comfort which will allow them to be operationally effective. The human body's tolerance limit to these terrain induced vibrations is reached before the tolerance limit of the vehicle itself. Therefore, the human body tolerance limit is used to evaluate a vehicle's performance and is termed ride quality. The Army has established a quantitative measure of ride quality which relates the terrain, the driver, and the vehicle dynamics. The Army uses ride quality to predict and establish ride characteristics, evaluate suspension systems and analyze weapon stabilization systems. This unit of ride quality is called "Absorbed Power" [1].

Absorbed power was a criteria developed in the late 1960's by the Army through scientific experiments in whole body vibrations using human subjects. These experiments established a human transfer function of energy transmitted to the body. Shortly after these experiments, the Army conducted field tests and established a "driver preferred limit" of 6 watts of absorbed power. In 1980 this limit was incorporated into system performance specifications of Army vehicle solicitations. Figure 1 is a pictorial representation of the ride measurement process. Force and acceleration signals are sent through the human transfer function and integrator respectively and then through an averaging circuit which is then displayed as a single number for a given piece of cross-country terrain.

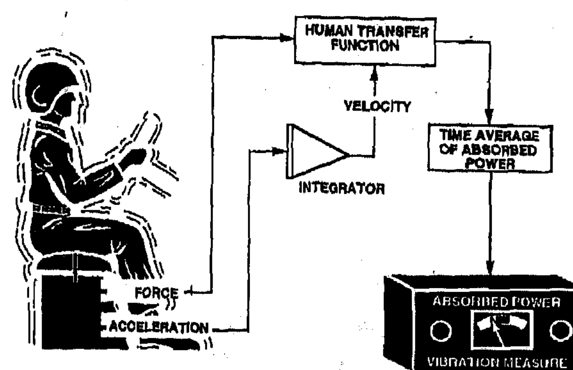

Figure 1. Ride Measurement Process

Not only does the vehicle require good ride quality, it also requires the suspension to provide for such things as good performance on side slopes and accommodate high centers of gravity. It also must utilize the suspension travel so that the vehicle road wheels are on the track and producing tractive effort in all types of terrain situations. In order to accomplish both of these missions, good ride quality and good terrain negotiation,

the selection of the spring and damping rates are a compromise. In the past the standard spring was a torsion bar and the damping was either a linear or rotary shock absorber.

Attempts to develop a suspension which would effectively accomplish both missions stated above lead to research into external in-arm hydropneumatic suspension technology, and more recently semiactive suspension technology [2] [3]. The in-arm suspension is one in which all of the suspension components are exterior to the hull of the vehicle. The suspension components are fitted within the roadarm (there is no separate strut or shock absorber), see Figure 2. The nitrogen gas provides the springing and the damping is provided by friction plates, see Figure 3. The suspension unit is charged with two different nitrogen charges. A higher pressure at the upper end of the nitrogen chamber and a lower pressure near the low pressure piston. As the roadwheel is forced in the jounce direction, the crank forces the low pressure piston down the cylinder increasing the nitrogen pressure giving the initial spring rate. When the lower chamber pressure reaches that of the upper chamber, the high pressure piston also begins to move, thereby increasing the volume of gas to be compressed and softening the spring. The dual piston/nitrogen chambers give the in-arm units their dual spring rates as shown in Figure 4. Some of the benefits of the in-arm system over the torsion bar system are weight and space savings, weight class commonality, and greater load leveling capability. Also, lockout and height control can easily be incorporated into this type of suspension.

Further research lead to the incorporation of the semiactive technology into the external in-arm hydropneumatic suspension units. Incorporation of this technology is considered very low risk and can provide the additional benefits of increased vehicle mobility, platform stability, ride comfort, and faster cross-country speed. Another expected benefit is increased component reliability due to decreased shock loads to the hull.

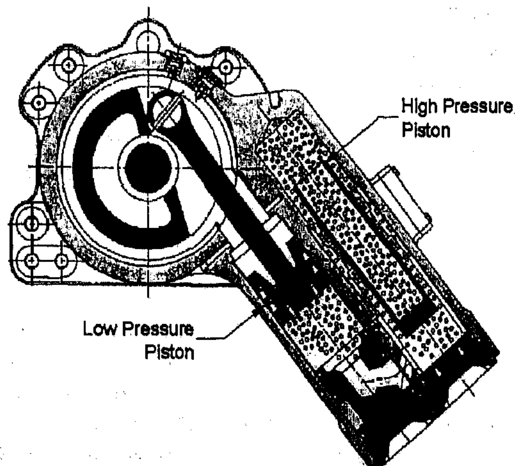

Figure 2. Hydropneumatic External In-Arm Suspension Cross-Section

For the purpose of this paper, a semiactive suspension is defined as one in which the damping forces are computer controlled in real-time. The system uses a damping control strategy to optimize ride and/or gross body motion of the vehicle. Minimizing the vehicle motions results in a more stable, and therefore a more level vehicle, with more even weight distribution over rough terrain. The benefits of semiactive technology has been proven in past tests sponsored by the Army and has shown an increase in a vehicle's cross-country speed by as much as 50 percent on an experimental vehicle [2] [3]. The objective of semiactive control is to minimize vehicle motion without degradation to ride quality and thereby increase cross country speed.

HARDWARE

The basic suspension utilized in this program is an external hydropneumatic in-arm suspension. Previous designs for passive units have included both the heavy and medium weight class. A variation of medium weight class design was incorporated into the Bradley test bed semiactive suspension design and is shown in Figures 2 and 3. Again, the passive technology is fully developed and therefore capable of being utilized as a platform for the semiactive controller.

The Bradley program's main goal is to design and fabricate a medium weight class in-arm vehicle set incorporating semiactive control for field testing. The program also includes the incorporation of an active track tensioning system and suspension lockout.

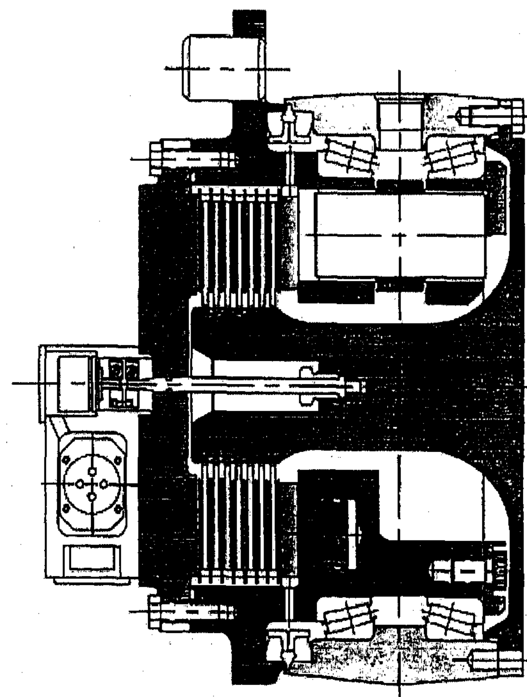

Figure 3. Rotary Friction Damper

Again, the spring curve for the units is shown in Figure 4. As described earlier, this is a dual rate spring providing a softer spring at higher levels of jounce travel. The damping curve is shown in Figure 5. The damper is a "bang-bang" damper and utilizes an "on-off" control strategy with a amplitude controlled dead-band.

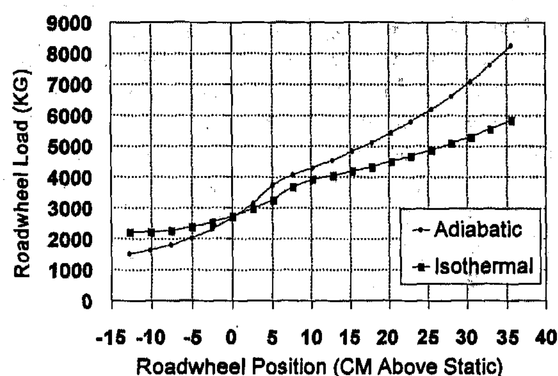

Figure 4. Suspension Unit Spring Curve

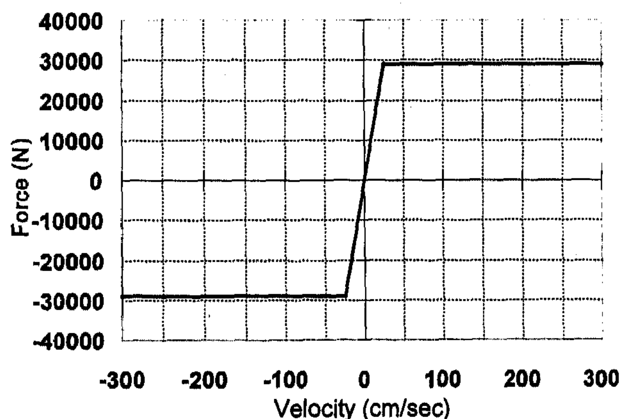

Figure 5. Suspension Unit Damping Curve

LABORATORY TESTING - PHASE I

The Bradley program was set up in a two phase approach. The first phase being a single unit road wheel station prototype to be tested on a suspended mass test rig. The second phase is a full vehicle set fabrication, installation, and field testing.

The laboratory testing was conducted on a single-unit suspended mass test rig, as shown in Figure 6. The simulated hull or suspended mass consisted of a 3208 kg block of concrete attached to a cantilever beam. The suspension unit was bolted to the concrete block and both the simulated hull mass and the suspension were instrumented. An actuator under the road wheel was fed a velocity dependent signal from digitized terrain and sinusoidal inputs.

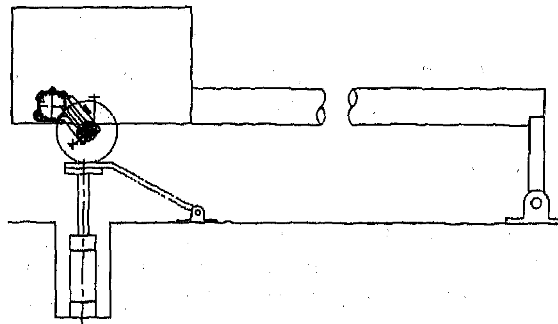

Figure 6. Suspended Mass Laboratory Test Rig

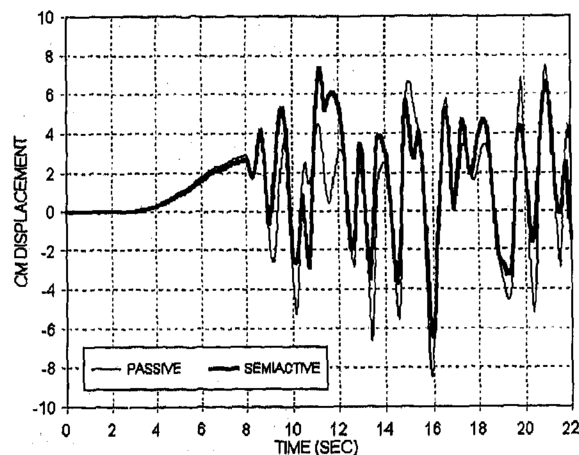

Figure 7. Laboratory Test Results Vertical Displacement 10 cm Bump Course at 32 kph

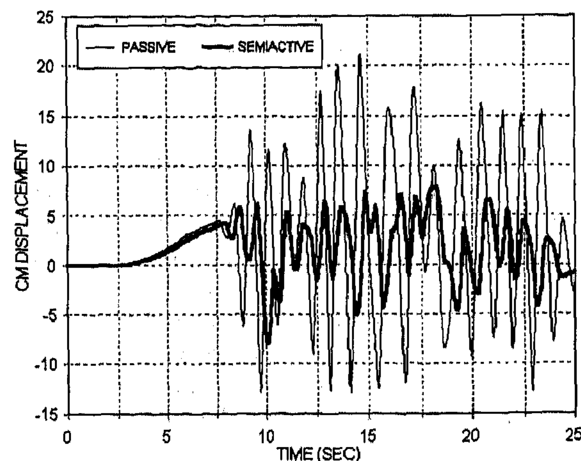

Figure 8. Laboratory Test Results Vertical Displacement 15 cm Bump Course at 32 kph

The objective of the laboratory testing was to insure both the hardware and controller were functioning properly. Minor adjustments in the controller algorithm were made to receive maximum benefit of the semiactive suspension.

Figures 7 and 8 show vertical displacement of the suspended mass for passive versus semiactive suspension configurations over a ten and fifteen centimeter bump course respectively. As shown in the above figures sprung mass amplitude can be markedly decreased with the use of semiactive control.

SIMULATION RESULTS

The simulation code used to predict the performance benefits of the semiactive suspension is a two dimensional dynamics model, Vehdyn II. Vehdyn II is a model developed by the Army Corps of Engineers [4]. It is a module included in the NATO Reference Mobility Model. The model is used to predict gross vehicle motions over rough terrain, to calculate absorbed power and peak acceleration and predict the ride and shock limiting speeds of a vehicle [5]. Figure 9 is a pictorial representation of the Bradley model. Some of the model limitations include the inability to model the roadarms or any nonvertical spring or damper effects, and the track is modeled as a spring element between adjacent wheels. The model is however, quite useful in determining overall vehicle performance without extensive computer time and has been validated with vehicle field tests.

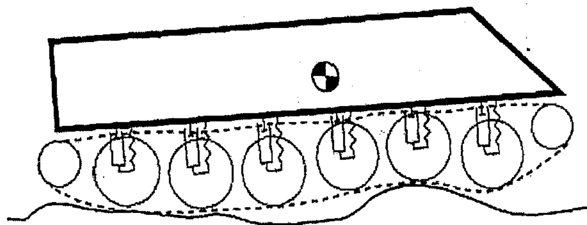

Figure 9. Pictorial Representation of Vehdyn Model

Figure 10 shows a simulated ride curve comparing the semiactive and passive suspension on a Bradley Fighting Vehicle. As shown there is a significant difference in the speed attained before the limiting six-watts of absorbed power is reached. The shock performance over half-round obstacles did not however show significant differences in the speed at which 2.5 g vertical acceleration is reached. Further evaluation and field testing is planned to confirm these findings.

Figures 11 and 12 show the pitch time history at the drivers location of the passive versus the semiactive suspension over a 3.81 and a 8.30 cm RMS roughness terrain. The vehicle speed was selected as the six-watt ride limiting speed for the passive configuration. As can be seen in the plots, the semiactive suspension control will reduce the pitch of the vehicle. More significant reductions can be seen with increasing terrain roughness. Similarly, Figures 13 and 14 show the heave time history over these same courses, and as in the pitch, heave can also be reduced. Table 1 is a consolidation of the RMS, max, and min of the pitch, heave and vertical acceleration signals for various roughness terrain. The maximum benefit for the semiactive suspension can be found in the RMS range up to 6 centimeters RMS. The average decrease in pitch motion over all terrain roughness is 16.2 percent. The vertical acceleration was decreased an average of 51.3 percent. Figure 15 shows a histogram of the vertical acceleration signal for 30.58 kph over a 3.81 cm RMS terrain. As shown in the histogram, the majority of the benefits of the semiactive suspension can be found in the reduction of the frequency of accelerations over 0.25 g's in the positive direction. It is believed that with further optimization of the semiactive algorithm, improvements should also be seen in the negative direction.

VEHICLE INSTALLATION - PHASE II

Phase II of the project is the fabrication and installation of the vehicle set on the Bradley test bed. One of the advantages of using an external in-arm suspension is the space savings by eliminating the torsion bars from crossing through the hull. Although on this project the space savings will not be utilized since this is a retrofit to an existing vehicle. The existing and new machined hull is shown in Figure 16. The retrofit of the new suspension requires road wheel relocation and the removal and relocation of support rollers, but otherwise the wheel travel or belly clearance is unaffected.

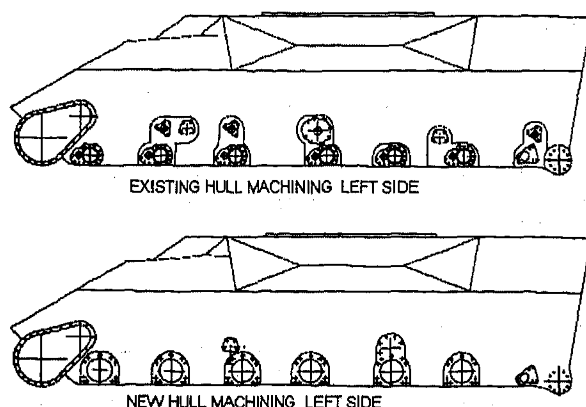

Figure 16. Vehicle Hull Modification

The installation requires plumbing the hydraulic and running the electrical cabling. The hydraulic power comes from a power take-off from the vehicle's engine. The hydraulic reservoir and pump will fit within the engine compartment. The controller resides in a 486 computer built in a rugged case and will mount in the crew compartment. On-board data acquisition is included for all accelerometers and potentiometers. Download links exist to download the data to other platforms.

PLANNED FIELD TESTING

Field testing is planned for the summer of 1997 and will consist of ride, shock, slalom and traverse testing against a passive Bradley Fighting Vehicle at the same weight. Information such as accelerations in the vertical, lateral, and fore-aft directions at different locations within the vehicle will be taken. Comparisons of six-watt ride limiting and shock speeds will be made. Pitch, heave, and roll movements will also be evaluated. Comparisons to the simulated vehicle is also planned.

CONCLUSIONS

Improvements in vehicle mobility can be gained with the use of semiactive suspension technology. This has been proven in both field tests and simulation results. The Bradley Fighting Vehicle has been shown to have superior mobility through the use of a semiactive suspension from both laboratory testing and simulation results. The use of these computer simulation codes make the technical evaluation of advanced suspension systems such as the semiactive suspension presented in this paper both a cost-effective and practical approach to exploring the Army's mobility needs. After initial computer evaluations, hardware should be built and evaluated if the simulation results show promising improvements. Prototype hardware mobility evaluations are still a necessary and prudent approach to long-term vehicle sub-system improvements.

The improvements in ride quality shown in this paper from both the laboratory testing and the computer simulation results are hoped to be duplicated in vehicle testing. Further publications are planned at the conclusion of the vehicle testing phase of this program.

Flow and Energy Pattern in Pyrotechnic Airbag Inflator-Canister System

ABSTRACT

The highly dynamic process in a pyrotechnic inflator and in a canister-airbag system was simulated by using two compressible gas thermal energy numerical models. First a 2-D model was used to simulate flow through the inflator porous media; then results from the first model were used as input to a second 2-D model to compute pressure, temperature and flow patterns in the airbag. Results show a complete picture of the dynamics of the airbag inflator - canister system during deployment.

INTRODUCTION

During airbag deployment hot gas under high pressure, produced by burning fuel in the center of the inflator, penetrates into the surrounding compound ceramic - metal porous media, exchanging heat with the matrix of the porous media, and exits the discharge holes positioned on the perimeter of the inflator. This process plays a significant role in the amount of thermal energy contained in the gas exiting from the inflator to the airbag, and thus affects the success of the deployment of the airbag. Two numerical models were used to simulate the fundamental transient thermal energy features of the inflator - canister - airbag system during deployment. The results from the two models reveal: (1) the thermal energy distribution among porous media, inflator wall and the gas, (2) the instantaneous pressure and temperature distributions in the ceramic - metal porous media, and (3) the temperature and pressure distributions and flow patterns in the canister and airbag. The aggressive nature of this highly dynamic process makes it technically difficult, if not impossible, to measure these data. Therefore, these numerical results, which are physically reasonable, and which satisfy fundamental principles of fluid mechanics and heat transfer, provide insight to the entire dynamic excitation and response.

In this paper, the fundamentals of the two models are first discussed, followed by an application to a passenger inflator-airbag system with some numerical results.

TWO DIMENSIONAL GAS THERMAL ENERGY MODEL IN THE POROUS MEDIA

BASIC EQUATIONS High temperature and pressure associated with gas generation and flow within the inflator is at a time scale of milliseconds in a spatial domain measured in centimeters. This process involves highly localized thermal non-equiliblium conditions between the gas and porous media. The conditions considered in the development of the equations of conservation of mass, momentum and energy are summarized as follows.

(1) A linear viscous loss term and a nonlinear inertial loss term have been added to the momentum equations.

(2) The heat exchange between porous media and gas follows a linear law, i.e., the heat transferred is directly media and the gas.

(3) Heat conduction of the gas is neglected in the energy equation, since a short transient process (order of 10^{-2} second) is considered in the present case.

(4) The porous media temperature is calculated by the first law of heat energy balance in the porous media only. Heat conduction in the porous media is neglected due to the same reason as stated in (3).

(5) The frame of the porous media is fixed, i.e., no deformation occurs during the transient process.

(6) There is no chemical reaction between the porous media and the gas. [Bachmat and Bear, 1986]

Under the above considerations a model for the 2-D transient compressible gas flow with heat transfer in porous media was derived by the control-volume method. The equations are summarized as follows, beginning with the energy equation, followed by the continuity, and x- and y-momentum equations:

$$L_0 = (u\frac{\partial p}{\partial x} + v\frac{\partial p}{\partial y} + \frac{\partial p}{\partial t}) - c^2(u\frac{\partial \rho}{\partial x} + v\frac{\partial \rho}{\partial y} + \frac{\partial \rho}{\partial t}) - (\kappa - 1)[\rho Q + \frac{\rho g}{K}\beta(u^2+v^2) + \rho R_{pm}\beta^2(u^2+v^2)^{\frac{3}{2}}] = 0 \quad (1)$$

$$L_1 = (u\frac{\partial \rho}{\partial x} + v\frac{\partial \rho}{\partial y} + \frac{\partial \rho}{\partial t}) + \rho(\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y}) = 0 \quad (2)$$

$$L_2 = (u\frac{\partial u}{\partial x} + v\frac{\partial u}{\partial y} + \frac{\partial u}{\partial t}) + \frac{1}{\rho}\frac{\partial p}{\partial x} + \frac{g}{K}\beta u + R_{pm}\beta^2 u\sqrt{u^2+v^2} = 0 \quad (3)$$

$$L_3 = (u\frac{\partial v}{\partial x} + v\frac{\partial v}{\partial y} + \frac{\partial v}{\partial t}) + \frac{1}{\rho}\frac{\partial p}{\partial y} + \frac{g}{K}\beta v + R_{pm}\beta^2 v\sqrt{u^2+v^2} = 0 \quad (4)$$

The set of equations is completed by including the equality (Wang and Wylie, 1995)

$$L_4 = \frac{\partial u}{\partial y} + \frac{\partial v}{\partial x} - (\frac{\partial u}{\partial y} + \frac{\partial v}{\partial x}) = 0 \quad (5)$$

in which p is the pore-volume averaged pressure, u, v are the area-averaged pore velocities(in x-direction and y-direction), K and R_{pm} are the hydraulic conductivity and non-linear resistance coefficient of the porous media, respectively, ρ is density of the gas, c is the isentropic wave speed in the gas, κ is the specific heat ratio, Q is the heat exchange rate, and β is the ratio of pore cross-sectional area to total cross-sectional area.

In addition to the conservation laws a relationship is needed to describe the heat transfer between the gas in the pores and the porous media. The porous media is a heat sink (or source) during the dynamic flow process. The amount of heat exchanged per unit mass and unit time is

$$Q = -\frac{1}{\eta}\frac{K_{ex}a_{sv}}{\rho}(T_g - T_{pm}) \quad (6)$$

in which K_{ex} is the convective heat transfer coefficient between the gas and porous media, heat/(unit area-s-degree), [Wakao and Kaguei, 1982], a_{sv} is the specific surface area of the porous media particles, area/unit volume, [Dullien, 1979, Wakao and Kaguei, 1982], η is the porosity of the porous media, and T_g and T_{pm} are the gas and solid material temperatures, respectively.

At an instant, in a control volume of gas and porous media matrix, δx by δy by unit depth, the time rate of increase of thermal energy in the porous media is just equal to the heat transferred from the gas to the porous media. This neglects heat conduction in the porous media during short transient flows.

$$(1-\eta)\rho_{pm}C_{ppm}\frac{\partial T_{pm}}{\partial t} = K_{ex}a_{sv}(T_g - T_{pm}) \quad (7)$$

The density and specific heat of the porous media are given by ρ_{pm} and C_{ppm}, respectively.

The literature provides relationships to assist in the evaluation of the various coefficients, K, R_{pm}, K_{ex} and a_{sv} in Eqs. (1) to (7) [Ergun, 1952, Sozen and Vafai, 1990].

$$K = \frac{\rho g K_g}{\mu_g} \quad (8)$$

$$R_{pm} = \frac{F\eta}{{K_g}^{1/2}} \quad (9)$$

$$K_g = \frac{\eta^3 d_p^2}{150(1-\eta)^2} \quad (10)$$

$$F = \frac{1.75}{\sqrt{150}\eta^{3/2}} \quad (11)$$

$$K_{ex} = 1.064C_{pg}\rho U(\frac{\mu_g C_{pg}}{k_g})^{-2/3}(\frac{\rho U d_p}{\mu_g})^{-0.41} \quad (12)$$

$$a_{sv} = \frac{6(1-\eta)}{d_p} \quad (13)$$

in which μ_g is the absolute viscosity of the gas, K_g is the permeability of porous media, F is a geometric factor, d_p is the diameter of the equivalent particle of the porous media, U is the total velocity of the gas flow, C_{pg} is the specific heat of the gas, and k_g is the thermal conductivity of the gas. According to Sozen and Vafai, 1990, the heat transfer coefficient in Eq. (12) is valid for Reynolds number, $\frac{\rho U d_p}{\mu_g}$, greater than 350.

Equations (1) to (5), with the substitution of Eq. (6), describe the dynamic gas flow and gas thermal energy response in the porous media matrix. Equation (7) describes the heat exchange between the gas and porous media matrix. They are solved with the characteristics-like method, while Eq. (7), which describes the heat exchange between the gas and porous media matrix, is solved with a finite-difference method. (Wylie and Streeter, 1993), using linear multipliers λ_1, λ_2, λ_3, and λ_4, is carried out in the following manner, $L_0 + \lambda_1 L_1 + \lambda_2 L_2 + \lambda_3 L_3 + \lambda_4 L_4 = 0$, which leads to a set of ordinary differential equations.

With a square computational grid $\Delta x = \Delta y$, and selected time step, Δt, integration of the compatibility equations along the path lines leads to the following set of equations.

$$A_{p1}p_P - c_E^2\rho_P = e_E \quad (14)$$
$$A_{p1}p_P + A_1 u_P + A_1 v_P - q_P\rho c^2\Delta t = e_1 \quad (15)$$
$$A_{p1}p_P + B_1 u_P - B_1 v_P + q_P\rho c^2\Delta t = e_2 \quad (16)$$
$$A_{p1}p_P - C_1 u_P - C_1 v_P - q_P\rho c^2\Delta t = e_3 \quad (17)$$
$$A_{p1}p_P - D_1 u_P + D_1 v_P + q_P\rho c^2\Delta t = e_4 \quad (18)$$

in which $q = \frac{1}{2}\left(\frac{\partial u}{\partial y} + \frac{\partial v}{\partial x}\right)$, and c assumes the local average value. The terms on the right side, e_E, e_1 to e_4, are determined by a bi-interpolation method based on the known values at points A', B', C', and D', Fig. 1. The parameters A_{p1}, A_1, B_1, C_1 and D_1 are a collection of variables. The simultaneous solution of Eqs. (14) to (17) provides variables p_P, u_P, v_P, q_P and ρ_P at each interior point. In order to save computer time and to avoid specification of conditions at singular points, the staggered grid, Fig. 1, is used in the model to discretize the computational domain (Wang and Wylie, 1995).

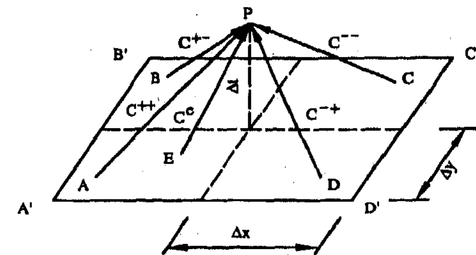

Fig. 1 Path lines in x-y-t space

Boundary Conditions for Gas Flow Computation, and Interface with Porous Media At each boundary, two of the four compatibility equations, Eqs. (15) to (18), are used together with the specified conditions of pressure and/or flow. Additionally, if there is flow out of the domain, Eq. (14) must be used, or if there is inflow, temperature (or a relationship for temperature) must be specified. Three types of boundary conditions which were used in this study are described.

Impermeable Boundary In this condition $q_P = 0$, and $u_P = 0$ at the right and left sides and $v_P = 0$ at the lower and upper limits. A local energy equilibrium condition is used here. This condition is approximated at an instant assuming that the conducted thermal energy flux at the computational node adjacent and interior to the boundary node is equal to the heat flux at the boundary. In numerical form this is

$$A_{P-2} q_{h_{P-2}} = A_P q_{h_P} \tag{19}$$

in which A_{P-2} and A_P are the areas through which heat flows at the node $2\Delta x$ interior to the boundary, and at the node on the boundary, respectively. $q_{h_{P-2}}$ is the unit heat flux through area A_{P-2}, ($q_{h_{P-2}} = -k_g \frac{\partial T_g}{\partial x}$, where k_g is the thermal conductivity of the gas). q_{h_P} is the heat flux at the wall ($q_{h_P} = A_P K_w (T_g - T_w)$, where K_w is the heat transfer coefficient between gas and wall, and T_w is the wall temperature). It is assumed that the thermal energy convected by the gas is small next to a solid wall. This is likely reasonable since the velocity normal to an impermeable wall must be small. With these definitions Eq. (19) becomes

$$A_{P-2} k_g \left(\frac{T_{g_{P-2}} - T_{g_P}}{2\Delta x}\right) = A_P K_w (T_{g_P} - T_w) \tag{20}$$

Specified Pressure and Temperature Boundary $p(t)$, $T_g(t)$ A left boundary position is used as an example of this type of boundary. The equation of state, $p_P = \rho_P R T_{gP}$, and Eqs. (17) and (18) are used to relate the horizontal velocity to pressure and temperature. It is also assumed that $v_P = 0$, and $q_P = 0$ at the left boundary.

Orifice Boundary The orifice equation

$$u_P = C_d \frac{A_h}{2\Delta y} \sqrt{\frac{2(p_P - p_0)}{\rho_P}} \tag{22}$$

is used together with three compatibility equations, $q_P = 0$, and $v_P = 0$ for a right boundary. A_h is the cross sectional area of the orifice and Δy is the grid spacing.

Equation (7) is discretized by an implicit scheme.

$$T_{pm_P}^{n+1} = \Big[\Delta t K_{ex} a_{sv} (T_{gP}^{n+1} + T_{gP}^{n-1}) + \big[(1-\eta)\rho_{pm} C_{ppm} - \Delta t K_{ex} a_{sv}\big] T_{pm_P}^{n-1}\Big] \Big/ \big[(1-\eta)\rho_{pm} C_{ppm} + \Delta t K_{ex} a_{sv}\big] \tag{23}$$

TWO DIMENSIONAL TRANSIENT COMPRESSIBLE GAS THERMAL ENERGY MODEL IN GAS DOMAIN

The time-varying thermal energy model includes the unsteady conservation laws of mass, momentum and energy. The governing equations are derived under certain fundamental assumptions.

(1) The compressible gas is considered non-viscous. The process is highly transient with high pressure, temperature and velocity changes, therefore, the viscous dissipation of momentum and energy is relatively small with respect to other energy components, and may

(2) A heat source or sink may or may not exist inside the the domain. The heat exchange could occur between gas and solid boundary, e.g., between gas and tank wall or between gas and canister wall, where a local energy equilibrium condition would be applied to supply a boundary condition.

(3) Heat conduction of the gas is neglected in the energy equation since the transient process is extremely rapid.

After some manipulation, and introduction of the isentropic wave speed, $c^2 = \kappa p/\rho$, the basic equations, ready for numerical transformation, are summarized as follows (Wylie and Wang, 1996).

$$L_0 = (u\frac{\partial p}{\partial x} + v\frac{\partial p}{\partial y} + \frac{\partial p}{\partial t}) - c^2(u\frac{\partial \rho}{\partial x} + v\frac{\partial \rho}{\partial y} + \frac{\partial \rho}{\partial t}) - (\kappa - 1)\rho Q = 0 \tag{24}$$

$$L_1 = (u\frac{\partial \rho}{\partial x} + v\frac{\partial \rho}{\partial y} + \frac{\partial \rho}{\partial t}) + \rho(\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y}) = 0 \tag{25}$$

$$L_2 = (u\frac{\partial u}{\partial x} + v\frac{\partial u}{\partial y} + \frac{\partial u}{\partial t}) + \frac{1}{\rho}\frac{\partial p}{\partial x} = 0 \tag{26}$$

$$L_3 = (u\frac{\partial v}{\partial x} + v\frac{\partial v}{\partial y} + \frac{\partial v}{\partial t}) + \frac{1}{\rho}\frac{\partial p}{\partial y} = 0 \tag{27}$$

in which p, u, v are the pressure and velocities(in x-direction and y-direction), respectively. The other symbols have the same meaning as in the first model. Equation (5) completes the set for tranformation in the characteristics - like method. A square grid, Fig. 1, is used and, as in the first model, integration of the transformed equations leads to the numerical model.

Prior to integration of the compatibility equations c was replaced by $\sqrt{\kappa p/\rho}$. This modification was found to be necessary to achieve better accuracy in thermodynamically controlled problems. Integration of the modified compatibility equations along the path lines leads to the following set of equations.

$$\ln\ p_P - \kappa \ln\ \rho_P = e_E \tag{28}$$

$$\ln\ p_P + \frac{\kappa}{c}u_P + \frac{\kappa}{c}v_P - q_P \kappa \Delta t = e_1 \tag{29}$$

$$\ln\ p_P + \frac{\kappa}{c}u_P - \frac{\kappa}{c}v_P + q_P \kappa \Delta t = e_2 \tag{30}$$

$$\ln\ p_P - \frac{\kappa}{c}u_P - \frac{\kappa}{c}v_P - q_P \kappa \Delta t = e_3 \tag{31}$$

$$\ln\ p_P - \frac{\kappa}{c}u_P + \frac{\kappa}{c}v_P + q_P \kappa \Delta t = e_4 \tag{32}$$

in which c assumes the local average value. The terms e_E, e_1, e_2, e_3, and e_4 are determined by the same way as those in the first model.

The treatment of boundary conditions is the same as that in the first model. An additional type of boundary, i.e., specified mass flow rate and temperature boundary $\dot{m}(t)$, $T_P(t)$, is described here. A left boundary position is used as an example of this type of boundary.

$$u_P = \frac{\dot{m}}{\rho_P A} = \frac{\dot{m} R T_{gP}}{p_P A} \tag{33}$$

The equation of state, $p_P = \rho_P R T_{gP}$, and Eqs. (31), (32) and (33) are used to relate the horizontal velocity to pressure and temperature. A is the area covered by each input point, and $\dot{m}$ is mass flow rate.

APPLICATION

The two models were applied to a typical inflator canster airbag system. The transient compressible gas thermal energy model through the porous media was first applied to the inflator with the measured pressure-time history and an estimated temperature-time history as the input data. The transient compressible gas thermal energy model in gaseous domain was then applied to the canister - airbag system using the mass flow rate and temperature time histories obtained from the computations carried out first in the inflator porous media. The operating environmental temperature in his modeling was 21.6 °C. The modeling processes and the esults are described separately in following subsections.

MODELING OF THERMAL - DYNAMIC PROCESS N INFLATOR The computational domain, which represents one quarter of a section through the inflator metal creen, is shown in Fig. 2. The spatial step was Δx = .0335 cm. The actual discharge holes were represented by hree slots, 30.48 cm long and 0.02205 cm wide. The total rea of the slots was equal to the total area of the discharge oles. The thermal conductivity and specific heat of the gas vere 0.0238 J/m-s-°K, 715.4 J/kg-°K; the specific heat and he density of the porous media were 474.4 J/kg-°K and 659.3 kg/m^3; the thermal conductivity, specific heat, and he density of the inflator wall were 220.9 J/m-s-°K, 897.3 /kg-°K, and 2720.0 kg/m^3; the porosity, η, of the porous nedia was 0.7287, and $\beta = \eta$. The hydraulic conductivy and non-linear resistance coefficient of the porous media vere estimated with the relations stated earlier, K = 0.32 n/s, R_{ms} = 1427.2 1/m.

The input boundary conditions were pressure and temerature at the fuel interface and are shown in Figs. 3a nd 3b. The boundary condition at the inflator wall was a o-flow condition, and a local heat energy equlibrium condiion was used here, except for the gas-flow holes. An orifice ormulae, with the 'choke' condition employed, was used at ach discharge hole.

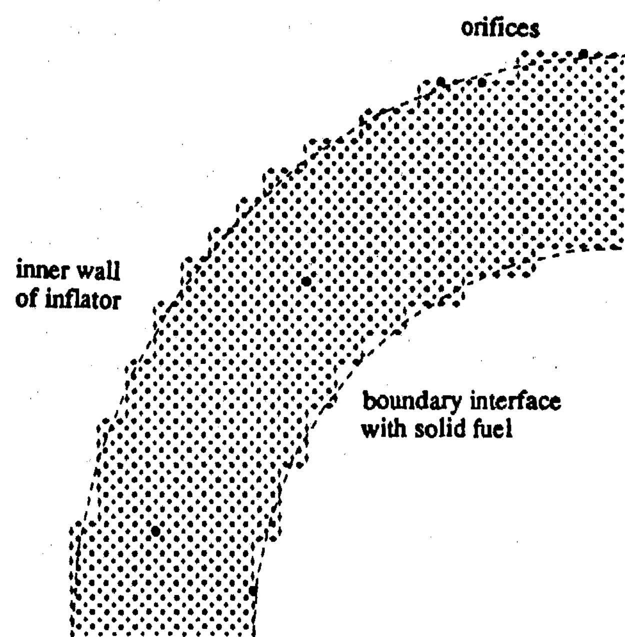

Fig. 2 Computational mesh in the porous metal screen

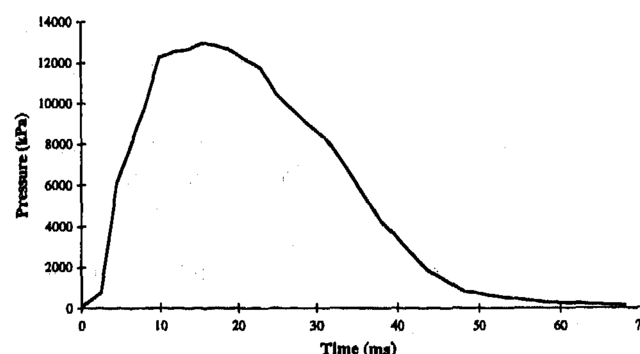

Fig. 3a Input pressure for 2-D porous model

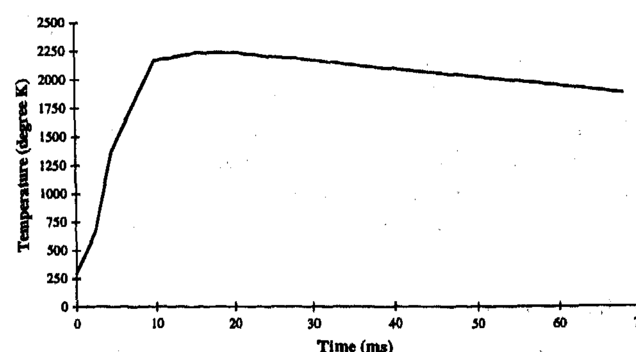

Fig. 3b Input temperature for 2-D porous model

Extensive computations were carried out to calibrate the heat transfer coefficients, K_{ex}, K_w, by using the data available. The values of K_{ex} and K_w were found as $K_{ex} = 7.653 \cdot (10)^6$ J/m^2-s-°K, $K_w = 1.526$ J/m^2-s-°K. These values were used for the final computation.

Graphic displays of the pressure contours, temperature contours, and flow pattern at 13 ms are shown in Figs. 4-6. The flow pattern is represented by the mass velocity, through the discharging holes, conservation of total mass (at the input and exiting through the discharge holes), the time histories of pressure at the input and the discharge holes, the time histories of the temperature of the gas and metal screen at the input and at the discharging holes, and lastly the time histories of total input thermal energy, the energy stored in metal screen, the energy going out with gas and the energy stored in the gas contained in metal screen, are shown in Fig. 7 to 11.

MODELING OF THERMAL - DYNAMIC PROCESS IN CANISTER - AIRBAG The semiaxes dimensions of the ellipse-shaped computational domain were 53.95 and 35.81 cm yielding a volume of the domain equal to the volume of the inflated airbag, 185 liters. The spatial step was Δx = 0.3173 cm. An actual vent hole of 5.08 cm in diameter was represented by two slots, 30.48 cm long and 0.3222 cm wide each. The total area of the slots was equal to the total area of the vent hole. The thermal conductivity and specific heat of the gas were 0.0238 J/m-s-°K, 715.4 J/kg-°K, and the heat exchange coefficient K_w at the canister and inflator walls was 0.171 J/m^2-s-°K.

The input boundary conditions were mass flow rate and temperature, which were obtained from the modeling of the thermal - dynamic process in inflator. They are shown in Fig. 7 by a dashed line and in Fig. 10 by a short dashed line indicated by 'at exit hole (gas)'. The boundary condition at the inflator wall is a no-flow condition, and a local heat energy equlibrium condition was used here, except for the gas-flow holes. An orifice formulae, with the 'choke' condition employed, was used at vent hole.

Two cases are presented, the first has no heat exchange between gas and solid walls, and the second includes heat exchange. The results for the case of no-heat exchange between gas and solid walls, $K_w = 0.0$, are shown in Figs. 12 to 16. Figure 15 provides a time history of the mass balance by showing the accumulated mass inflow at each instant, the instantaneous stored mass, the accumulated mass outflow, and the sum of the latter two. Figure 16 provides a similar time history of the energy at each instant. The results for the case with heat exchange between gas and solid canister and inflator walls show similar behavior as those in the case with no heat exchange. Only the pressure and temperature contours are shown in Figs. 17 and 18. Comparisons between the two cases are presented in Figs. 19 and 20.

CONCLUSIONS

The results from the two models show a complete picture of the dynamics of the compressible flow and thermal energy distribution of the airbag inflator-canister system during the deployment. Overall mass and energy balances are achieved in the whole system, which adds credibility and some substantiation to the numerical results.

Several important implications may be drawn from the results.

(1) The gas density change during this highly transient event plays a significant role in the overall response. Most of the gas passes directly to the discharge holes of the inflator, however, as much as holes merely packs up the void space during the early stages of the fuel burn. This is while the pressure is high and the matrix temperature is still low. Following the peak pressure, and as the temperature of the metal matrix rises the density of the gas drops and the gas exits the inflator.

(2) Two thirds of the thermal energy released from the burning fuel is absorbed by the metal screen during the first 60 - 80 ms period. This amount is the major source of thermal energy responsible for the temperature response on the outer wall of the inflator in the 200 seconds after the deployment.

(3) The pressure drop in much of the region of the metal screen is very small, about 1.0% of peak pressure, and the biggest pressure drop occurs near the discharge holes of the inflator. Even in that vicinity the drop is only about 5% of peak pressure. This suggests that the pressure measured through the tube connecting to the inflator wall may be a reasonable representation of the actual pressure produced by the burning fuel.

(4) There is a large temperature gradient across the porous metal, with the exit gas temperature less than one third of the temperature produced by the burning fuel ($\sim$ 537 °C at 22 ms). The gradient is the largest near the fuel-porous metal interface. This reflects the transient nature of the process and indicates most of the thermal energy absorbed is stored in the inner part of the porous metal screen.

(5) The pressure and temperature are almost uniformly distributed in the airbag at any instant. A big drop in pressure and temperature occurs in a very small region next to the vent hole due to the high discharge velocity.

(6) The maximum pressure is about 69 kPa in the bag and 52 kPa at the vent hole in the non-heat-exchange case, and about 67 kPa in the bag and 51 kPa at the vent hole in the heat exchange case. The pressures are higher than might be expected inasmuch as gas leakage through the bag wall fabric and the canister was not included, nor was any energy consumed in expanding the airbag. The maximum temperature is about 374 °C in the bag and 339 °C at the vent hole in the no-heat-exchange case, and about 357 °C in the bag and 328 °C at the vent hole in heat-exchange case. The amount of heat absorbed by the canister and inflator wall from the hot gas during the deployment is less than 3 kJ, which may raise the temperature of the canister wall about 3 °C.

(7) The obvious temperature gradient along the canister wall, shown in the temperature contour plot, in the case

of having heat exchange, compared with the temperature contour in the case of no heat exchange, indicates the effect of the heat transfer between gas and canister and infaltor wall.

Cavitation During Head Impact

ABSTRACT

The effects of stress in brain material was investigated with experimental and computational idealizations of the head. A water-filled cylinder impacted by a free traveling mass serves to give insight into what could happen to the brain during impact. Under an impact of sufficient velocity, cavitation can occur on the cylinder boundary opposite impact. Limited internal vaporization of the fluid may also occur during severe impact events. Cavitation occurred in these experiments at accelerations greater than 150 g's. Head forms of different sizing will experience an acceleration magnitude inversely proportional to the size difference to produce a similar pressure/cavitation response.

INTRODUCTION

The effect of stress in the brain as a mechanism of injury is rarely considered in head impacts, even though there have been some experimental studies indicating fluid vaporization (cavitation) through pressure limiting effects. These effects have been observed in impact tests using repressurized human cadavers and live anesthetized primates, where negative gage pressures of less than one atmosphere have not been observed unless skull fracture occurred [1, 2, 3]. Despite the possible fluid vaporization and no observed injury, the authors hypothesized that fluid vaporization limited the gage pressure to a negative one atmosphere. The theory was that the cavitation occurred either in the cerebral spinal fluid or between the dura and the skull, and was not significant enough to cause injury as geometric attenuation effectively reduces the force of cavity collapse.

To study this hypothesis, an experimental and numerical analysis of a simple model of the human head under impact was used [4, 5]. A water filled 14-cm diameter cylinder was struck by a 10-kg free-flying mass. Rigid-body acceleration-time-histories and the pressure at the fluid-cylinder interface were monitored during impact. Comparisons between the experimental results and the results of a two-dimensional computational model were made.

As a result of this work, the following view of head impact was developed: when the head receives a blow and a positive pressure develops under the point of impact, a small cavity, opposite the impact, can form between the skull and the dura. Vaporization limits the maximum pressure drop in the head to vapor pressure. Since the brain is nearly incompressible, the small amount of volume needed to create the cavity is accomplished by either pushing a very small amount of material down the foramen magnum or by skull deformation.

This leads to the following possibility for a negative gage pressure-limiting impact phenomena that could occur at the skull-dura interface. During severe impact to the human head, a greater tension would develop between the cerebral spinal fluid and the dura, than between the dura and the skull. The dura would then move with the brain cerebral spinal fluid. As the dura moves away from the skull, a small cavity (of thickness less than 10^{-5}m) could form representing a slight stretching between the skull and the dura of the periosteum. Although it may be possible that enough surface tension could develop between the skull and dura for a cavity to form on either side of the dura, this does not seem as likely as the above suggested mechanism. Therefore, it is this motion of the dura as coupled with the small fluid flow through the foramen magnum that can have a significant effect on the pressure response of the brain during impact. If the impact is severe enough, it may be possible to produce fluid vaporization and the associated violent cavity collapse. This violent cavity collapse, which could be a mechanism of injury, is strongly modified by the dura motion minimizing the amount of damage that could occur.

*This paper was previously published in part at the 1996 AGARD Conference.

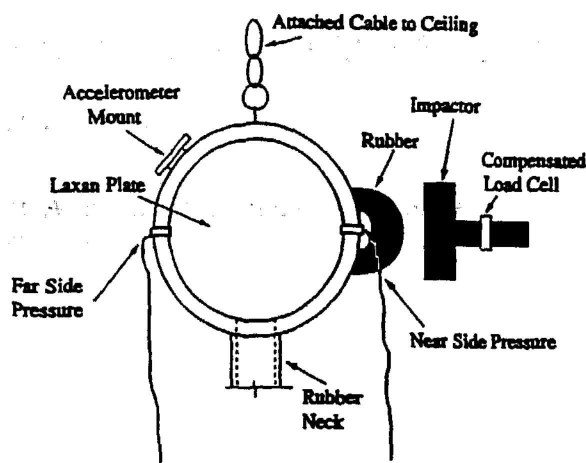

Figure 1: Experimental setup.

Recently, a follow up study indicated that under complex loading conditions, cavitation could occur in the brain material – not just at the boundary [6]. It was found that if the head underwent pre-impact acceleration immediately before the head strike, a vaporous region could form in the brain material and internal cavitation was likely. As a result, it was postulated that, in a vehicle environment, head impact could generate internal cavitation. Seeking further understanding, the same simplistic physical model of the head is used in this current study. In addition to cavities forming at the skull-dura boundary cavities in the brain material are addressed, with implications of potential cellular tissue damage. No attempt is made to model the anatomical structures of the head, the skull-dura boundary, the complex geometry of the head, head impact response, skull deformation, head angular motion, or brain shear. Instead, a simple physical model is used to generate test data. These data are modeled by a numerical simulator to gain insight into cavitation and into the general effect of pre-stressing, such as neck loading, on pressures in the brain material.

PHYSICAL MODEL

The physical model used is briefly outlined herein; it has been discussed in more detail in earlier papers [3, 4, 5, 6]. The simplified mechanical head form consisted of two parts: an internally polished aluminum cylinder and a rubber neck attached to the base of the cylinder, Figure 1. The cylinder was closed at each end with flat plates of 1.3 cm thick plexiglass, and for most of the tests, the plexiglass was reinforced with aluminum channel. To complete the head form the cylinder was connected by a rigid joint to a flexible viscoelastic rubber neck structure; fluid flow between the cylinder and the neck was through a two-centimeter diameter hole at the head neck interface. A nine-accelerometer array, used to measure three-dimensional motion (six degrees of freedom), was rigidly affixed to the aluminum cylinder and pressure transducers monitored the interface of the fluid and the cylinder.

The fluid tap water used to fill the system was boiled for several hours and allowed to return to room temperature. Before filling the cylinder with the fluid the air in the cylinder was evacuated and a partial vacuum was maintained. The vacuum was used to draw the fluid through a valve into the neck, then through the hole in the base of the cylinder. A vacuum was maintained until the cylinder was filled and no visible cavities or vacant spaces could be observed. Before each test series the mechanical head form was impacted several times and inspected to ensure that no air or cavities were visible in the cylinder.

The impact was delivered through the center of mass of the cylinder by a 10 kg free-traveling mass fitted with an inertial-compensated load cell assembly. The impacting surface consisted of a flat rigid 5-cm diameter disk [1, 2, 3]. To bring the contact force time-history closer to that of a head impact, a neoprene rubber hemisphere was fixed to the cylinder so that loading impact to the cylinder came through the neoprene hemisphere. The impact mass velocity was measured by timing the pulses from a magnetic probe which sensed the motion of targets in the mass.

COMPUTATIONAL MODEL

Two finite difference models were used to simulate the impact response of the fluid-filled cylinder, a continuum model and a discontinuous or discrete model. For both models it was assumed that boiling the tap water removed the free gas. Therefore, even though tap water had a significant number of nucleation sites to allow for fluid vaporization in the impacted cylinder and plastic neck, there was no free gas in the water. It was also assumed that even though there was no visible air in the physical model, it was impossible to remove all of the air at the boundaries of the water and the cylinder walls. The air at these boundaries was modeled as a continuous thin layer less than 10^{-6}m thick. Finally, it was assumed that the flow velocities through the neck were proportional to the force acting on the fluid in the neck.

CONTINUUM MODEL. The continuum model is based upon the two-dimensional unsteady equations of motion and continuity in a compressible fluid continuum. The procedure is based upon Henke's method [7] that was applied to fluids by Wylie [8, 9]. The linearized version of the more general compressible flow equations that describe pressure waves in a two-dimensional continuum provide the most simple case to develop the method. A combination of equations for the conservation of mass and momentum in the longitudinal and lateral directions are linearized into a set of four characteristic-like equations. The numerical procedure is developed by integrating these equations along paths in space and time, Figure 2. In this linearized model with constant isentropic wavespeed, $\Delta x = \Delta y$ in the computational grid.

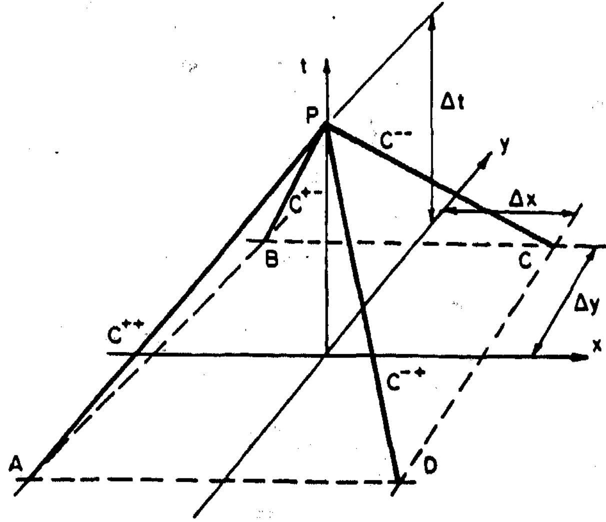

Figure 2: Staggered grid for continuum model.

The following set of equations result:

$$\frac{p_P}{\rho c} + u_P + v_P - q_P \Delta x = e_1 \quad (1)$$

$$\frac{p_P}{\rho c} + u_P - v_P + q_P \Delta x = e_2 \quad (2)$$

$$\frac{p_P}{\rho c} - u_P - v_P - q_P \Delta x = e_3 \quad (3)$$

$$\frac{p_P}{\rho c} - u_P + v_P + q_P \Delta x = e_4 \quad (4)$$

in which

$$e_1 = \frac{p_A}{\rho c} + u_A + v_A + q_A \Delta x \quad (5)$$

$$e_2 = \frac{p_B}{\rho c} + u_B - v_B - q_B \Delta x \quad (6)$$

$$e_3 = \frac{p_C}{\rho c} - u_C - v_C + q_C \Delta x \quad (7)$$

$$e_4 = \frac{p_D}{\rho c} - u_D + v_D - q_D \Delta x \quad (8)$$

where for point P, p_P is the absolute pressure, u_P is the x-direction velocity, v_P is the y-direction velocity, and $q_P = (\frac{\partial u}{\partial y} + \frac{\partial v}{\partial x})/2$. Equations 1 through 4 are applied along lines C^{++}, C^{+-}, C^{-+}, and C^{--}, respectively, Figure 2. This two-dimensional spatial grid in the $x - y$ plane with time represented in the third dimension was used to simulate the plexiglass cylinder. Handling of the vaporization-free gas at the water-cylinder (or skull-dura) interface requires special consideration.

At the cylinder's perimeter the pressure drop is limited to vapor pressure as pressures below this are not physically possible. Under these conditions, in the absence of free gas, the fluid is assumed to vaporize, the pressure is fixed to vapor pressure, and a cavity is permitted to develop. The cavity grows while the liquid moves away form the boundary, and collapses as the liquid moves back to the boundary. In the model a small amount of air is assumed to exist at the wall and isothermal expansion and compression of the gas layer is assumed. The ideal gas law is used to relate the cavity volume to pressure. The gas law may be written as

$$V_{air} = \frac{C_4}{p_p - p_v} \quad (9)$$

where V_{air} is the volume of free gas at any boundary node; p_p is the absolute pressure at that node; p_v is the vapor pressure of water; and C_4 is the product of the gas constant, absolute temperature, and the mass of free gas at the node. The volume of air per unit depth at each boundary node is equal to the air thickness multiplied by two distance intervals.

A boundary condition is used at the neck node to model the effect of the rubber neck on the dynamic response of the cylinder. With a relatively low wave speed in the rubber neck, it was assumed that the neck was long enough so that the far end condition did not influence the dynamic response at the cylinder-neck connection. This meant that the neck acted like an infinitely long tube. The additional equation necessary to interact with the C^{-+} and C^{--} equations was provided by the following one-dimensional compatibility equation for the neck

$$p_P = p_i - \rho\, c_i\, (v_P - v_i) \quad (10)$$

In equation 10 $p_i = 1$ atmosphere (absolute), $v_i = 0$, and c_i is the wave speed in the rubber neck. The variable q_P was set to zero, enabling a solution for the variables p_P, u_P, and v_P at each computational time step. Figure 3 illustrates a square grid of latticework elements. The compatibility equations used in the method of characteristics, without friction produce the following equations for point P in Figure 3.

DISCONTINUOUS MODEL. Because the first method of modeling requires a continuum it can be used to estimate cavitation only at the boundaries but not inside the fluid. This is a result of the discontinuity caused by the cavities formed inside the fluid media. To address this problem a second method is used. A description of this method and its equivalence to the first method are found in [9, 10]. A brief description of this approach as it relates to the cylinder follows.

The numerical procedure to analyze two-dimensional transients is essentially the same as in one-dimensional problems. At internal nodes, or line element intersection points, a common pressure is assumed at each instant and the mass conservation law must be satisfied. A scaling relationship is needed between the acoustic wavespeed, a, in the line element and the acoustic velocity, c, in the two-dimensional domain [9].

$$a = \sqrt{2}c \quad (11)$$

$$p_P = p_A - a\rho(u_2 - u_1) \quad (12)$$

$$p_P = p_B - a\rho(v_2 - v_1) \quad (13)$$

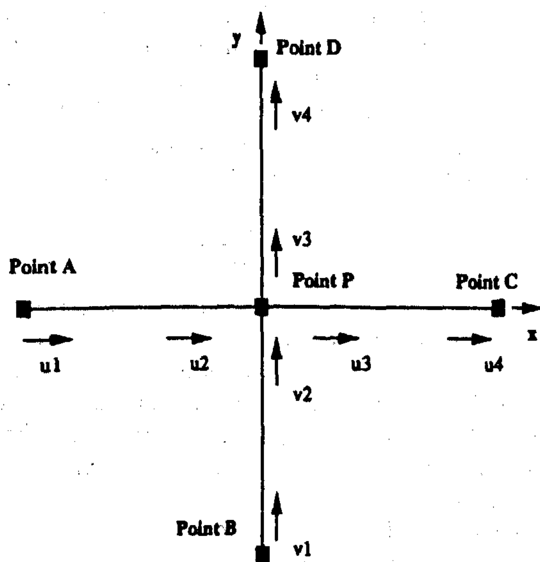

Figure 3: Latticework elements and velocities for discrete model.

$$p_P = p_C + a\rho(u_3 - u_4) \tag{14}$$

$$p_P = p_D + a\rho(v_3 - v_4) \tag{15}$$

where g is gravity, p_P is the pressure at point P, u_1 is the horizontal velocity just to the right of point A, v_2 is the vertical velocity just below point P, etc. Conservation of mass at any instant provides the fifth equation to solve for the five variables $(p_P, u_2, u_3, v_2, v_3)$.

With the second model, when low pressures develop in a region of the domain, one of two procedures is used depending on whether computation is at a boundary or an interior point. At an interior point, the minimum allowable pressure is vapor pressure, and the liquid vaporizes to form a vapor cavity which grows and collapses in response to the fluid dynamics. When the transient would have the pressure drop below vapor pressure, the pressure is set to vapor pressure, and the four velocities at the node, Figure 3, are computed. A time-dependent cavity volume per unit depth, V_V is then calculated from continuity

$$\frac{dV_V}{dt} = (v_{out} - v_{in})\Delta x \tag{16}$$

in which v_{in} is the net velocity to the left or below the volume, and v_{out} is the net velocity to the right or above the cavity. The size of the cavity at each point grows and collapses in response to the dynamic behavior. At the boundary, the procedure is the same as at the boundary in the first method, that is, isothermal expansion and compression of the gas layer is assumed.

RESULTS FROM EXPERIMENTAL AND CONTINUUM MODELS

The parameters used in the model were those of water under standard conditions. The density of water, ρ, was 1000 kg/m^3, the Bulk Modulus was 2.05 GPa; the wave speed, c, was 1435 m/s; the step distance interval, Δx, was 0.00318 m; and the time step, Δt, was $2.22(10^{-6})$ sec. Vapor pressure was set at 4550 Pa (absolute). The acceleration recorded from the physical model was input to the computer model to generate pressure-time histories at various points in the cylinder. As mentioned before, determined efforts were made to remove all of the air from the physical model, however, it is likely that a microscopic layer existed at the fluid/cylinder boundary. Therefore, on the perimeter an initial thickness of air of 10^{-6}m was used to model this effect.

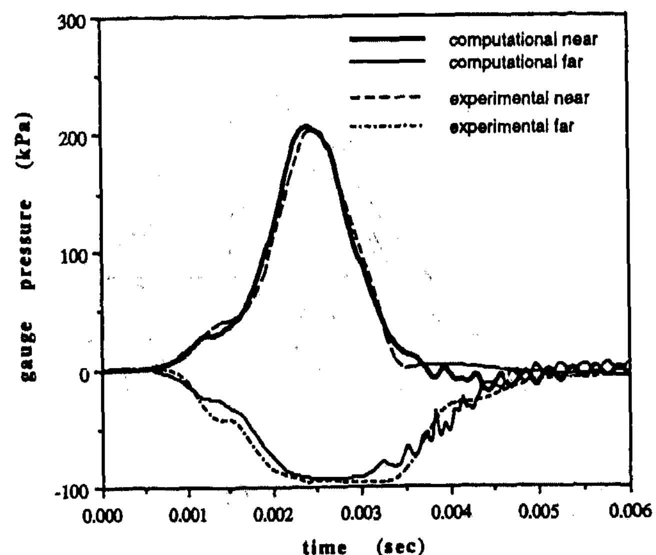

Figure 4: Low acceleration pressure response.

The initial conditions for the model were set such that there was no velocity in the cylinder and the pressure everywhere was atmospheric. The right and left boundaries were then accelerated according to a digitized acceleration from a specific experimental run. Two runs are evaluated here, a low acceleration (5 m/s impact velocity) and a high acceleration (8 m/s impact velocity). Both are analyzed in the model with vaporization at the boundary. The points presented for comparison are the near side and the far side pressure-time histories of the extreme left and extreme right boundaries.

LOW ACCELERATION (5 M/S IMPACT VELOCITY). An impact test was considered appropriate for this study if: 1) the impact velocity was within 0.1 m/s of 5 m/s; 2) no visible air could be seen in the cylinder before and after impact; and 3) the peak angular accelerations during impact were less than 100 rad/s^2. In the set of impact tests that met the above requirements the angular and linear accelerations and velocities were similar and reasonably close to that of a rigid body. Peak linear accelerations were within 5 percent of 190 g's and there was less than 0.01 rad of rotation. Therefore, for this set of tests it was assumed that: the motion of the cylinder was one-dimensional, the acceleration of each point on the alu-

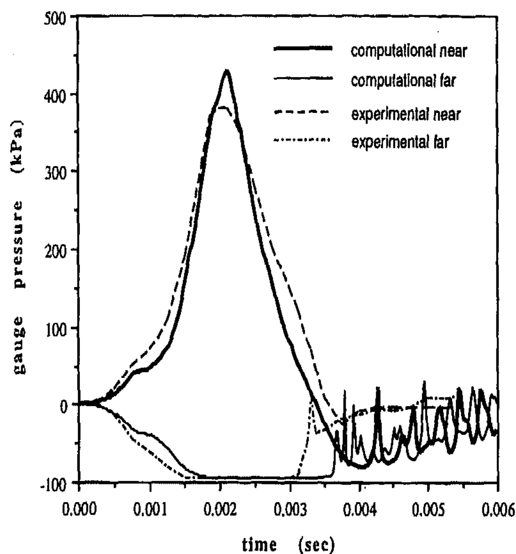

Figure 5: High acceleration pressure response.

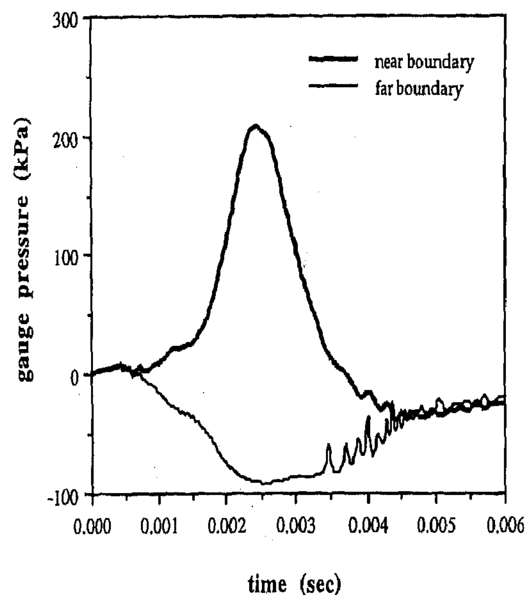

Figure 6: Low acceleration pressure response with 20-g neck acceleration.

minum cylinder was equal to the tangential acceleration obtained from the nine accelerometer array, and that each impact represented a repeatable event. In simulating this set of tests rotation did not need to be considered in the mathematical model. The near side and far side pressures from these tests also represented repeatable phenomena. As can be seen from Figure 4 the computational results compare very well with the experimental results. Both the experimental and computational results show the effect of the vaporization/free gas boundary though the experimental results show a slightly sharper drop to vapor pressure.

HIGH ACCELERATION (8 M/S IMPACT VELOCITY). The requirements for the 8 m/s tests differ from the 5 m/s tests only in impact velocity, that is, the impact velocity had to be within 0.1 m/s of 8 m/s. The motion of these tests was also one-dimensional without rotation. Although these tests were repeatable in terms of acceleration and near side pressures, the far side pressures were not. The differences occur at a time near the end of impact as the negative pressure starts to rise. Additionally, the magnitude of the pressure overshoot varies from test to test.

As is the case for the 5 m/s run, the minimum pressure on the far side for the 8 m/s run is limited to vapor pressure, Figure 5. In the model, low pressure lasted longer implying a larger vapor cavity, and the subsequent pressure rise is due to the vapor cavity's violent collapse. The near side pressure peak of the computational model is somewhat higher (by about 15 percent) than the experimental results. The computational results also show a more narrow peak. For the most part, however, the experimental results and the computational results for the near side compare reasonably well. The far side experimental data show a smaller vapor cavity growth than the computational results as the pressure is at vapor pressure for about 0.4 ms less in duration. However, the experimental runs gave some variations as to the exact time of vapor cavity collapse (6). Some of this variation may be experimental in nature as the sampling rate may be low enough (10,000 Hz) that the exact magnitude of the instantaneous pressure spike after cavity collapse cannot be obtained.

DISCRETE MODEL RESULTS

If it is assumed that the numerical model reliably reflects the response of the physical model at the measured points, then it is reasonable to use the model to estimate the response at points where measurements cannot be made. In addition, it is also reasonable to evaluate impact conditions in the numerical model that were not tested in the physical model. In this study the physical model was struck by a free traveling mass and the pressure response at the cylinder fluid boundary was measured. All cavitation occurred at the fluid cylinder boundary. To build on these results we used the computer model to estimate the cavitation response inside the fluid as a result of an impact similar to that of the test, and also a hypothesized neck loading.

The impacts of the physical model and simulation of these impacts by the computational models represent a stationary-test subject struck by a moving mass. However, in most automobile crashes the occupant is moving and strikes a moving object. The motion normally sub-

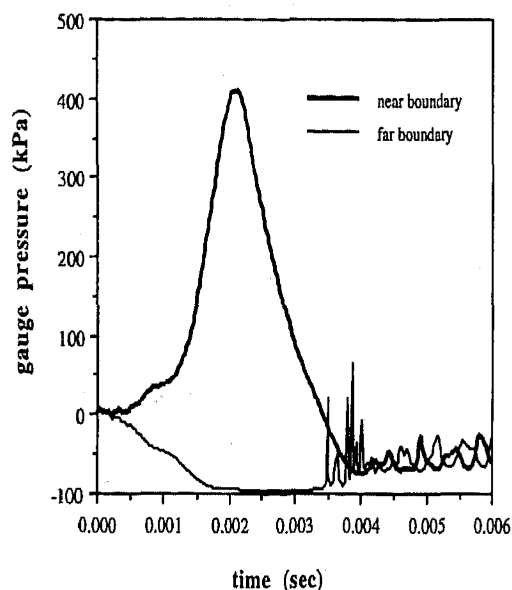

Figure 7: High acceleration pressure response with 20-g neck acceleration.

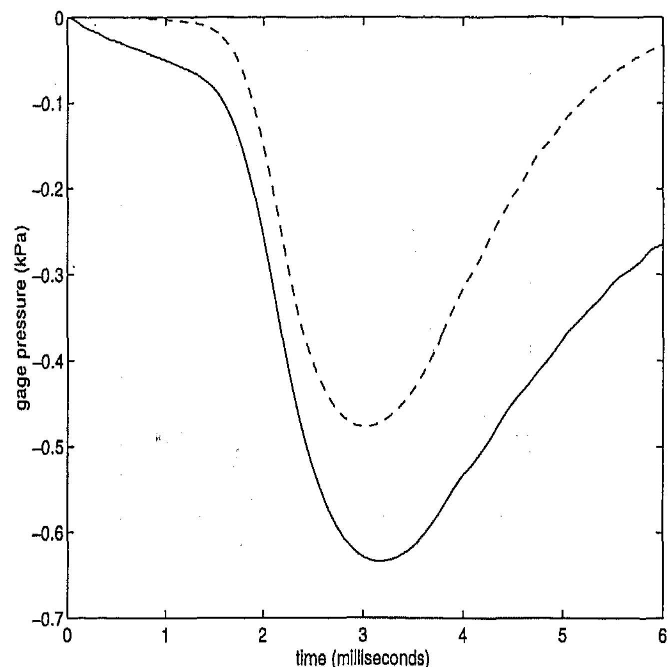

Figure 8: Fluid displacement with time for the continuum model (no internal vaporization, dashed line) and for the discrete model (with internal vaporization and neck loading, solid line) at the high acceleration.

jects the occupant to a force through the neck. This force can produce an acceleration perpendicular to the impact load and is typically of longer duration and lower magnitude. Therefore, the following results represent impacts similar to those above with the addition of a constant acceleration from the neck, in this case the acceleration is about 20 g's. Figures 6 and 7 show the near and far side boundary pressure histories of the low and high acceleration impacts, respectively, with a 20-g upward acceleration at the neck. When comparing Figures 6 and 7 with Figures 4 and 5, respectively, it can be seen that the additional stress incurred by the 20 g's results in a more violent cavity collapse. Greater internal cavitation is predicted by the model under the 20-g neck acceleration. The second model is able to predict an internal vaporous zone with small cavities (on the order of 10^{-6} m in diameter) at a number of internal nodes. Figure 12 shows the internal response of the fluid when the 20-g neck acceleration is added to the acceleration from the impact event. The figure shows the extent of the vaporous zone (the white region) in the cylinder at a time of 3.1 ms. The computational model demonstrates that the higher the acceleration from impact the greater the chance of cavitation in the fluid material. However, as illustrated by Figure 12, even at the low velocity the potential for internal cavitation exists when additional loading is included. By providing a constant vertical acceleration, in addition to the time-varying horizontal acceleration, the vector addition results in a larger resultant acceleration on the container. During peak acceleration the change is small. However, during low horizontal acceleration periods the prestressed vertical loading changes the magnitude and direction of the resultant significantly. This change in the resultant acceleration biases the vaporous zone towards the top of the cylinder. This is particularly evident for this case since the onset of vaporization is well before the time of peak horizontal acceleration, and the largest cavity size is beyond the time of peak horizontal acceleration. The numerical model also shows that the vertical acceleration on the head produces a higher net mass outflow at the neck, Figure 8 (less than 1 mm of fluid displacement), thus contributing to lower overall internal pressure and corresponding vaporization. Therefore, the amount of vaporization associated with this acceleration profile is greater than the amount of vaporization if the same resultant acceleration was entirely in the horizontal direction.

DIMENSIONAL SCALING

It is possible to investigate the effect of cylinder size on cavitation response. In the computational model, the size of the cylinder was reduced by scaling all relevant dimensions (diameter, thickness, neck size, etc.) by a scaling factor. The pressures scale to the sizing ratio, i.e., a cylinder 1/5 the size of the original cylinder undergoes a pressure response 1/5 the size. This can be observed in Figure 9 when vapor pressure limitations are not included in the model. When vaporization is included in the model and when the larger cylinder experiences more vaporization than the smaller cylinder, the pressure observed on the impact side

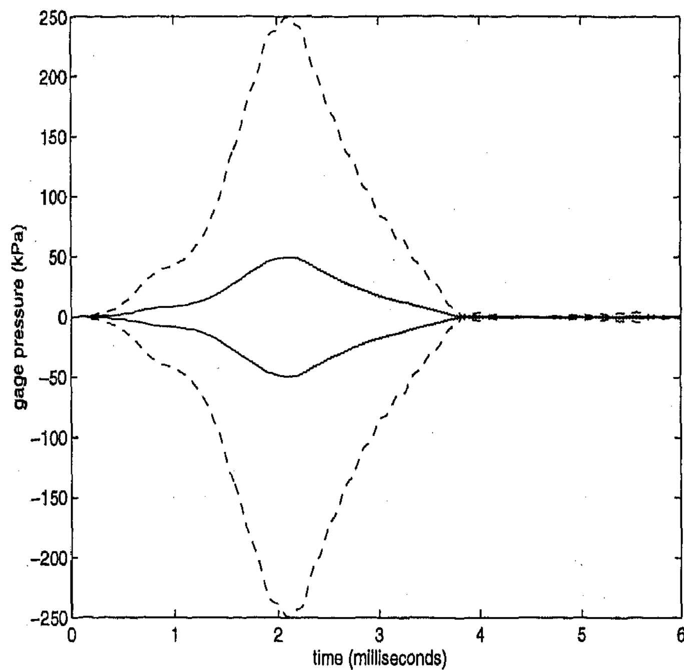

Figure 9: Pressure-time history for high acceleration when cylinder is reduced by a factor of five (solid line) and compared to standard size response (dashed line) when the pressure response is not limited to vapor pressure.

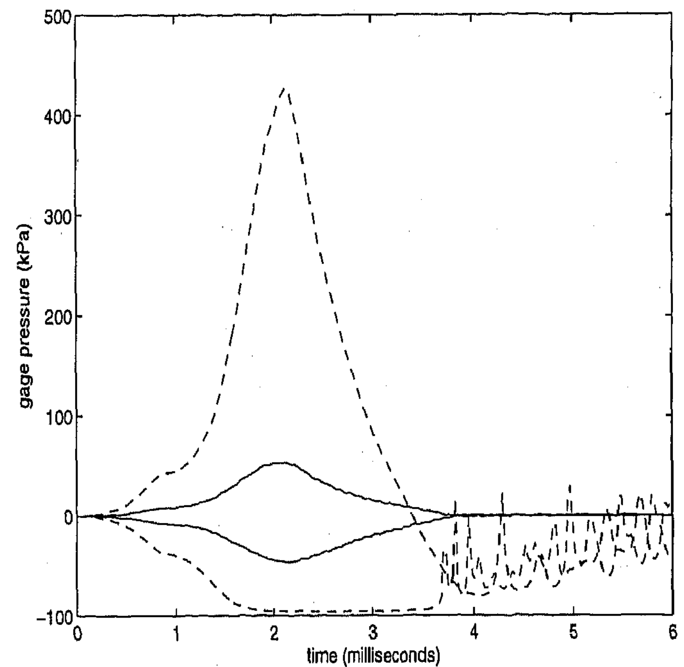

Figure 10: Pressure-time history for high acceleration when cylinder is reduced by a factor of five (solid line) and compared to standard size response (dashed line) when the pressure response is realistically limited to vapor pressure.

of the cylinder is much greater than the scaling ratio, Figure 10. This is because when the distal pressure response is limited to vapor pressure (as it must be to model reality) the impact pressure response must be greater than if there were no vaporization in order to conserve fluid momentum. The effectiveness of scaling directly by the size ratio is demonstrated when a cylinder 1/5 the size of the original is accelerated by a magnitude 5 times greater than the original acceleration, Figure 11. The pressure response for this case is nearly identical to that of the original cylinder undergoing the original acceleration. These results have relevance for comparing the impact response on primates to that of the impact response on humans. In an impact environment, pressure/cavitation response would remain approximately the same if the impact velocity is increased by the dimensional scaling factor. These results confirm what might be expected, that is, during an impact sufficient to produce cavitation for primate studies, greater acceleration of the impacted head form would occur.

DISCUSSION

Complex loading conditions are common in an automobile crash. In most automobile crashes the occupant is moving with the vehicle before it crashes. As the vehicle slows down the occupant keeps moving. Normally the head and torso will move differentially and a load will develop through the neck, resulting in angular as well as linear motion. If the head makes contact with a hard object during

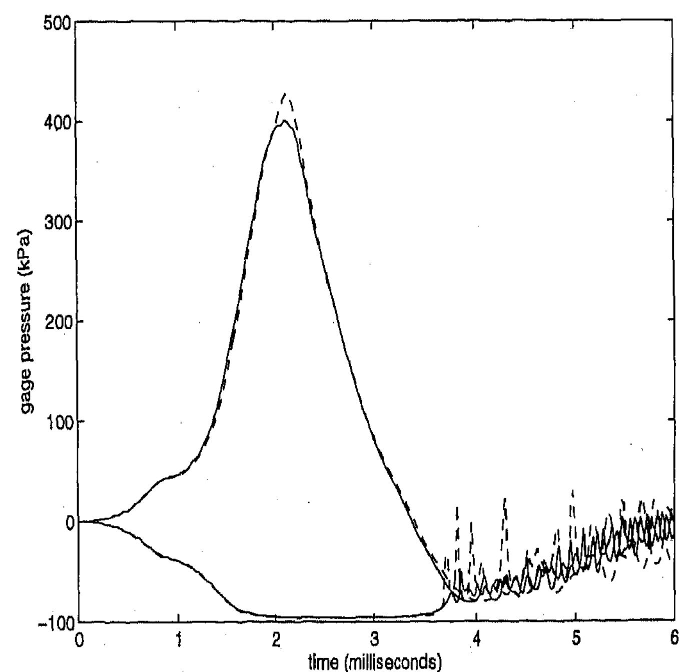

Figure 11: Pressure-time history for high acceleration when the original cylinder size is reduced by a factor of five and the original acceleration is increased by a factor of five (solid line). Also plotted is the pressure response under original 1:1 conditions (dashed line)

impact, the neck force produces an acceleration perpendicular to the impact load, creating a complex loading, that can affect the cavitation response. The influence is similar to what has been observed in low pressure transients in pipes, i.e., gravity may have a profound effect on cavitation during water-hammer events [9]. By changing the angle of the pipe with respect to the earth the cavitation response can be enhanced or eliminated. Therefore, the pre-stressing of the fluid by gravity before a water-hammer event affects the cavitation response.

A discussion of the pressure distribution in a closed container during acceleration may help in visualizing internal cavitation. For a constant horizontal acceleration the pressure pattern is:

$$p = p_0 + \rho k g x \tag{17}$$

where x is measured from the front of the container, p_0 is the reference pressure at the front, k is the number of g's of acceleration, and p is the absolute pressure. Low pressures causing vaporization are always initiated at the boundary. If the low pressure pulse is visualized to be initiated at the far side boundary ($x = D$), the magnitude of the pressure pulse causing vaporization is:

$$\Delta p = -p_v + p_0 + \rho k g D \tag{18}$$

where p_v is absolute vapor pressure and D is the container diameter. The pressure at the wave front is

$$p - \Delta p = p_v - \rho k g(D - x) \tag{19}$$

That is, for any x the pressure is trying to reach a value less than vapor pressure, a necessary condition for internal cavitation. It is the combination of the sloped initial gradient and the limitation in the pressure excursion to not less than vapor pressure that creates internal cavitation. Invariably, the largest cavities develop at the boundary. However, distributed internal vaporization can occur and will be more severe for high acceleration.

Vertical accelerations on the head may be more severe since the additional acceleration may create a high pressure in the vicinity of the neck, which would force material down the foramen magnum thus increasing the likelihood of internal cavitation. Even a small net outflow reduces the overall pressure, which amplifies the opportunity for cavitation. A time-varying acceleration, such as experienced in an accident, complicates a transient pressure pattern, but the above discussion provides the fluid dynamic basis for internal cavitation.

Both the physical and computational model used in this study are over-simplified versions of the human head. However, the same mechanism that influences pressure and cavitation in the cylinder under impact may influence pressure cavitation in the human head under impact. When the head or the cylinder is abruptly accelerated a positive pressure develops under the point of impact and negative pressure develops opposite the impact. When there is enough acceleration then a small cavity from fluid vaporization forms opposite the impact. At low accelerations the model does not compute significant cavitation away from the boundary. The dominant vapor cavity is always located at the skull/fluid boundary. However, if there are large accelerations, if a pre-existing stress is added to the load, or if there are complex loading conditions, then cavitation is possible inside of the fluid.

Therefore, it is reasonable to assume that when testing human surrogates an impact to a stationary head is unlikely to produce cavitation in the brain material. However, it is possible for cavitation to occur opposite impact at the skull-dura boundary, in the brain material near the skull-dura boundary, as well as elsewhere in the brain if there is pre-existing stress or a complex load path. Such conditions would exist in a vehicle crash as the occupant moves with respect to the vehicle before head impact. To attempt to understand what might happen in a vehicle crash, the model was pre-stressed according to estimated neck loadings. In addition, it is possible to generate pre-existing stress from other sources such as previous accelerations, angular acceleration, or angular velocity.

The numerical model predicts a cavitation zone on the boundary opposite impact with more cavitation occurring in the upper far side quadrant than in the lower far side quadrant. There is a variable void fraction throughout the zone at any instant. A more sizable cavity develops at the boundary. The cavitation zone grows spatially during the early stages of the low pressure, then reduces the size and disappears just before the collapse of the boundary cavity. Small amplitude pressure spikes are associated with the condensation of the internal vaporous zone. The largest pressure spike occurs at the instant of boundary cavity collapse. This type of behavior is entirely in keeping with low-pressure transients in liquid pipelines [9]. In this setting, high frequency pressure oscillations are common during the collapse of a vaporous zone, followed by larger amplitude pulses, normally associated with isolated cavity collapse at boundaries, or at high points in the pipeline.

Cavitation has been proposed as a mechanism of counter-coup lesions, which are found in the area of the head opposite impact [11, 12]. This hypothesis states that during impact an area of pressure low enough to cause a cavity exists at the counter-coup site. However, the exact mechanism by which cavitation may cause injury is unknown. Cavitation erosion is a well-known damage mechanism in fluid mechanisms [13]. However, the conditions of occurrence are quite different from those that occur herein and in head impacts in that it normally appears under high velocity flow near an imperfect surface. Small vapor bubbles form, grow and collapse all within 1 to 3 ms. The violent collapse occurs at a time scale of micro seconds, during which time high intensity pressure spikes may do localized physical damage to a solid surface if the phenomena is repeated over a sufficiently large number of cycles. Pressure intensities of the order of a gigapascal may be possible, and temperatures as high as 5,000°C [13]. Because most of the published data addresses damage in metals, cavity creation does not play a significant role; instead, the damage done by cavitation is the result of violent cavity collapse. However, there may be additional mechanisms of damage in brain tissue. When a vaporous region is formed in the

brain, large local strains in the tissues that have contact with each micro-void develop. The micro-voids are generally small enough so that geometric attenuation limit the magnitude of the effect. Nonetheless, if this occurs near a sensitive cellar structure, then it is possible that significant disruption of cellular neurofilament, microtubular structure, or axioplasmic transport might occur. Therefore, the size of the cavity and the forces generated during expansion or collapse do not have to be as large as in metals to cause damage in brain tissue. They could be as much as several orders of magnitude smaller.

Therefore, cavitation damage in brain tissue may be more common and have a greater variety of modes than previously thought. Injury attributed to other mechanism may be the result of cavitation. Cavitation damage/cell-disruption mechanism could be a cause of some of the diffuse axonal injuries (DAI) seen in head injuries from vehicle accidents. It is possible that the cellular disruption causes local damage that does not cause immediate cell death, but instead disrupts the cell activity to the degree that visible injury occurs later [14, 15, 16, 17]. The mechanism of numerous micro-voids forming a large vaporous region, by its nature, would produce damage that could be non-local and defuse throughout the brain. Cavitation requires the high accelerations generally driven by head strikes which are considered the sole or dominant cause of head injuries in the automobile environment (DAI inclusive) [18].

Although the complexity of head injury with apparent multiple injury modes created by many possible injury mechanisms appears to preclude one mechanism, cavitation is consistent with many of the observed biomechanics. For example, the 150-g acceleration for the initiation of vaporous regions to form in the head as an injury mechanism is consistent with the results previously observed [19]. It is also consistent with the logic behind HIC, both acceleration magnitude and duration are important. Short duration accelerations need higher accelerations to produce equivalent cavitation strain or accompanied violent collapse in the brain.

In addition, the smaller the brain cavity the greater the acceleration needed to produce cavitation and the associated damage. This is consistent with observations that it requires greater acceleration to cause damage in the smaller brain sizes [20, 21]. The acceleration necessary to cause damage in a primate is greater than that in a human. This acceleration could be either linear or angular or a combination of both. Angular acceleration adds significant complication for predicting where cavitation will occur in both primates and humans. For example, if the head is spun about its center of mass without linear acceleration (difficult to do if the head is attached to the neck) then cavitation will occur internally without any surface events. If both the linear and angular accelerations are complex such as occurs in a head impact in the automobile environment, then cavitation could occur at multiple locations in the brain.

For both large and small brains it is important to have a pressure gradient (caused by linear or angular acceleration) of sufficient duration to cause cavitation damage. This damage could be produced by impact or inertial load. However, the accelerations needed to produce cavitation are unlikely to occur by inertial loads in an automobile environment. Instead, impacts of the head would be the only way to produce cavitation type damage. This is consistent with previous results [18] in which no injury to the brain material occurred without impact in the automobile environment. Coupled with the acceleration response, impacts produce additional complexity in that the pressure gradients are also influenced by the skull deformation.

IMPLICATION FOR BIOLOGIC SOFT TISSUE MODELING

The results presented here have implication for modeling of biologic material. As a result of cavitation, it is reasonable to expect that soft tissue will have a material model that is a function of the state of stress, both the yield surface and elastic response. For example, shear response is considered important in brain injury mechanisms. As discussed above, when the head acceleration exceeds 150 g's then some form of voids in the brain can occur. How these voids affect the response of the brain in terms of shear, local brain material properties, volumetric and shape changes, energy management and damage properties is unknown. When the head acceleration exceeds 200 g's cavitation response can be violent and there is the chance that the temperature of the collapsing cavity can exceed 5,000°C [22, 23, 24]. In addition, brain material also has weak Van der Walls bonding forces and may behave like organic polymers with both tension/compression and shear response a function of hydrostatic forces. It may turn out that a brain material model, or any soft tissue model, may have to be developed that takes into account the state of stress including the effects of cavitation and micro voids. Furthermore, it has been reported [25, 26] that the Casimir effect can be significant in biological materials. This may also affect how voids form in brain tissue and influence their effect on response and injury.

In the experiments and in the computational model no deformation occurred. Deformation in the human skull can cause both magnitude and phase differences in the pressures as well as contaminate the acceleration response [2]. However, it would seem reasonable to assume that an impact which increases the skull volume, front to back or back to front, would cause greater cavity formation and conversely, an impact that decreased volume would decrease cavity formation.

CONCLUSIONS

This paper presents a limited experimental and computational study of the impact response of the head with regard to cavitation. Because of the complex nature of the cavitation phenomenon during an impact event more work is necessary before the results can be generalized. However, the following conclusions can be made for non-skull fracture cases:

1. Computational models of the head, addressing severe head impacts, should include some form of fluid vaporization at the skull-brain boundary and in the brain material.
2. The potential for cavitation during impact is influenced by pre-existing stress.
3. Vertical loading on the head by the neck before impact can affect the potential for cavitation in the brain material. This is particularly true if the preloading causes a higher pressure at the base of the head, leading to an outflow of material through the foramen magnum.
4. Cavitation in the form of micro-voids inside the brain material may cause local cellular damage that does not produce immediate cell death. It may be one of the causes of diffuse axonal injuries (DAI).
5. The pressure response due to impact can be scaled in proportion with the physical size of the head form unless there is cavitation occurring. Head forms of a different sizing will experience an acceleration inversely proportional in magnitude to the size difference in order to produce a similar pressure/cavitation response.
6. Cavitation may be more common than previously thought because there may be more than one damage mechanism.

ABSTRACT

The William Lehman Injury Research Center has conducted multi-disciplinary investigations of one hundred seventy-eight crashes involving adult occupants protected by safety belts and air bags. In all cases, serious injuries were suspected. Nine cases involved serious heart injuries. These cases are not representative of crashes in general. However, when used in conjunction with National Accident Sampling System; Crashworthiness Data System (NASS/CDS) they provide insight into the most severe injuries suffered by restrained occupants in frontal crashes.

Heart injuries are rare, but when they occur they are usually life threatening. NASS/CDS shows that heart injuries comprise about 0.2% of the injuries in frontal tow-away crashes. In the NHTSA file of Special Crash Investigations (SCI) of air bag cases, heart injuries are reported in 1% of the occupants over 15 years of age. Twenty-five percent of the fatally injured occupants had heart injuries, and 83% of those with heart injury died. In the Lehman Center cases, heart injuries are present in 5.1% of the cases. Forty percent of the fatally injured had heart injury, and 78% of the victims with heart injury died. There is a compelling urgency for the early diagnosis and treatment of heart injuries. Studies of the limited data available provide the basis for premises to better define triage criteria for restrained occupants. This paper suggests two additional triage criteria, based on observations from multi-disciplinary studies. These include: (1) passengers in 2-point belts and crashes of 25 mph or higher, with the lap belt unfastened or with the seat full forward; (2) drivers in crash conditions which delay the air bag deployment or permit the driver to be close to the air bag at deployment.

NASS/CDS DATA ON HEART INJURIES

Heart injuries are rare events. The NASS/CDS samples tow-away crashes on US highways. The risk of any injury to an occupant is about 45%. Less than 0.25% of all injuries in frontal crashes are heart injuries.

For the purpose of this study, only frontal crashes are considered. The NASS/CDS 1988-1995 indicates a yearly average of 2,088,961 passenger car occupants in frontal tow-away crashes (excluding crashes with subsequent rollover or ejection). Forty-five percent of these occupants were injured. On the average, each injured occupant had 2.52 injuries recorded. Serious (AIS 3+) injuries accounted for 3% of all injuries. For those occupants protected by 2-point belts, the risk of serious injury was twice as high as for those protected by 3-point belts or 3-point belts with air bags. The total number of AIS 3+ heart injuries is estimated at 5,100 per year. About 38% of these occur in the 7.5% of the population protected by 2-point belts, while 28% occur in the 49% of the population protected by 3 point belts.

Table 1 shows the fraction of heart injuries as a percentage of all injuries, and as a percentage of serious (AIS 3+) injuries for each type of restraint system. The heart injury fraction among serious injuries is much larger than the fraction of all injuries. This relationship demonstrates that when heart injuries occur, they are nearly always serious injuries.

TABLE 1. Heart Injury Percentages in Frontal Crashes

Restraint	Heart Injury % of Injuries	Heart Injury % of AIS 3+
None	0.15%	4.0%
3-point Belt	0.15%	6.5%
2-point Belt	1.20%	27.4%
Belts + Air Bag	0.03%	0.9%
Air Bag Only	0.30%	5.1%

The data in Table 1 also indicates that the air bags plus belt system have the lowest heart injury fractions of all protection systems.

Among occupants protected by 2-point belts, heart injuries comprise 27.4% of their AIS 3+ injuries. The small number of AIS 3+ injuries result in an error band of 16% for the 27.4% heart injury fraction. Still, the risk of heart injury for 2-point belt protected occupants is much higher than for other protection systems. The increased heart injury fraction for this population is further accentuated by the 2.5 times higher frequency of all AIS 3+ injuries among the 2-point belt protected population compared to the 3-point belt protected population. Each year there are 157,000 occupants

protected by 2-point belts in frontal crashes. About 65,000 thousand of these occupants are injured, and suffer about 1,900 heart injuries.

HEART INJURY MECHANISMS

The William Lehman Injury Research Center supports a multi-disciplinary crash investigation team at the Ryder Trauma Center, one of the most comprehensive Level I Trauma Center in the United States. The criteria for admission to the study are as follows: (1) the subject must have been injured inside a post 1980 passenger car that was involved in a frontal collision; (2) the subject must have been protected by a safety belt, an air bag, or both; (3) at the crash scene, the subject must have met trauma criteria (see Table 2) for suspicion of injuries of a severity which justified transporting to the Ryder Trauma Center, or must have suffered subsequent complications which required emergency interventions; (4) the subject must have agreed to have all records included in the study. All admissions to the Ryder Trauma Center were evaluated for possible admission to the study. All of those that were found to meet study criteria were asked to participate.

TABLE 2. Adult Trauma Criteria

- Systolic BP $\leq$ 90 (Shock)
- Respiratory rate < 10 per minute or > 29 per minute
- Glasgow Coma Scale $\leq$ 12
- Penetrating injury to head, neck, chest, abdomen or groin
- Paralysis
- Amputation proximal to wrist or ankle
- Ejection from motor vehicle
- Paramedic Judgment: High Index of Suspicion of Injury
- Second or third degree burns $\geq$ 15% Total Body Surface Area

Detailed crash and injury investigations are documented for each seriously and fatally injured motor vehicle occupant who was protected by a belt system and/or an air bag. The crash investigation is performed by an experienced crash investigator, and the injuries are assessed and described by the Center's medical staff.

Previous results of multi-disciplinary analysis have been reported in earlier papers [Augenstein, J., [and others]., 1994, 1995 and 1996] . Initial improvements in triage criteria were documented in a NHTSA report [Lombardo, 1993].

In general, heart injuries are serious, and often require immediate and urgent treatment. Yet, in some cases, the heart injury may be difficult to detect. Clues from the crash may assist in detecting these serious and time critical injuries. One of the objectives of the Lehman Center research is to identify clues which may be used to assist in diagnosing heart injuries.

There are several heart injury patterns which have been observed among the injured cases at the William Lehman Injury Research Center. These injuries are depicted in Figure 1 and summarized as follows:

1- Contusion of the surface of the heart. This injury others listed can degrade the heart's function, resulting in lowering the blood supply to the brain and to critical organs. Minor contusions may have no clinical impact. Major contusions may drastically reduce the hearts pumping ability (that is a reduction in cardiac output). Bleeding from the contused outer surface of the heart may produce fluid in the pericardial sac. This is called pericardial tamponade. The result can be severe deterioration of cardiac output.

2- Rupture of the ventricle. This injury is generally associated with compression of the heart while filled with blood. The right ventricle operates at a lower pressure than the left ventricle and can withstand less over pressure. Rupture is most likely to occur in the right ventricle. This injury causes loss of heart function, and bleeding into the pericardium. Immediate treatment is required.

3- Laceration or rupture of the atrium. This injury causes loss of heart function, and bleeding into the pericardium. Immediate treatment is required.

4- Laceration of aorta. This injury frequently occurs at the end of the aortic arch. It may be caused by displacement of the heart relative to the aortic attachment. Immediate treatment is typically required.

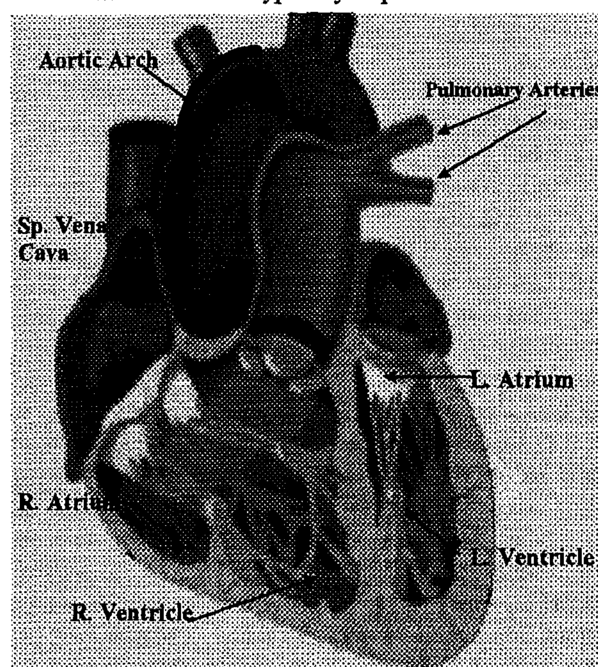

Figure 1. Diagram of Heart

The injuries in cases at the William Lehman Research Center are more severe than observed in NASS/CDS. The heart injuries comprise a larger portion of the injury population. Seventy-eight percent of the occupants with heart injuries died. The injury rate for each restraint system is summarized in Table 3. In this sample, the relative risk of heart injuries for air bag protected occupants is slightly higher than the average rate of 5.1%.

Table 3 indicates that among occupants with severe injuries, heart injuries remain a small percentage. However, 78% of occupants with heart injury died. An estimated twenty-five percent of those who died from heart injuries may have been saved if the time for diagnosing and treating the

injury could be reduced. Observations made at the crash scene may be vital to the rescue and treatment of occupants with heart injuries.

TABLE 3. Number of Cases and Percentage of Heart Injuries in Lehman Center Data

Restraint	Number	Heart Injury
3-point Belt	74	2.7%
2-point Belt	36	5.6%*
Belts + Air Bag & Air Bag Only	68	7.4%
All	178	5.1%

CASES OF BELTED PASSENGERS WITH HEART INJURIES

Only two cases of passengers with automatic 2-point belts have entered the Lehman data. Both cases (100%) had fatal heart injuries. These cases involve healthy young adult men in frontal crashes. Both were front seat passengers, and both may have been asleep at the time of the crash. The drivers in both cases were braking and bracing heavily prior to the crash, and received only minor injuries. These cases are summarized as follows.

CASE 95-029A1

Figure 2. Case Vehicle 95-029A1 Hyundai S-coup, 1994

This crash occurred at 4:33 AM and involved a 1994 Hyundai S-coup (Figure 2). The driver lost control of the vehicle, mounted a curb, impacted a line of small shrubbery, and then a 17 inch diameter palm tree. The impact direction was 12 o'clock. Damage started 5 inches to the left of centerline and continued for 17 inches. The maximum crush was 30 inches, and the delta-V was calculated at 32 mph. Rescue was delayed by the time to call for help in the early hours of the morning and by a lengthy extraction. The victim was air lifted to the Trauma Center, and arrived approximately 45 minutes after the crash. The injuries were as follows:

Laceration, left atrium	AIS-5*
Fracture, anterior right rib cage (2-3)	AIS-3
Abrasions, contusions and lacerations to face, trunk, abdomen, and knees	AIS-1

* *This injury may have been survivable*

The passenger died of his heart injury before it could be diagnosed at the trauma center. More rapid crash identification, location and recovery may have prevented this fatality.

CASE 95-034AP

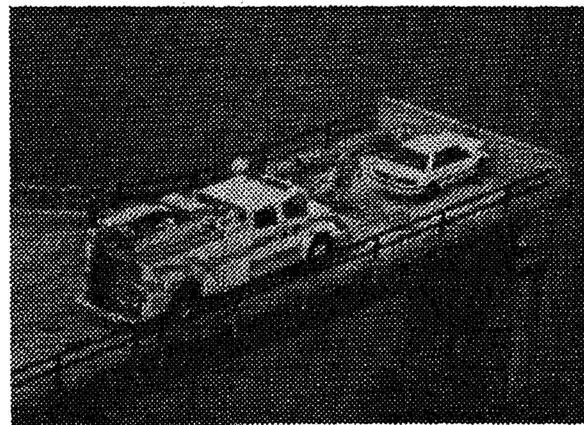

Figure 3. Case Vehicle 95-034AP Mazda Protégé, 1994

This crash occurred at approximately 5:00 AM. The vehicle was a 1994 Mazda Protégé (Figure 3). The driver entered a closed road in a sparsely traveled area and impacted a concrete barrier with a delta-V of 29 mph. The vehicle created tire skid marks for 55 feet before striking the barrier. The extent of damage was 18.5 inches of crush uniformly distributed across the front of the car. Intrusion was 9 inches for the left toepan, and 11.5 inches for the right toepan. The passenger was 32 years old, 72 inches tall, and weighed 175 lb. He was protected by a shoulder belt, and he was wearing a manual lap belt. A suitcase was jammed behind the seat, and his seat was in the full forward position. The suitcase remained wedged behind the seat after the crash, and no permanent deformation of the seat structure was observed. His injuries were as follows:

Laceration, distal arch of aorta (contained in mediastinum)	AIS-5
Contusion, heart	AIS-3
Contusion, right lung	AIS-3
Fracture, rib, right (2-7); left (4-9)	AIS-5
Laceration, spleen	AIS 2
Contusion, bowel and mesentery	AIS 2
Laceration, parietal pleura, right	AIS-2
Fracture, foot, right	AIS-2
Lacerations abrasions, and contusions (x9)	AIS-1

**complication: brain stem herniation.*

Due to the remote location of the crash, and the early hour of the morning, the crash was not discovered for more than 30 minutes. The occupant expired at the scene. More rapid discovery may have prevented this fatality.

DISCUSSION OF BELTED CASES WITH HEART INJURY

An examination of 30 mph crash tests of the Hyundai S-coup and the Mazda Protégé shows that these vehicles both produced chest injury measures well below the requirements of the federal standards. In the 30 mph tests, the 50% male dummies are positioned with the seat midway along the seat track. The shoulder belt is used, but not the lap belt. The results of 30 mph tests are shown in Table 4.

TABLE 4. Injury Measures For Passenger In 30 Mph Frontal Crash Test

VEHICLE	HIC	Chest G
Allowable	*1000*	*60*
Hyundai S-coup		40
Mazda Protégé	418	39

In the case with the Mazda Protégé, the passenger was using his lap belt. Crash tests at 35 mph are available to indicate the performance of the Protégé with the lap belt fastened. The results are: HIC - 612; Chest G - 51.

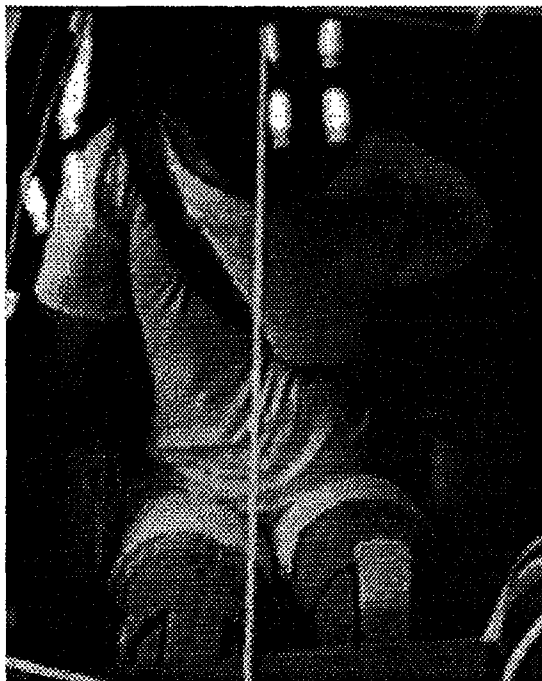

Figure 4 2-point Belt Position in Crash Test of Hyundai S-coup

All these values for chest injury are well below the 60 G's allowed in the standard. However, an examination of the test films suggest that the chest G measures may not adequately account for the concentration of load produced by shoulder belt. In the tests without lap belt, the shoulder belt rides very high on the chest.

Figure 4 is a frame taken from the crash test film of the Hyundai S-coup. In this 30 mph crash into a barrier, the position of the belt over the heart is evident. The concentrated loading of the 2-point belt, when the lap belt is not used, may increase the risk of heart injuries, as observed in the NASS/CDS data.

Figure 5 Belt Position In Mazda Protégé with Seat Full Forward

Figure 5 shows the geometry of the belt system in a Mazda Protégé, with the seat in the fully forward position. The vehicle was tested with the seat in its middle position, so that a more favorable geometry results. The lower portion of the shoulder belt is positioned higher on the chest as the seat moves forward. This change may increase the loading of the chest and the risk of heart injuries.

The observations from crash tests, supported by Lehman Center cases with passenger heart injury suggests that heart injury producing loading may be induced by the shoulder belt, under crash severities around 30 mph and higher.

In searching for clues for early detection of heart injuries, the following criteria is postulated for future application of the Lehman Center research:

- Passenger occupants in 2-point belts and crashes of 25 mph or higher and with the lap belt unfastened or the seat fully forward.

AIR BAG CASES WITH HEART INJURY NHTSA SPECIAL CRASH INVESTIGATION CASES

The NHTSA Special Crash Investigation (SCI) file contains records of 1258 drivers who were in vehicles with air bag deployment. The criteria for inclusion in this file is varied. Consequently, it is not possible to extrapolate results to determine nationally representative frequency of occurrence. However, the file is useful for examining injury patterns among air bag protected occupants.

The file contains 56 cases with fatal injuries. Twenty-five percent of the fatal cases had severe heart injuries. Among the fatal crashes with severe heart injury, 64% were at crash speeds of less than 20 mph. Thirty-six percent were at crash severities of less than 15 mph. In addition to the fourteen fatal injuries, there were three drivers with AIS 3+ heart injuries who survived.

A summary of 14 cases of drivers with heart injury documented in the NHTSA Special Crash Investigation study is shown in Table 5. Three documented cases of driver heart injury were not included in Table 5 because they involved predominately side impacts or driver ejection. The columns in Table 5 show the case number; the vehicle year, make and model, the crash severity (mph); the heart injury AIS; the object struck; the occupant's age, sex, weight (lb.), and height (in); the object contacted by the occupant which most likely caused the injury; whether the occupant died; whether the belt was worn; and remarks which may have influenced the outcome.

The data from Table 5 indicates 11 cases of heart injury at crash speeds below 23 mph. Four of these were impacts with trees or poles. Four were impacts with the rear of another car, and two were impacts with the side of another vehicle. These types of crashes produce relatively low acceleration crash pulses, which may delay the deployment of air bags. It is probable that the occupant may have been close to the deploying air bag in these cases. Of the seven fatally injured drivers in crashes at speeds below 19 mph, four were older than 70, and six were less than 65 inches tall. Preexisting heart disease was reported in two of the older drivers. A close position of the driver relative to the air bag at the time of deployment was suspected for most of the cases. In the higher severity crashes with the occupant belted, multiple impacts of the vehicle may have contributed to the occupant's position and injuries.

LEHMAN CENTER HEART INJURY AIR BAG CASES

The Lehman Center has investigated five crashes with air bag deployment and heart injury to drivers. Four of these cases were either at crash severity's well above 30 mph, or involved massive intrusion. One case was at 23 mph and is summarized as follows.

CASE 93-026A

Figure 6. Case Vehicle 93-026A Infinity M-30, 1992

This crash occurred at 11:22 AM at a city intersection. The driver of a 1992 Infinity M-30, suddenly swerved into the opposite lane and impacted the front of a stationary vehicle (Figure 6). The delta-V was 23 mph, and the crash direction was one o'clock. The maximum crush was 20 inches, with no compartment intrusion. The driver

was a 67 year old male, 69 inches tall, weighing 137 lb. He was not wearing the 3-point belt when his air bag deployed. The pre-crash trajectory suggest that the driver may have blacked out, and he may have been close to the bag at deployment. His injuries were:

Laceration, cardiac atrium, right	AIS-5
Laceration, liver	AIS-2
Laceration, spleen	AIS-2
Lacerations abrasions, & contusions (x6)	AIS-1

The driver expired in resuscitation approximately 30 minutes after the crash. The injuries indicate that this relatively frail person was not adequately protected by the air bag.

NASS/CDS FATAL CASES

The NASS/CDS for the years 1990-93 contains 26 driver fatalities with air bag deployments. Analysis of the fatal cases which may have been caused by the air bag was conducted by Lund [Lund 1996]. According to this study, 7 of the 26 cases, involved frontal impacts as the only harmful event. Another 7 cases involved frontal impacts with multiple harmful events.

The authors found three frontal single impact cases and one frontal multiple impact case in which the air bag may have contributed to the injuries. Each case involved serious heart injuries. The suspected air bag induced injuries were as follows:

Case 917902111;
Unbelted, 35 year old female,
5'6", 160 lbs.
Delta V 46mph, Front to rear car-to-car crash

Injuries: Laceration, right ventricle	AIS-5
Contusion, interventricular septum	AIS-4

Case 930512511;
Belted , 62 year old female
5'2", 179 lbs.
DV 29mph , Pole impact

Injuries: Laceration, right ventricle	AIS-5
Flail chest, bilateral	AIS-5

Case 930600611;
Unbelted, 64 year old male
5'7", 160 lbs.
Delta V 29mph, Tree impact

Injuries: Laceration, right atrium	AIS-6
Fractures, bilateral ribs	AIS-4
Laceration, superior vena cava	AIS-3

Case 920813311;
Unbelted, 58 year old male,
6'0", 187 lbs.
Delta V unknown, Multiple impacts with shrubs

Injuries: Fractures, bilateral rib with hemothorax	AIS-5
Laceration, heart	AIS-3
Laceration, pericardium	AIS-2

DISCUSSION OF AIRBAG CASES WITH HEART INJURY

The NASS/CDS indicates that heart injuries are very rare among occupants protected by air bags. However, a number of heart injuries have been investigated at the Lehman Center, in the Special Crash Investigation Study, and in the NASS/CDS fatalities. The heart injury frequency in these data sets is much higher than seen in NASS/CDS. Of particular concern is the frequency of heart injury in low speed, low acceleration crashes. Crashes involving car-to-poles and car front-to-car-rear are over represented in these crash types. In these classes of crashes, the vehicle initially decelerates more slowly than in a barrier crash. Consequently, the crash is more difficult to detect by present day crash sensors, and the occupant may move closer to the air bag before the bag deploys.

In addition, older and short statured drivers are over represented in the low speed fatal crashes from NASS/CDS and from the SCI file. Older drivers have lower tolerance to heart injuries and present air bags may be too stiff to provide protection in low speed crashes. In low severity crashes, less powerful air bags may be beneficial to this population.

In the higher severity crashes, multiple impacts may be a factor which increases heart injury risk.

The data also suggest that severe heart injuries may be occurring more frequently than recognized in the NASS/CDS data.

CONCLUSIONS

Heart injuries are rare but serious events in the NASS/CDS data. The data from the William Lehman Injury Research Center shows a higher concentration of heart injuries, of nearly 5% of the injuries suffered by patients meeting trauma center triage criteria.

Heart injuries require immediate recognition and treatment. Clues from the crash would be desirable in aiding the detection of heart injuries. Additional clues currently being explored by the Lehman Center include the following:

- Passenger occupants in 2-point belts and crashes of 25 mph or greater with the lap belt unfastened or the seat fully forward.
- Drivers in crash conditions which delay the air bag deployment or permit the driver to be close to the air bag at the time of deployment. The presence of elderly persons and small statured persons in this type of crash adds to the index of suspicion.

In the data from Special Crash Investigation Cases of air bag crashes, heart injuries represent about 1% of the injuries but 25% of the fatalities. The majority of these fatalities occurred at crash speeds below 22 mph. Crashes involving poles and car-front to car-rear impacts are over-represented in these lower severity crashes. Older persons, and short statured persons are also over-represented. In the higher severity crashes, multiple impacts are a frequent complicating factor. Combinations of these factors may be useful in suspecting the presence of rare, but serious heart injuries.

ACKNOWLEDGMENT

This research was conducted with the support of the National Highway Traffic Safety Administration.

ABSTRACT

This work addresses and evaluates the likelihood of human casualty in highway crashes, projected on the basis of field crash data that may become available electronically by sensors at crash time, and/or observed at the crash scene by emergency attendants. Termed collectively as a "crash signature", such data are treated as predictors and are selected from: crash severity, general area of damage, direction of force, occurrence of rollover, intrusion, vehicle crush and its specific horizontal location, collision partner, vehicle class and size, occupant age, gender, restraint use and type, seating position, and other. Crash signatures are converted into responses such as: (a) the likelihood of the most severe outcome, fatality or survived injury, by severity AIS per occupant; and (b) the same per vehicle. Cars are the vehicles selected for this investigation. A likelihood is quantified by a probability of occurrence, as a function of a string of predictors selected for maximum resolution and sensitivity, and minimum contribution to error. Likelihood determinations are performed via maximum likelihood based logistic regressions, best suited for treating dichotomous responses: "yes or no" such and such a response or outcome. Each likelihood is accompanied by a standard error or by upper and lower confidence bounds, and each procedure is evaluated by pertinent scores. All cited procedures and findings are based on the data of the National Accident Sampling System (NASS) files 1988-1995, compiled by the National Highway Traffic Safety Administration (NHTSA). This provides a nationally representative sample of about 95,000 crash involved car occupants, and 190,000 incurred injuries, all with attributes that collectively encompass as a minimum the predictors and responses cited earlier. The paper provides pertinent predictive relations which, notwithstanding complexity, are fully programmable. Probabilities of specific outcomes may vary from nearly zero to virtually 100%, depending on circumstances. Detailed and illustrative findings are presented in tabular and graphic forms.

INTRODUCTION

The advent of high volume highway accident records, many of them nationally representative and of a research caliber, addressing a broad spectrum of crash, vehicle, occupant, and casualty attributes, makes it easier now to address and evaluate several important issues in highway safety.

At the same time, the wide scope and the complexities of the available data point to the need for developing ways and means in order to

capture the essential aspects of the highway crash environment in a succinct and insightful fashion. The purpose of this paper is to take a first cut in responding to the cited need.

BASIC DATA

The data compiled in the eight years, 1988-1995, of NASS/CDS are the basic data used. The NASS weights, necessary for national projections, are used as weighing factors in any data processing procedure.

Many outcomes and their severity may be considered individually or in combinations for the purpose of human casualty prediction. Also many crash, car, occupant, and injury attributes are in principle available in the accident experience to assist, as predictors, in the derivation of said algorithms on the basis of a crash signature. The number and type of predictors are often limited by practical considerations imposed by the type of contemplated applications, the strength of probability --predictor correlation, and by the amount and quality of available data for the derivation of the algorithms.

NOMINAL PROCEDURE FOR TREATING THE RAW DATA

In view of the dichotomous nature of the outcomes at issue (e.g. "Yes" or "No" Fatality or MAIS 3+) a maximum likelihood procedure, specifically a logistic regression with weighing factors, is used to fit various algorithms to the raw data. Essentially, the probability of casualty is projected as:

P = 1 / [1 + exp(-w)] (1)

w = A0 + A1*PRED1 + A2*PRED2 + ... (2)

where PRED1, PRED2, etc are the selected predictors; and A0, A1, A2, etc are coefficients estimated by the logistic regression.

When dealing with analyses of data from the NASS, it must be taken into account that this file contains a sample as opposed to a census of national data. In order to deal with this, the applicable statistical procedures are those prescribed in "Survey Data Analysis" (SUDAAN) software, Research Triangle Institute, Research Triangle Park, North Carolina, 1992. Such procedures are applicable in the analysis of data from multi-stage sample designs, like that of the NASS.

ESTIMATION OF STANDARD ERRORS AND CONFIDENCE BOUNDS

The SUDAAN logistic procedure yields values for coefficients: A0, A1, A2, etc appearing in (2). The same procedure provides also the covariance matrix: COV(Ai, Aj). This helps in the calculation of the variance of the argument w of the probability appearing in (1). Specifically, the variance of w is given by:

var(w) = Sum[Cov(Ai, Aj)*xi*xj] (3)
over all i and j

Note that i or j assume the values: 0, 1, 2, etc, corresponding to the intercept and the predictors appearing in relation (2). When an analyst assigns desirable values to xi and xj, an application of (3) yields the variance: var(w).

Moreover, to a first approximation, the variance of the probability (1) is given by:

var(P)={exp(-2w)/[1+exp(-w)]**4}*var(w) (4)

and the standard error of P is:

seP = square root [var(P)] (5)

Also to a first approximation, the 95% confidence bounds of P are given by: P +/- (1.96 * seP)

ADDRESSED PREDICTORS

In this paper the basic data, i.e. data concerning car occupants involved in towaway crashes, are used for the derivation of algorithms that estimate: (a) the probability of a crash involved occupant being a fatality; (b) the probability of a crash involved occupant with at least one injury of maximum severity MAIS 3+; and (c) the probability of a crash involved occupant with at least one injury of MAIS 2+. Extension to other outcome populations is readily evident. Short notation for the predictors addressed in developing algorithms is given below:

ONEVEH Single Car Crash
BIGTRK Collision with Large Vehicle
ROLL Planar Crash with Rollover Occurrence
DELTAV Total Delta V, mph
GADSP Side Damage, Passenger Compart.
GADSNP Side Damage, Excluding Passenger Compartment
GADB Rear Damage
DOFS Direction of Force: 8-10 & 2-4 O'Clock
DOFB Direction of Force: 5-7 O'Clock
MAXC Maximum Crush, inches
INTRU Intrusion, 6 inches or more, in Front
CURBWT Car Curb Weight, in 100 lbs
FRPAX Right Front Seat Pasenger
RRPAX Rear Seat Pasenger
BELT Safety Belt Use
BEBA Air Bag Deployment & Belt Use
AGE Car Occupant's Age
FEMALE Occuppant's Gender
OCCWT Occuppant's Weight, lbs
OCCHT Occuppant's Height, inches
ENTRP Entrapment
EJC Complete Ejection
EJP Partial Ejection

These predictors are alternatives and operate in conjunction with a baseline that addresses unrestrained male car drivers, in primarily planar and frontal crashes with other cars. Thus, given the cited baseline, the only two alternatives addressed above for a collision partner are: ONEVEH and BIGTRK. Similarly GADSP, GADNSP, and GADB are the alternatives to frontal damage included in the baseline. Top damage is not addressed because of a relatively low incidence.

In fact it is important to note that rollover in general is not included in the development of the algorithms at issue. This is necessitated by the desire to include Delta V as a most influential parameter. This parameter is not defined in general rollover. Thus, predictor ROLL appearing in the above list covers the crashes which are initially planar, with a possible subsequent rollover.

Other implicitly understood alternatives not named in the above list are: direction of force 11 to 1 O'Clock, driver's seat, no restraint use, male occupant, and no ejection. These are baseline attributes. Most other attributes are either binary (yes or no), or continuous.

PROGRAMMABLE ALGORITHMS

Optimal algorithms are presented below in order of increasing complexity. Relation (1) is always the basic platform. The simplest way of formulating the exponent "w" is in terms of DELTA V, the most influential parameter, as shown below:

w = A0 + A1*DELTAV (6)

where DELTAV=Total Delta V in mph continuously.

The logistic regression (1) and (6) applied on the basic data, seeking the probability for fatality or MAIS 3+ or MAIs 2+, yields the coefficients A0 and A1 and the associated standard errors, with numerical values shown in the first cluster of Table I. Next we address the more complex, but still relatively simple, fit shown in (7) below:

w = A0 + A1*DELTAV + A2*DOFS + A3*DOFB (7)

where in addition to DELTAV we include:
DOFS = 1 if the direction of force is 8-10 or 2-4 O'Clock, else DOFS=0;
DOFB = 1 if the direction of force is 5-7 O'Clock, else DOFB=0; and if DOFS=DOFB=0 then the direction of force is 11 to 1 O'Clock.

Numerical values for the coefficients A0, A1, A2, and A3 appear in the second cluster of Table I.

In a similar fashion we augment the resolution of the algorithms by including additional predictors as shown in the following three progressively complex cases:

w = A0 + A1*DELTAV + A2*DOFS + A3*DOFB
+ A4*AGE + A5*BELT + A6*BEBA (8)

w = A0 + A1*DELTAV + A2*DOFS + A3*DOFB
+ A4*ROLL + A5*FRPAX + A6*RRPAX
+ A7*AGE + A8*BELT + A9*BEBA (9)

w = A0 + A1*ONEVEH + A2*BIGTRK + A3*ROLL
+ A4*DELTAV + A5*GADSP + A6*GADSNP
+ A7*GADB + A8*MAXC + A9*INTRU
+ A10*CURBWT + A11*FRPAX + A12*RRPAX
+ A13*BELT + A14*BEBA + A15*AGE
+ A16*FEMALE + A17*OCCWT + A18*OCCHT
+ A19*ENTRP + A20*EJC + A21*EJP (10)

where in addition to predictors defined earlier,
AGE = occupant's age in years continuously;
BELT = 1 if a safety belt is in use; else BELT=0;
BEBA = 1 if an air bag deploys in addition to a safety belt in use; else BEBA=0;

ROLL = 1 if car rollover occurs; else ROLL=0;
FRPAX = 1 if the occupant is in front seat right; else FRPAX=0;
RRPAX = 1 if the occupant is in rear seat; else RRPAX=0; if FRPAX=RRPAX=0 then we deal with the driver;
ONEVEH = 1 if this is a single car crash; else ONEVEH=0;
BIGTRK = 1 if the collision partner is a big truck; else BIGTRK=0; if ONEVEH=BIGTRK=0 then the collision partner is a car;
GADSP = 1 if the damage area is on the car's side and includes the passenger's compartment; else GADSP=0;
GADSNP = 1 if the damage area is on the car's side but excludes the passenger's compartment; else GADSNP=0;
GADB = 1 if the damage area is rear; else GADB=0;
MAXC = maximum crush, in inches continuously;
INTRU = 1 if 6 inches or more intrusion occurs in the front compartment; else INTRU=0;
FEMALE = 1 if the occupant is female; else FEMALE=0;
OCCWT = occupants weight in lbs continuously;
OCCHT = occupants height in inches
ENTRP = 1 if entrapment occurs; else ENTRP=0;
EJC= 1 if a complete ejection occurs; else EJC=0;
EJP=1 if a partial ejection occurs; else EJP=0; if EJC=EJP=0 then No Ejection Occurs.

Numerical values for the coefficients appearing in relations (8), (9), and (10) may be found in the third, fourth, and last cluster of Table I, respectively.

Note in the results shown in Table I that most predictors are binary, except for such predictors as Delta V, Age, etc which are continuous variables. The magnitude of coefficients for such continuous predictors must be interpreted in conjuction with the units of their measurement. Thus the coefficient value of 0.177 for Delta V in Table I (A) goes along with a Delta V in mph. It represents the increase per mph of the corresponding term in the algorithm. Similarly coefficients associated with: age, maxc, curbwt, occwt, and occht elsewhere in the cited Table must be interpreted on a basis of: per each year of age, per each inch of crush, per each 100 lbs of car curb weight, per each lb of an ocupant's weight, and per each inch of an occupant's height, respectively.

GOODNESS OF FIT AND PREDICTED V. OBSERVED OUTCOMES

A car's crash severity, Delta V, is such a strong determinant of occupant casualty outcome that it covers most of the variability observed in the field experience with relatively small errors. See for example Table I (A). Nevertheless, both the predictive resolution of an algorithm, and the goodness of the fit to the field data improve as further predictors are included, even if they are less influential than Delta V.

However beyond a certain point, diminishing returns become evident as may be seen in the progression of algorithm complexity, from (A) to (E) in Table I. As more predictors are included in the analysis, some prove to be quite marginal, given that the error of their coefficient assumes values comparable to the coefficient proper. Thus caution is recommended in order to avoid misleading results and conclusions.
Except for predictors with coefficient errors approaching the coefficient values, all predictors and all algorithms shown in Table I have been found statistically highly significant, on the basis of various statistical scores. Said algorithms account for most of the variability observed in the field experience. Discernible improvements are evident as one progresses from (A) to (C) in Table I, but beyond that point, further improvements are marginal and they may be misleading.

Quantitatively speaking, the bottom line for taking or not taking into account the influence of a predictor is the magnitute of the error relative to the coefficient of the predictor at stake.

In addressing the association of predicted probabilities of a certain outcome with actually observed outcomes we determined that the percentage of correct predictions varies from about 75% to 96%, depending on algorithm complexity and severity of predicted outcome. In addition, we used a score known as Somer's D that measures association on a 0 to 1 scale (no

association to perfect association). For the algorithms that project probability of fatality (A to E in Table I) the cited indicator was found to have values: 0.686, 0.727, 0.801, 0.803, and 0.850, respectively. The corresponding values for MAIS 3+ outcome are: 0.587, 0.626, 0.686, 0.691, and 0.748, respectively.

NUMERICAL APPLICATIONS & ILLUSTRATIONS

The probability of fatality among towaway crash involved car occupants, without any further qualification, is about 0.6%. For injured occupants at MAIS 3+, or at MAIS 2+ the probability is: 6.8% and 14.7%, respectively. These may be considered as alternative statements for casualty rates per 100 occupants.

Each of these rates may be resolved by crash severity, Delta V, with the help of algorithm (6). The results of this resolution are shown in Fig. 1. Further resolution, i.e. by direction of force in addition to Delta V, is provided when algorithm (7) is applied. Figure 2 illustrates results relevant to MAIS 3+. A similar algorithm may provide resolution by Delta V and restraint use and type. Results concerning MAIS 3+ are illustrated in Fig. 3. Resolution by Delta V and occupant's age is illustrated in Fig. 4.

The results obtained via relatively simple algorithms, as illustrated in Figs 1 to 4, could equally well and perhaps more appropriately be obtained from more complex algorithms that encompass the predictors at stake in the cited figures, plus additional predictors that could be influential.

More complex algorithms can be applied for obtaining results concerning one or a few predictors of immediate interest, with stipulated values. In practice this method is applied to a multi-predictor algorithm by assigning to predictors, other than those of immediate interest, their mean values on the basis of the field experience. The advantage of using this more cumbersome method is that the additional predictors are frozen at values common to the entire population under consideration, something that helps minimize possible confounding effects. It is also understood that no additional predictors should be entertained unless they have statistically significant coefficients, i.e. small errors.

MULTI-PREDICTOR ALGORITHMS

Very long and cumbersome algorithms may result if one insists on including many interesting and available predictors, even if all are statistically significant. Applications and results may become intractable. For this reason we developed a good approximation to the projection of a casualty probability on the basis of a known coefficient, without having to make a full application of a cumbersome algorithm. As a first approximation, the following relation holds:

DeltaP = P*(1-P)*A (11)

where DeltaP is the casualty probability increment resulting from the inclusion of a predictor with coefficient A, in any case where a probability P has been projected in the absence of said predictor. Note that in relation (11) the probability P and the increment DeltaP are on a 0 to 1 basis, as opposed to 0 to 100%. Also note that the increment becomes a reduction when coefficient A is negative.

It is evident that the increment or reduction varies from zero, at P=0, to a maximum at P=0.5, and back to zero at P=1. For convenience, relation (11) is graphically illustrated in Fig. 5, for four different values of regression coefficients: 0.25, 0.50, 1.0, and 2.0. Other values are readily obtained by interpolation.

The primary application of (11) is to assist in the quantification of effects described by the coefficients of multipredictor algorithms, such as those appearing in Table I (D) and (E). It is evident that (11) should be applied stepwise, especially when an one step application leads to the absurd result of (P+DeltaP) > 1. For the same reason (11) is applicable to individual evaluations, as opposed to an evaluation of several influences combined.

REVIEW OF THE RESULTS

It is informative to review the numerical results obtained by the algorithms in this paper, in comparison with results known from earlier and independent studies concerning factors that

influence the rates, or probabilities, of casualty. Note, for example in Fig. 1, that the probability of MAIS 3+ is about 50%, consistent with a widely held benchmark.

Resolution by direction of force, see Fig. 2, shows the 8-10 and 2-4 O'Clock impacts to dominate the threat of serious casualty, with the 11-1 O'Clock impacts second, and the 5-7 O'Clock impacts in the familiar distant third rank.

As recognized in several restraint effectiveness studies, the effectiveness of restraints is about 50% from about 10 or 15 mph DeltaV to about 30 mph. Thereafter, the effectiveness starts declining and becomes negligibly small at high crash severities. This is readily evident in the algorithm results shown in Fig. 3.

The small superiority seen for "belt & air bag" v. "belt only" in Fig.3 is actually substantially larger when the results are controlled for possible confounders beyond crash severity only. This is evident in the relevant coefficients appearing in multi-predictor algorithms such as those shown in Table I (C) to(E).

Furthermore, by comparing the relevant restraint coefficients as a function of casualty severity, it appears that the superiority of "belt & air bag" v. "belt only" is dominant at high casualty severities, e.g. fatalities or MAIS 3+, but declines at lower severities, e.g. MAIS 2+. This situation, although still confused by the accompanying statistical uncertainties, is consistent with the notion that the air bag is very effective in preventing high severity injuries although it may cause lower severity injuries.

The multipredictor algorithm (10), with coefficients shown in Table I (E), reveals quantitatively several factors of strong influence, fully consistent with qualitative notions held intuitively. Beyond Delta V, age, and restraint use or type discussed earlier, strong influences are seen here associated with rollover, ejection (whether complete or partial), with entrapment, intrusion, and maximum crush. Recall that positive coefficients are associated with an increase of casualty probability that may be approximately, and one at a time, estimated via (11).

Such an estimation is illustrated in Fig. 6 for the strong influences cited above. Most other influences, as implied by their coefficients in Table I(E), are either weak when considered in conjunction with strong influences, or are not significant in view of the accompanyig standard error.

CONCLUSIONS

Research reported in this paper, although still not fully mature, provides useful applications in succinct and insightful descriptions of the car crash environment. In adition, several further applications may be anticipated. For example, practitioners of post-crash emergency care for traffic accident casualties, from emergency vehicle dispatch centers to trauma centers and hospitals, could benefit from ways of projecting casualty severity on the basis of a crash signature.

Such adjunct information could supplement anatomical and physiological information, currently used, in order to enhance the timeliness and appropriateness of emergency care decisions. This is especially applicable if the additional information becomes available at crash time, well before the emergency care complex is fully activated. Essentially, the advent of high tech, low cost sensors and electronics that may soon be carried on cars and other vehicles, could allow the transmission, at crash time, of crucial information concerning crash circumstances, crashed vehicle(s), and crash involved occupants.

Irrespective of electronic acquisition of crash signatures at crash time, as discussed above, very similar information could be retrieved and transmitted by emergency attendants after they reach the crash scene. It becomes then a matter of translating this information into data useful to dispatch and emergency teams, either ready to attend the accident scene, or preparing for appropriate treatment(s) in emergency facilities. This paper has addressed and evaluated the state-of-the-art in translating advance notification data, either from vehicle mounted sensors at crash time, or from emergency attendants at the scene.

Injury Mechanisms and Field Accident Data Analysis in Rollover Accidents

ABSTRACT

Rollover accidents are responsible for a significant percentage of crash injuries. Increasing seat belt restraint use is the most effective way to reduce rollover injuries. Injuries to restrained occupants are also of interest. It has been suggested that head/neck injuries are caused by roof crush, and that modification to roof structures and seat belt systems would lead to a substantial reduction in severe rollover injuries. Field accident data and rollover testing are used to evaluate the relationship between roof crush, seat belt design, and severe rollover injuries.

INTRODUCTION

Rollover accidents are one of the most dangerous types of accidents, in terms of either fatalities or incapaciting injuries per occupant [NHTSA, 1992]. Table 1 compares the distribution of occupants, the distribution of Harm, and the Harm per occupant by accident type using 1988-1994 National Accident Sampling System (NASS) Crashworthiness Data System (CDS) data. Harm is a method developed by the National Highway Traffic Safety Administration (NHTSA) for weighting injuries according to their severity and their frequency [Mallarias, 1985]. Only 8% of occupants in this file were involved in a rollover, but their resulting injuries accounted for 17% of the total Harm. This phenomenon is attributable, at least partially, to the higher incidence of ejection in rollover accidents. Ejected occupants have a much higher likelihood of serious injury compared to occupants who are retained in the vehicle. The nature of rollover accidents result in more ejections than other accident modes.

SEAT BELT EFFECTIVENESS IN ROLLOVER ACCIDENTS

Seat belt restraints demonstrate their highest effectiveness in rollover accidents because they essentially eliminate the ejections that would otherwise occur. It has been estimated that rollover casualties could be reduced by as much as 75% if all occupants used safety belts [Felrice, 1992]. Evans, using Fatal Accident Reporting System (FARS) data, found an overall seat belt effectiveness of about 40% (in reducing fatalities) for front seat occupants [Evans, 1991]. The effectiveness in rollover accidents, however, was 68% for all vehicles that experience rollover, and almost 80% for vehicles whose first event was a rollover. The higher effectiveness in rollover accidents was attributed to the seat belt's ability to prevent occupant ejection. Table 2, (from Evans, 1991), shows seat belt effectiveness broken down into two components: 1) the portion of effectiveness attributable to ejection prevention, and 2) the balance of the effectiveness. This latter category represents the reduction of fatal impacts with the vehicle interior.

	OCCUPANTS	HARM	HARM PER OCCUPANT
FRONT	43 %	37 %	2.2
SIDE	23 %	30 %	3.4
REAR	8 %	2 %	0.8
ROLLOVER	8 %	17 %	5.9
OTHER	5 %	10 %	5.5
UNKNOWN	13 %	4 %	0.9
TOTAL	100 %	100 %	

TABLE 1
DISTRIBUTION OF OCCUPANTS, HARM, AND HARM PER OCCUPANT BY ACCIDENT TYPE [1988 - 1994 NASS CDS].

The dramatic influence of seat belt restraints on Harm reduction in rollover accidents is also evident in the NASS CDS 1988-1994 data. Table 3 presents the distribution of occupants, the distribution of Harm, and the Harm per occupant for vehicles which have rolled over. While 61% of the occupants in this sample were belted, their injuries accounted for only 27% of the Harm.

	OVERALL FATALITY REDUCTION	REDUCTION FROM EJECTION PREVENTION	REDUCTION FROM IMPACTS WITH VEHICLE INTERIOR
ALL ACCIDENTS	41%	18%	23%
ROLLOVER ACCIDENTS	68%	50%	18%

DISTRIBUTION OF OCCUPANTS, HARM AND HARM PER OCCUPANT IN ROLLOVERS BY RESTRAINT USE.
[1988 - 1994 NASS CDS]

Partyka evaluated serious and fatal injuries to rollover occupants in the 1982-1989 NASS and CDS [Partyka, 1991]. As expected, the effect of seat belts was dramatic. Unrestrained occupants were 4.7 times more likely to be seriously injured than restrained occupants. In addition to preventing ejection, the data indicated that seat belt restraints also provide substantial benefits to non-ejected occupants in rollovers. Unrestrained, non-ejected occupants received serious injuries six times more often than restrained occupants. In fact, the number of serious and fatal injuries to belted occupants was so low that detailed analysis was difficult. For the 7 years of NASS data studied, there were only 77 restrained rollover occupants with AIS 3+ injuries and detailed injury data, and only 51 restrained, unejected, fatal occupants with injury information. For these 128 occupants, the most frequently injured body region was the torso, followed in order by the head, limbs, and the neck. The 5 most frequently occurring combinations of injured body region and its vehicle contact source are shown in Table 4.

Partyka noted that the restraint system itself was the highest ranked injury/contact source. However, it was noted that most of the restraint system induced injuries occurred in very severe accidents where unrestrained occupants would likely have received injuries at least as severe. Table 5 presents national annual estimates of serious injuries to belted occupants in rollovers, (from Partyka, 1991). Note that less than 8% were head or neck injuries from roof area contacts.

ROOF INTRUSION AND RESTRAINED OCCUPANTS IN ROLLOVERS

Much attention continues to be focused on the effect of roof crush and restraint system design on head/neck injuries, even though these injuries account for only a small

portion of the severe injuries experienced by restrained occupants in rollover accidents. It has been suggested that if restraint systems were designed to keep the pelvis tight against the seat cushion, minimizing vertical head excursion, there would generally be sufficient head room to prevent head to roof contact in rollover accidents, thus significantly reducing rollover injuries.

The actual relationship between roof intrusion and occupant injury is much more complex. Intrusion generally refers to a reduction in occupant compartment volume due to collision deformation. Intrusion can occur in all accident modes (frontal, side, rear, rollover etc,) and in any primary direction (vertical, lateral or longitudinal). Intrusion may be causally related to injury in four ways:

1. The intruding surface can move to a new location where there may be an occupant contact that would not otherwise occur.

2. The intruding surface can change shape or increase in stiffness, which may result in a more hostile contact configuration.

3. The occupant can contact the intruding surface while intrusion is taking place, increasing the local contact velocity between the occupant and the intruding surface.

4. In extremely severe cases, the intrusion can "crush" or "squeeze" the occupant between two surfaces.

While intrusion may be causally related to injury in some instances, it is somewhat misleading to talk about intrusion when the deformation is due to contact with a fixed object such as a tree or the ground. When "intrusion" occurs as a result of contact with a fixed object, the contact velocity between the occupant and the contact surface does not increase. The intruding surface does not move to a different location. It simply stops against the ground, tree, or other fixed object. When a vehicle goes sideways into a tree, the door comes to a stop against the tree, while the rest of the vehicle continues to move and deform around the tree. Thus, the door does not move or intrude into the occupant space, it is at rest. The occupant impacts and comes to a stop against the arrested door and/or the tree. The velocity of the occupant relative to the tree is simply the occupant's pre-impact velocity, regardless of whether or not the vehicle sustains "intrusion". This contact velocity is not increased as "intrusion occurs," nor is the location of the occupant contact altered by intrusion. In fact, if an injury occurs, it likely occurs before the "intrusion" takes place. The same is true of roof intrusion caused by ground contact. The roof hits the ground and stops in the vertical direction; the occupant hits the ground with the roof structure sandwiched between. Other parts of the vehicle often continue to move toward the ground resulting in "roof crush," but neither the occupant/roof contact velocity nor the location of contact are affected by the subsequent deformation.

FIELD ACCIDENT DATA, ROOF CRUSH, AND INJURIES

If there is a causal relationship between roof crush and head/neck injury, one would expect to find a correlation in the field accident data. However, establishing a <u>causal relationship</u> between intrusion and injury requires more than just finding a <u>correlation</u> [Strother, 1984]. There are many confounding factors in current field accident data bases which make it difficult to determine whether a correlation exists. The most significant limitation is the inability to account for differences in rollover crash severity. It is reasonable to assume that the likelihood of injury in a rollover accident increases as the accident severity increases. Digges and Klisch attempted to establish a measure of accident severity by evaluating the hard copy files of 140 single vehicle rollover accidents contained in the 1988-89 NASS CDS [Digges, 1992]. Factors such as roll type, trip force and roll rate at trip were evaluated. No reliable measure of rollover crash severity was found which could distinguish the 140 cases studied, or which could be used to distinguish rollover accidents in general.

Over the years, many field accident data studies have looked for, but have not found, a correlation between roof crush and injury [Mackay, 1970; Huelke, 1972; Wilson, 1972; Provensal, 1982; Strother, 1984; Plastiras, 1985; Biard, 1989]. Three recent studies claim that a correlation does exist, and claim it is evidence of a causal relationship. These studies, as well as two additional recent studies which found no correlation, will be briefly reviewed.

Friedman and Friedman performed a "limited" analysis of the 1982-1983 NASS data and claimed to have found a 4 to 1 increase in the risk of injury when the occupant is in the proximity of roof crush [Friedman, 1985]. It was acknowledged by the authors that prior evaluations of field accident data had not found a correlation; they attributed their unique findings to a methodology that matched the location of roof crush to the location of the occupant. Their methodology used the Collision Deformation Classification (CDC) to categorize roof crush location [SAE, 1980]. The intent was to isolate occupants who were seated in the area of roof intrusion and to determine whether they had a higher injury exposure than occupants who were not seated in the area of roof intrusion. However, essentially all of the occupants were categorized as "near" the roof crush. This methodology did not distinguish "near" and "not near" occupants -- they were virtually all categorized as "near." Careful analysis revealed that the "correlation" found by Friedman was not the result of matching the location of roof crush with the occupant's location, it was simply a result of failing to take into account important variables such as ejection, seat belt use, injury type, and accident severity [James, 1995].

More recently, Rains and Kanianthra evaluated head, neck and face injuries, and their relationship to headroom reduction [Rains, 1995]. The study was limited to non-ejected, properly restrained front seat occupants in vehicles which rolled at least 180 degrees and experienced no additional impacts. A total of 155 such cases were extracted from the 1988-92 NASS CDS data. Only head, neck and face injuries from contact with upper interior sources were evaluated. A methodology was developed to estimate headroom reduction, using vehicle measurements, occupant's recorded height, and roof intrusion measurements. There were too few data to evaluate the magnitude of headroom reduction vs. injury severity, therefore, occupants were categorized as either "injured" or "uninjured." Almost 80% of the "injured" occupants experienced only AIS 1 injuries. A correlation was suggested between these minor injuries and headroom reduction, although the authors noted that the confounding effects of other important factors, such as accident severity, were not accounted for and might be responsible for the correlation.

The intent of the previously-referenced 1992 Digges study was to establish some measure of crash severity for rollover accidents so that the effect of factors such as roof

crush could be evaluated. They were unable to establish a crash severity measure, but curiously found that: "There seems to be a correlation between roof crush and fatality rate, and it is likely that strengthening the roof would aid in reducing fatalities in rollovers" [Digges, 1992]. The "correlation" was established by grouping 173 non-ejected occupants from the 140 serious accident cases into 2 groups: occupants in a vehicle with top damage CDC extent 4-5, and occupants in a vehicle with top damage CDC extent 6-7. The "correlation" is based on the fact that 5% of the occupants in the CDC extent 4-5 vehicles received fatal injuries, while 20% of the occupants in the CDC extent 6-7 vehicles received fatal injuries. There were only 14 non-ejected fatal occupants in the study, and only 2 of them were restrained. 85% of the fatalities used to establish the "correlation" were not restrained. There is no information provided about the injuries, or whether the injuries might be related to roof crush. More importantly, there was no measure of accident severity with which to categorize these cases. All of these accidents involved severe roof crush, CDC extent 5 being roof crush to the level of the window sill. The most interesting finding from this study was not this alleged "correlation" but the finding that, in these vehicles with roofs crushed down to the beltline and beyond, the average injury severity for non-ejected, restrained occupants was only AIS 1.2 (minor-moderate injuries).

In a second study by Partyka, the injuries experienced by drivers in vehicles with roof intrusion were evaluated using data from the 1988-1990 NASS CDS [Partyka, 1992]. Vehicles were evaluated that rolled at least 180 degrees, had roof intrusion in the driver's seat area, and in which the driver received some injury from contact with the intruding roof. Approximately 80% of the drivers in these cases received only minor injuries. In fact, most injuries from contact with the roof, when the intrusion magnitude was less than twelve inches, were minor injuries. Only in cases when roof intrusion magnitude was greater than twelve inches were the majority of the injuries severe. In the three years of accident data evaluated, there were 918 drivers in vehicles that had rolled at least 180 degrees and had vertical roof intrusion. They represented 280,121 weighted drivers, of which only 0.6% had AIS 3+ injuries from contact with roof structures.

It was determined by Partyka that these data were insufficient to establish whether intrusion increased either the frequency of injuries or the severities of injuries. Several data limitations were noted: (1) the magnitude of roof crush likely reflects crash severity and there is no way to adjust injury rates for differences in crash severity, (2) it is not possible to estimate the number of times occupants contacted the intruding roof structures when injury did not occur, since only contacts resulting in injury are recorded, (3) it is not possible to determine the percentage of occupant contacts with non-intruded roof structures that do not result in injury, and (4) because injuries do occur when occupants contact non-intruded roofs, preventing roof intrusion may not necessarily prevent injury from roof contact. The author went on to note that "while these data describe the frequency of roof intrusion and the associated injuries, they do not indicate how reductions in intrusion frequency or severity would affect injury frequency and severity."

The most comprehensive study made to evaluate the correlation between roof crush and head/neck injury was performed by Moffatt and Padmanaban in 1995 [Moffatt, 1995]. This study examined 60,758 single vehicle rollovers, involving 96,154 occupants, using police reported data from Florida, Texas, Michigan and North Carolina. Using data from police reports avoids the problem of limited sample size in the NASS, but the cases provide less information with less reliable descriptions about the accident and the injuries. Nevertheless, what makes this study particularly unique is that the roof strength (from FMVSS 216 tests) was known for each of the accident vehicles.

Injury data from police reports is coded using the KABCO scale (K = fatal injury, A = incapacitating injury, B = non-incapacitating injury, C = possible injury, O = no injury). Each occupant injury is estimated by the police officer at the time of the accident. Only rarely is there a follow-up evaluation after the occupant has received medical treatment. Of the occupants in the police report data used by this study, 128 were also investigated in the NASS program. The reliability of police report injury data could therefore be evaluated by comparing the NASS injury data to the police report injury data for these 128 cases. The police report injury assessment agreed with the NASS injury assessment in 69% of the cases. Evaluation of the nearly 100,000 occupants found no relationship between roof strength and the likelihood of severe injury. Equally interesting was the finding that there was no relationship found between roof strength and the likelihood of severe roof damage.

CRASHWORTHINESS DATA SYSTEM (CDS) ANALYSIS

The second Partyka study [Partyka, 1992] examined the effect of roof intrusion in the first three years of NASS CDS (1988-1990) data. The CDS data contain information about the ten most severe intrusions in each vehicle. The information includes the location of the intrusion (by occupant seated position), the intruding component, the magnitude of intrusion, and the direction of intrusion (vertical, longitudinal or lateral). Injuries that are associated with any intruding component are also coded.

There are now 7 years of accident data available (1988-1994). There are 3,102 restrained, non-ejected occupants, 12 years of age or older, who were in rollover accidents. They represent a national estimate of 1,081,510 "weighted" occupants. Of these, 2744 occupants (990,363 weighted) were seated under vertical intrusion of either the roof or some other upper interior structure (roof side rail, front windshield header or back light header).

Table 6 summarizes these data and shows the number of occupants with severe (AIS 4+) injuries for each

category. The percentage of occupants with severe injuries is smaller for the subgroup of occupants who were seated under vertical roof intrusion. The Harm per occupant has also been computed as is shown in Table 6. Again, the

TABLE 6
OCCUPANTS IN ROLLOVER ACCIDENTS (12+ YEARS OLD)
[NASS CDS 1988-1994]

occupants seated under vertical roof intrusion experienced a lower overall Harm. These findings are consistent with the numerous studies which have found no correlation between roof crush and injury. Note that these findings are based on the methodology proposed by Friedman, i. e. matching the occupant location to the intrusion location. However, in contrast to Friedman's analysis, the analysis of the new CDS data shows no correlation. Friedman's analysis did not separate restrained from unrestrained occupants, and was made using the older NASS data, which does not contain detailed intrusion information. A total of 41 occupants (6743 weighted) seated under vertical roof intrusion sustained a MAIS 4+ injuries. These cases were examined in more detail. The roof intrusion was not always coded as the source of the severe injury. In fact, only 16 occupants (1590 weighted) received their severe injury from contact with a roof that had sustained vertical intrusion. Table 7 summarizes the data for occupants seated under vertical roof intrusion. Only 0.2% received severe injuries from the intrusion. The data indicate that for restrained occupants in rollover accidents, there is no correlation between roof crush and injury. The data also show that injuries associated with vertical roof intrusion do not represent a large portion of severe rollover injuries.

[NASS CDS 1988-1994]

TEST DATA

There are very few well-documented staged rollover tests with restrained dummies in which occupant kinematics and injury mechanisms can be evaluated. Real world rollovers include a large number of trip mechanism variations. It is difficult to simulate all of these trip mechanisms during testing. The dolly rollover procedure developed for FMVSS 208 is most often used because it provides a measure of control over the trip location and the vehicle roll direction. It does not, unfortunately, simulate the occupant motion prior to and during the trip phase. In spite of the controlled initial conditions and trip mechanism, the timing and location of specific vehicle/ground contacts and the resulting roll motion of the vehicle during staged testing are not repeatable. Another limitation of rollover testing is that the biofidelity of dummies in the rollover test mode has not been established, nor has there been development of appropriate vehicle and dummy instrumentation to measure all of the variables of interest. Nevertheless, full scale rollover tests with restrained dummies do provide valuable insights about general occupant kinematics and injury mechanisms.

The most comprehensive rollover test series was conducted by Bahling, et al. and is often referred to as Malibu II [Bahling, 1990]. A total of 8 1983 Malibu 2-door vehicles were rolled using the FMVSS 208 rollover procedure. Four tests were performed using vehicles equipped with production roof structures and four tests were performed using vehicles with roll cage reinforced roof structures. In each test, instrumented Hybrid III 50th percentile male dummies in the front outboard seats were restrained with the production 3-point belt system. Belt slack was added so that the dummy's static vertical excursion in an inverted vehicle was essentially the same as that measured when three human volunteers were inverted in the same vehicle. The average excursion measured with the volunteers was 9.9 cm (3.9 in.). All of the tests were passenger side leading, with a velocity of 51.5 km/hr (32 mph). The roll motion in each test was different, ranging from 3 to 4 rolls; the run out distance varied from 22.6 meters (74 feet) to 31.1 meters (102 feet). A pronounced difference in the roll motion was noted between the production roof vehicles and the roll cage vehicles. During the first passenger ground contact with the passenger side roof rail, the roll cage vehicle roof deformed less causing the vehicle's center of gravity to follow a higher trajectory as the vehicle continued its roll. This resulted in the driver's side roof rail of the reinforced vehicles making fewer ground contacts compared to vehicles with production roofs.

Immediately after trip, while the vehicle was airborne, centrifugal force caused the dummy to move upward and outward to the extent allowable by the lap belt and vehicle interior. Both dummies' heads tended to remain against the roof side rails, and moved away only when the vehicle's velocity was altered by significant ground contact. When the roof contacted the ground, the head adjacent to that side of vehicle generally maintained its orientation relative to the roof and roof rail, and was decelerated with the portion of the roof in contact with the ground. The head on the opposite side from the ground contact generally moved towards the impacted side of the vehicle. Wheel

contacts with the ground also altered the vehicle's velocity and caused dummy motion. For example, when the right side tires contacted the ground, the near-side passenger dummy leaned against the door, and often tried to go out the window, while the off-side driver dummy moved laterally inboard, rotated out of the shoulder belt, and loaded the lap belt. The buttocks of both dummies came off the seat cushion early in the test and never returned to the original seated position until the end of the test. There was no indication of a "squeezing" injury in any of the tests, regardless of the extent of roof crush.

In comparing the performance of the production roof vehicles to that of the roll cage vehicles, the researchers considered a peak neck compression load in excess of 2000 N as a "potentially injurious impact (PII)." Table 8 shows the distribution of PII's using this criterion. The higher frequency and severity of trailing roof rail PII's to the driver dummy are the consequence of the substantially different vehicle roll motion between vehicle types, which results in fewer trailing roof rail ground contacts to the roll cage vehicles.

The established Hybrid III neck injury criteria for compression loading is not based on peak neck load; it is a function of both the magnitude of the load and the duration of the load. See Figure 1 [Mertz, 1994]. Using the established Hybrid III injury criteria as the basis for PII produces the distribution shown in Table 10. There is no significant difference between the number of PII's with each vehicle type. However, comparing the frequency and severity of PII's in the production vehicles to the roll cage vehicles should not be used as the sole basis of evaluation. The stark difference in frequency and severity of roof contacts experienced by the two vehicle types can make direct comparison of PII frequency misleading. Table 11 shows the number of missed roof contacts and the number of roof contacts with no associated PII's for the production roof and roll cage vehicles. One would expect to see more PII's with the production roof vehicles because they experienced more roof/ground contacts.

Proper analysis of these tests would categorize the specific neck loading circumstances experienced by the dummies in both types of vehicles and determine whether

	PASSENGER LEADING ROOF RAIL	LEFT ROOF PANEL	DRIVER TRAILING ROOF RAIL	NON ROOF-TO-GRND CONTACTS	TOTAL

MALIBU II TEST SERIES:
DISTRIBUTION OF POTENTIALLY INJURIOUS IMPACTS
USING PEAK NECK COMPRESSION LOADS OF 2000 N

Friedman has presented a different analysis of the Malibu II data in which he claims that the performance of the production roof vehicles was substantially worse than the performance of the roll cage vehicles [Friedman, 1991]. He used a peak neck compression load of 4000 N as the criterion for a PII. He also evaluated the data using a criterion of 5000 N peak neck compression load plus 1000 N of concurrent shear force. Table 9 summarizes the PII's using these two criteria. Friedman claimed that his analysis of the Malibu II data demonstrates a causal relationship between neck injury and roof crush, since there are more PII's with production roof vehicles as compared to the roll cage vehicles.

roof crush made, or could potentially make, the loading circumstance more frequent or more severe. The preliminary analyses indicate that neck loadings can occur: 1) when there is no roof crush, 2) when there is only a few inches of roof crush, and 3) when there is substantial roof crush. There are only 2 instances (3L5 and 7L4) of neck loading with substantial roof crush (i. e., static crush in excess of 110 mm, 4.3 in) in the Malibu II test series. A detailed timing analysis of both of these instances was presented in the original study. The instrumentation and high speed film indicated that the neck loads occurred prior to the roof deformation. Therefore, the roof crush, even though substantial in magnitude, did not increase the frequency or severity of the loading circumstance.

TABLE 11
MALIBU II TEST SERIES

Another series of staged rollover tests was conducted by Sakurai et al. [Sakurai, 1991]. The series consisted of 12 ramp rollover tests using three different model vehicles. Each test was run at 50 km/hr (31 mph). The roll motion was developed by driving the right side tires onto a ramp while quickly generating right steer at the steering wheel, resulting in the vehicles rolling left side leading. Nine of the tests rolled one revolution, one test was one-half revolution, and the remaining two tests were one and one-half revolutions. The front seat outboard positions had instrumented Hybrid III dummies, restrained with three-point belts. As in the Malibu II tests, the centrifugal forces caused the dummies to move upward and outward to the extent permitted by the belts, even though the vehicle kinematics and trip mechanism were different for the two tests. The right dummy head moved into this position and remained there until the end of the test. The left dummy also moved upward and outward until its head was in contact with the roof rail. As the left roof rail contacted the ground, it stopped; the head also stopped, while the torso continued towards the head, axially loading the neck. The high speed camera and dummy instrumentation indicated that the peak neck compression load occurred prior to any substantial roof crush, a finding similar to that of the Malibu II test series.

A third series of rollover tests with restrained dummies was reported by Friedewald, [Friedewald, 1996]. These tests were conducted using the FMVSS 208 dolly rollover procedure. The vehicle instrumentation and high speed film were used to determine the contact forces between the ground and the vehicle roof structure. They found that the peak contact forces were similar in tests where the magnitude of roof crush was substantially different. The difference in roof crush magnitude was a function of contact duration, and not contact force. A series of tests were run with a production vehicle, and similar prototypes with both reinforced and weakened roof structures. The reinforced roof structures generated higher contact forces, and actually experienced larger crush magnitudes compared to the production and weakened roof structures. The roof crush magnitudes were a function of the rollover kinematics; reinforcement of the roof increased the contact forces, but had no influence on the roof deformations. (This finding is consistent with the finding by

Moffatt and Padmanaban, where the field accident data showed no correlation between roof strength and roof deformation.)

The Friedewald tests demonstrated dummy kinematics similar to that seen in both the Malibu II and Sakurai tests; the centrifugal forces caused the heads to move outward and upward until they are in contact with the roof rail above the door. The highest dummy loading occurred when the vehicle's rocker panel made ground contact, as opposed to roof/ground contact. The dummies in the two tests presented in the paper received loadings representing only minor injury.

HEAD EXCURSION WITH INVERTED VEHICLES - When a restrained occupant is inverted during a rollover accident, there will be motion of the head toward the roof. There are three forces acting upon the occupant to cause this motion: gravity, centrifugal forces, and vertical deceleration forces. The magnitude of vertical head excursions depends upon many factors including the restraint system geometry, belt slack, rotational velocity, vertical accelerations, occupant position, occupant body fat distribution, occupant spinal structure, etc. Vertical head excursion test data from two published studies, in addition to unpublished test data from Collision Safety Engineering, provide a basis for some preliminary assessments.

In 1995 Arndt et al. presented results of their efforts to minimize vertical head excursion in a rollover environment [Arndt, 1995]. Seven volunteers and a 95% percentile male Hybrid III dummy were statically tested in various configurations of lap belt angle, slack and pretension. The lap belts were not intended to represent an actual production restraint system. Rather, they were attached to an unpadded rigid seat that had no provisions for adjustablity. The lap belt was adjusted to either 2.5 cm (1.0 in.) of slack, 5.0 cm (2 in.) of slack, no slack with 64 N (14 lb) of pretension, 222 N (50 lb) pretension, or 444 N (100 lb) pretension. The force was applied by subjecting the subjects to a one G acceleration through simple inversion.

Two lap belt geometries were evaluated, one at 45 degrees and one at 90 degrees. A lap belt angle of 90 degrees is the most optimum angle for limiting vertical excursion, but it is inappropriate for frontal impacts. In fact, the FMVSS's do not allow lap belt angles of 90 degrees [CFR 571.210 S4.3.1.(b)]. The 444 N (100 lb) pretension is also "optimum" for limiting vertical excursion, but this load is much higher than what is typically used in production pretensioners. In fact, the 222 N (50 lb) pretension load caused enough pain for the human volunteers that no volunteer tests were performed with the 444 N (100 lb) pretension load. Therefore, the performance of the 90 degree lap belt with 444 N (100 lb) pretension is likely better than what can be expected of any practical production restraint system in terms of minimizing vertical excursion. Figure 2 shows the human volunteer and dummy excursion data for the 90 degree lap belt with 222 N of pretension and, the 45 degree lap belt with 222 N of pretension. The static

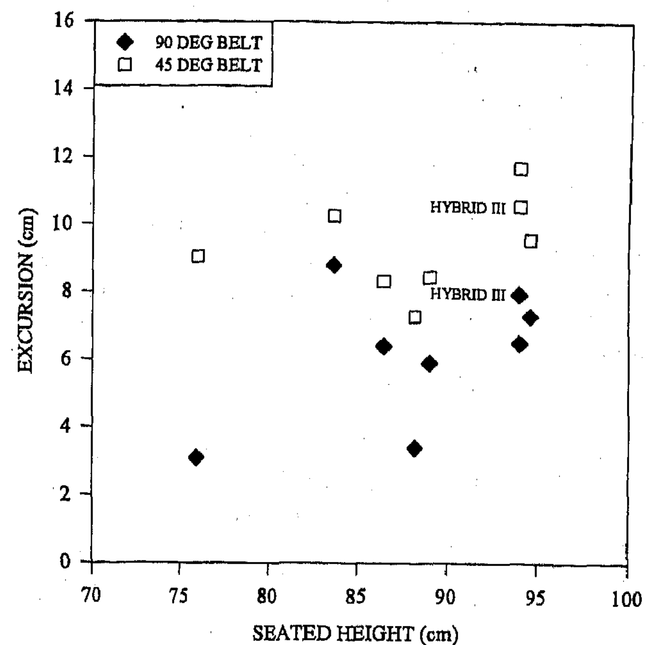

FIGURE 2
VOLUNTEER HEAD DISPLACEMENT VS. NORMAL SEATED HEIGHT
STATIC TEST, 222 N (50 lb) BELT TENSION
[ARNDT 1995]

Hybrid III dummy excursion for the 90 degree, 444 N (100 lb) pretension belt system is not given in the paper. Noting that the one G acceleration environment was unrealistically low compared to real world rollover accidents, the Hybrid III test dummy was subjected to a five G vertical acceleration pulse. The vertical head excursions were two to three times greater under these dynamic loading conditions. Figure 3 presents the dynamic head excursion for the 45 degree, 222 N system, the 90 degree, 222 N system, and the 90 degree 444 N system.

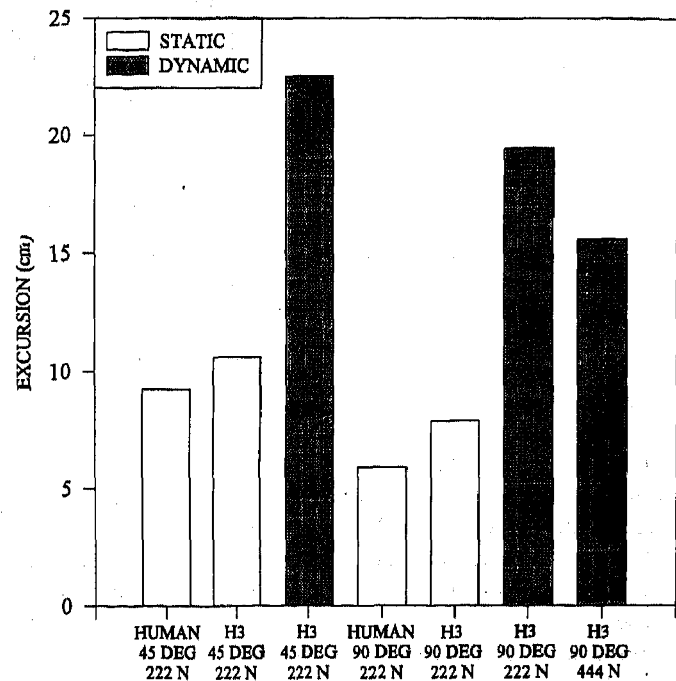

FIGURE 3
STATIC AND DYNAMIC EXCURSION
OF 95 % MALE HYBRID III DUMMY
[ARNDT 1995]

In 1996, Herbst et al. published the results of vertical head excursion testing [Herbst, 1996]. A seat buck was built to which different production vehicle seats and restraints systems could be attached. The buck was mounted in a rotisserie which inverted the seat for static excursion measurements, or the seat could be dynamically rotated at a rate of about 100 degrees per second. Three volunteers representing a 5th percentile female, a 50th percentile male, and a 95th percentile male were tested using three different production restraint systems. Belt slack was not measured, but the volunteers adjusted the belts to be comfortable. No webbing preload was used. Under the static one G acceleration condition, average occupant excursion for the small, medium and large volunteers was 14 cm (5.5 in.), 17 cm (7 in.), and 20 cm (8 in.) respectively. The geometry of each belt system was then reconfigured to minimize vertical head excursion. Figure 4 presents the static and dynamic vertical head excursion data for the production and the modified systems. Not surprisingly, the vertical head

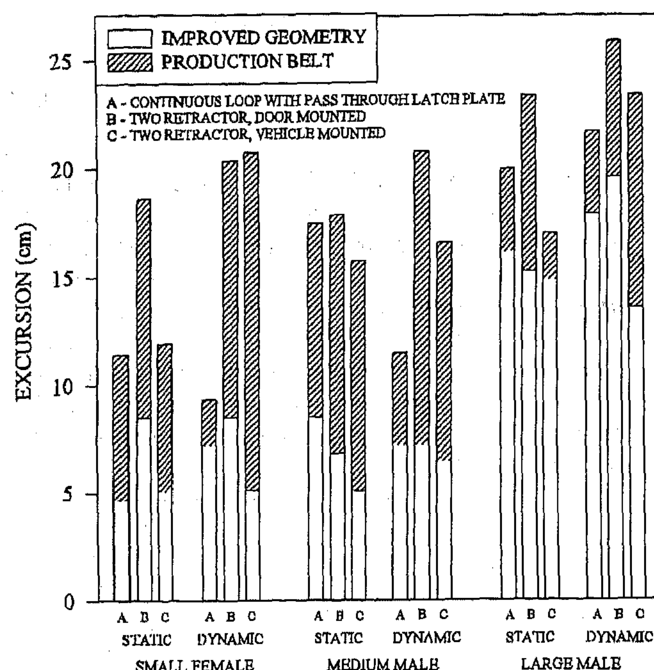

FIGURE 4
STATIC AND DYNAMIC VOLUNTEER VERTICAL EXCURSION TESTS
[HERBST 1996]

excursion magnitude was reduced by the modified system in every case. However, static excursions of 4.7 to 16.1 cm (1.9 to 6.3 in.) were still observed. There are some anomalies in the data which make the test procedure questionable. One would logically expect the dynamic excursions to be greater than the static excursions. However, the dynamic tests produced equal or less vertical head excursion than the static tests in about one third of the cases. One would also expect the larger volunteers to have greater excursions than the smaller volunteers. The 50th percentile male volunteer, however, had equal or less excursion than the 5th percentile female volunteer in one third of the tests. The dynamic data is difficult to interpret because the center of rotation and its relationship to each occupant is not given. The roll rate of 100 degrees per second is about one third of what was experienced in the Malibu II rollover testing. Due to the "squared" dependency of force upon rotation rate, one would expect the centrifugal forces to be approximately nine times higher on the occupants in a real world rollover situation. In the Arndt dynamic tests, only five times the force (5 G's) yielded two to three times the excursion. Two and a half times the modified excursion amounts in the Herbst tests yields excursion magnitudes of 12 to 40 cm (5 to 16 in.). These excursion magnitudes are sufficient for the head to make contact with the roof in almost all vehicles even without taking into account the impacts between the vehicle and the ground.

Ground Contact - Static rollover tests were conducted by Collision Safety Engineering, Inc., to analyze the relationship between occupant size, headroom, roof contact, and ground contact. The tests consisted of restraining human volunteers in several production vehicles and inverting the vehicle in a quasi-static roll motion. Test volunteers were a 5th percentile female and an 80th percentile male. It was observed that emergency locking retractors would lock before any significant occupant or seat belt movement had taken place. At the 135 degree position, an artificial ground plane was placed in contact with the vehicle roof rail as shown in Figure 5. The occupant was allowed to hang out the driver's door window, and the relationship of the occupant's head to the artificial ground

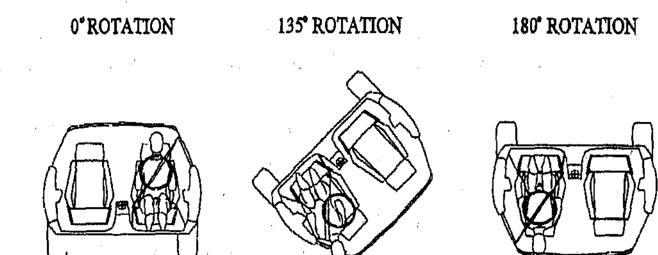

FIGURE 5
COLLISION SAFETY ENGINEERING
HEAD EXCURSION TEST PROCEDURE

was measured. In every case, the occupants head penetrated through the artificial ground plane from 1.2 cm (0.5 in.) to 6.5 cm (2.5 in.). Vehicle rotation then continued to 180 degrees, and the occupant was allowed to hang in the belts. In all cases involving the 80th percentile male, the occupant's head was in contact with the roof. The 5th percentile female contacted the roof in several instances, and was within an inch of the roof in all cases. This represented vertical head excursion of approximately 12.7 cm (5 in.) for each volunteer. Specific values, vehicle types, and measurements from the tests are listed in Table 12. Neither the occupant size nor the type of restraint system had any significant effect on the measured static excursion values. In essentially every tested configuration, the occupant's head went through the ground plane when the vehicle was at 135 degrees, and came in contact with the roof at 180 degrees, in a one G environment.

UNDER ONE G ACCELERATION

Discussion - While it may be possible to reduce vertical head excursion through restraint system design, it does not appear likely that head contact with the roof and roof rail can be eliminated, especially under dynamic loading conditions.. Dynamic testing with dummies suggests that excursions in excess of 20 cm (8 in.) can be expected even with restraint systems designed to minimize excursion. Dynamic excursions of humans will likely be greater than those of dummies because the human spine can straighten and actually elongate under vertical loading. Pretensioners will likely have little effect on vertical excursion magnitudes. They are designed to take up slack in the belt prior to occupant loading. Typical pretensioners exert 100-200 N (22 - 45 lb) of belt tension. In a rollover accident, the pre-trip deceleration of the vehicle will most likely cause the occupant to load the lap belt prior to the actuation of any sensor triggered by vehicle roll angle. If the occupant loads the lap belt with the force level of the pretensioner prior to actuation there will be no pretensioner effect. Pretensioners are not designed to "pull" the occupant back into position. Such a pretension would produce excessive forces and input energy.

Even if it were possible to keep the head from contacting the undeformed roof and roof rail in dynamic loading conditions, some roof crush will occur even with stronger roof structures. In fact, the data suggest that strengthening roof structures may not have a significant effect on roof crush magnitudes. It must also be remembered that eliminating head/roof contact will not eliminate head contacts; the head will simply go out the window and be exposed to ground contact. The lateral motion of the head cannot be ignored.

It is important to assess the performance of restraint systems in accident modes other than rollover before modifications are proposed to reduce vertical head excursions. Considerations must include the overwhelming greater frequency of frontal impacts, occupant size variations, comfort and convenience and its effect on usage rates.

CONCLUSIONS

Prior evaluations of field accident data have found no correlation between roof crush and injury. Recent studies have claimed to find a correlation and suggest that it indicates the existence of a causal relationship. These studies are flawed by either failing to distinguish restrained from unrestrained occupants, or by failing to distinguish between minor and severe injuries. Analysis of the recent NASS CDS field accident data are consistent with the finding that no correlation exists between roof crush and occupant injury. The CDS field accident data also suggest that there are few serious injuries associated with roof intrusion.

Rollover testing with restrained instrumented dummies indicates that centrifugal forces cause the dummies' heads to move upward and outward until they are in contact with, or in close proximity to, the roof prior to roof contact with the ground. When the roof contacts the

ground, peak neck compression loads occur prior to any substantial roof deformation.

The magnitude of roof crush is a function of the vehicle roll motion, which is different in every rollover event. Both field accident data analysis, and rollover testing have suggested that stronger roof structures do not necessarily result in reduced roof crush.

Current production seat belt systems can be modified to reduce vertical head excursion, but it is unlikely that head contact with the roof and roof rail can be eliminated. If head to roof contact could be eliminated, lateral motion of the head out of the window opening will expose the head to contact with the ground.

Measuring Head Restraint Force and Point of Application During Low-Speed Rear-End Automobile Collisions

Jonathan M. Lawrence, Gunter P. Siegmund, and Jeff S. Nickel
MacInnis Engineering Assocs.

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

In order to assess the head and neck kinetics of human subjects exposed to low-speed rear-end impacts, a method for measuring the magnitude and line of action of the force between the head and the head restraint was required. In addition to being accurate and repeatable, the design was required to maintain original seat back and head restraint geometry, mass, stiffness, and height adjustment. This paper presents a design using strain gauges applied to the head restraint tubes, upper seat back, and custom replacements for brackets attaching the head restraint to the seat back. The background theory and free-body analysis, the analog math circuitry, and a dynamic calibration procedure are presented. Overall force magnitude and line-of-action errors are quantified, and a sample output from a human subject undergoing a rear-end collision with a speed change of 8 km/h is presented.

INTRODUCTION

As part of an investigation into the kinematic, kinetic and muscular response of the human head and neck during a low-speed rear-end automobile impact, a means of measuring the force between the head and head restraint was required. To solve for reaction forces and moments at the atlanto-occipital joint, the head restraint contact force and its line of action were required. Mertz[1] conducted a similar analysis using a test sled with a specifically-constructed seat made of rigid planar seat and seat-back panels joined by a rigid hinge connection capable of rotating after a pre-set torque was reached. Mertz used two axes of a single tri-axial load cell to measure the head contact force and rigidly mounted the load cell to the seat back. As noted by Mertz himself, the shortcoming of this instrumentation arrangement was the difficulty determining the point on the head through which the head restraint contact force acted. He visually estimated the contact point from high speed video, but noted that the error in this method was "...large, and hence the computed values of head torque for cases in which the headrest was used are dubious...."

A specific goal of our study was to test human subjects in an actual seat in an actual automobile. Head contact with the head restraint was expected in most tests and therefore a method of predicting head restraint force magnitude and line of action relative to the head was needed. Figure 1 shows free-body diagrams of the human head and head restraint in the sagittal plane.

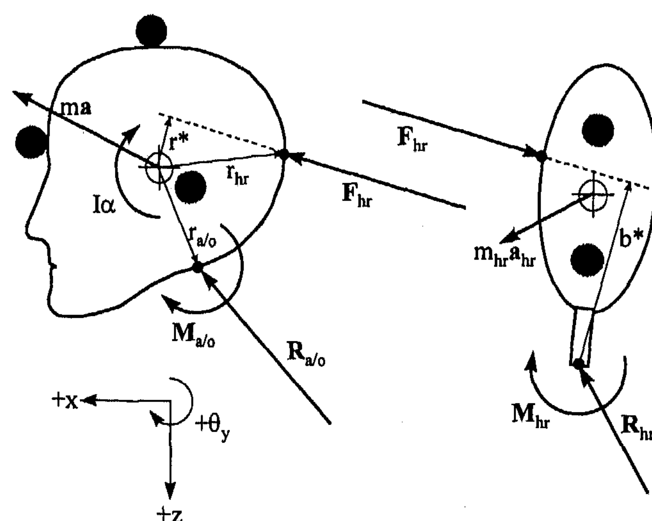

Figure 1. Free-body diagram of the head and restraint

To calculate $\mathbf{M}_{a/o}$ and $\mathbf{R}_{a/o}$, the following quantities are required: head mass m, head moment of inertia I, head linear acceleration at the center of mass $\mathbf{a}$, head angular acceleration α, the head restraint contact force $\mathbf{F}_{hr}$, and the position vectors from the center of mass to the head restraint contact point $\mathbf{r}_{hr}$ and the atlanto-occipital joint $\mathbf{r}_{a/o}$. Head accelerations can be determined from accelerometry and high speed video and resolved to an estimated position for the head center of mass. The head restraint force $\mathbf{F}_{hr}$ and the offset b* of its line of action is determined from measurements of the reaction force $\mathbf{R}_{hr}$ and reaction moment $\mathbf{M}_{hr}$ after inertial compensation for the head restraint mass. Using video targets (shown as gray circles in Figure 1) on both the head and head restraint, the line of action of the head restraint force can be mapped onto the head to determine $\mathbf{r}_{hr}$ or more importantly the moment arm r*. The other position vector $\mathbf{r}_{a/o}$ can be estimated from magnetic resonance (MR) films.

This paper describes a method of measuring the magnitude, direction and location of a force applied to an automobile head restraint. Although the kinetic analysis will be limited to the sagittal plane, the system was designed to measure three-dimensional forces and moments to confirm that non-sagittal-plane components were negligible. The design used strategically-applied strain gauges on the head restraint, head restraint supports, and upper seat back to build a custom 6-degree-of-freedom load cell using the seat structure. This type of design minimized changes to the head restraint geometry, mass, and stiffness, and allowed the head restraint height to remain adjustable.

The first part of this paper outlines the background and theory behind the design. Equations are then developed for two-dimensional and three-dimensional configurations as well as a least-squares calibration procedure. The accuracy and repeatability of the completed design are then assessed, followed by a sample data set from a rear-end collision with a speed change of 8 km/h.

Vehicle and Seat - The vehicle chosen for our tests was a 1990 Honda Accord LX sedan. Test subjects sat in the right front seat. A schematic of the Accord's upper seat back and head restraint is shown in Figure 2. The head restraint consists of a fabric cover over foam padding and a rigid plastic core. The top of an inverted U-shaped, chromed-steel tube is embedded in the rigid core and its two legs slide in plastic sleeves inserted into mounting brackets welded to the top of the seat back frame. The plastic sleeves clip into the metal brackets with tapered barbs on their lower ends. The outboard plastic sleeve is also screwed to the mounting bracket and has a spring-loaded latch which engages four notches in the U-shaped tube to lock the head restraint height. From the lower three latched positions, the head restraint can be adjusted up without depressing the latch. The inboard leg of the U-shaped tube was free to slide vertically in its plastic sleeve, although this sleeve was replaced with a locking sleeve for our tests.

BACKGROUND

Strain gauges are primarily sensitive to strains along one axis. However, strains along the gauge axis at the gauge location may result from a combination of internal stresses, i.e., axial and bending stresses in a beam (see Figure 3). Using strain gauges on the top and bottom of the beam, the strains due to the axial force and in-plane bending moment can be differentiated.

The axial force causes strains of equal magnitude and direction at both gauge locations, i.e., tension or compression. The bending moment causes strains of equal magnitude (assuming symmetrical cross-section), but opposite directions at each gauge location, i.e., one tensile and the other compressive. Adding the two strain gauge signals cancels the bending moment strains and leaves a combined strain proportional to the axial force. Subtracting the two signals cancels the axial force strains and leaves a differential strain proportional to the bending moment. Strains caused by out-of-plane bending can be minimized by mounting the gauges near the beam's neutral axis for out-of-plane bending.

Addition of strain gauge signals is achieved by wiring the two gauges to opposite arms of a Wheatstone bridge circuit (Figure 4a). Alternatively, subtraction is achieved by wiring the gauges to adjacent arms (Figure 4b). Therefore, pairs of gauges can be used to build analog axial-force or bending-moment transducers.

2-D Theory - Consider a two-dimensional head-restraint subjected to a force of unknown magnitude and direction applied at an unknown point on the head restraint. This configuration is shown in Figure 5 with strain gauges at positions 1 through 6. Free-body diagrams for sections through A and BC are shown in Figure 6. Equations for F_z and F_x as a function of strain are as follows:

$$F_z = k_1(\varepsilon_1 + \varepsilon_2) \quad (1)$$

$$F_x = k_2(\varepsilon_3 + \varepsilon_4) + k_3(\varepsilon_5 + \varepsilon_6) \quad (2)$$

where k_i's are constants which depend upon the cross-sectional area and the stiffness of the structure, and ε_i is the strain at gauge i. If the geometry and stiffness of the beam are the same at B and C, then $k_2 = k_3$.

The total applied force on the structure is the vector sum of F_x and F_z and the angle θ_y of the force is

$$\theta_y = \tan^{-1}\left(-\frac{F_z}{F_x}\right) \quad (3)$$

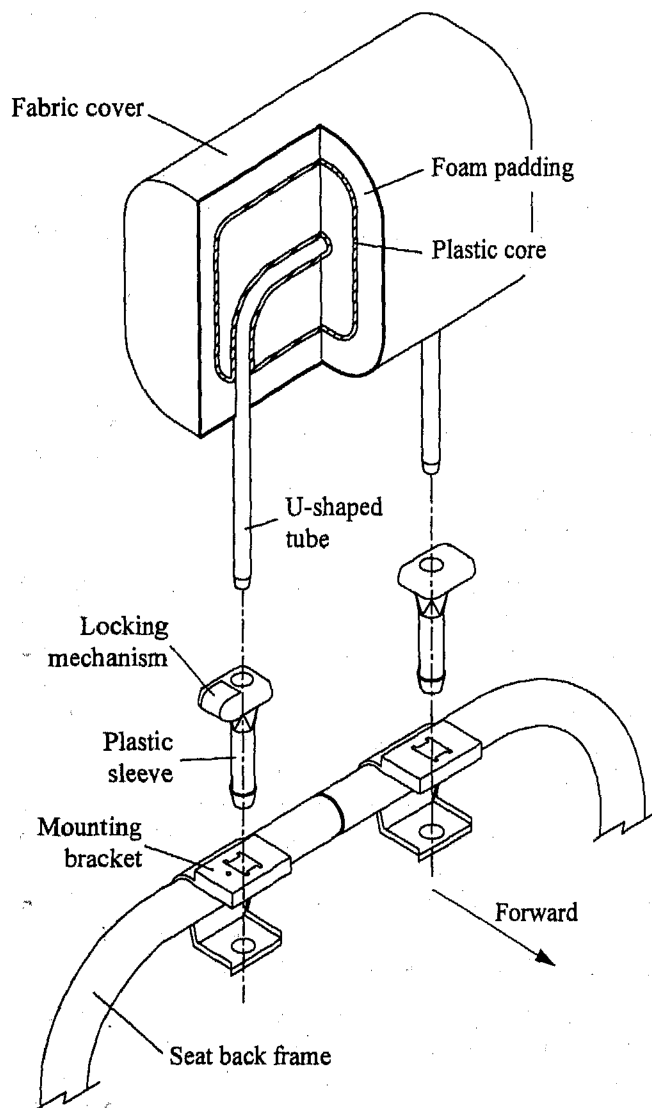

Figure 2. Honda Accord head restraint configuration. Locking height adjustment is present on the outboard side only.

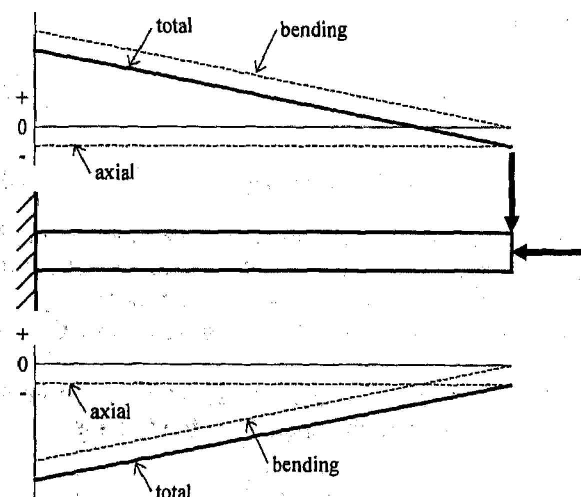

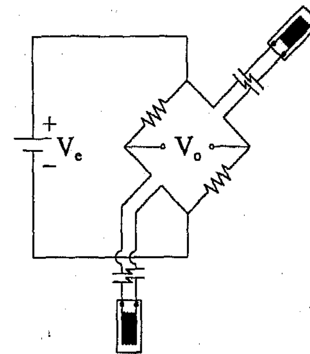

Figure 3. Strains on the top and bottom surfaces of a cantilevered beam subjected to combined compression and bending (+ve strain corresponds to elongation).

		26	back			30	back
		27	top			31	top
		28	bottom			32	bottom
I	z	33	right	J	x	37	right
		34	left			38	left
		35	front	K	x	39	right
		36	back			40	left

Summing moments about points A and B and setting them to zero yields the following equations:

$$Fa = k_4(\varepsilon_1 - \varepsilon_2) \tag{4}$$

$$Fb = k_5(\varepsilon_3 - \varepsilon_4) + k_6(\varepsilon_5 - \varepsilon_6) + k_7(\varepsilon_5 + \varepsilon_6) \tag{5}$$

Note that moments are proportional to the difference between a strain gauge pair and forces to the sum of a strain gauge pair. The third term in equation 5 should be multiplied by the distance c, however because c remained constant for our test series, it can be incorporated into k_7.

3D Theory - The same theory can be applied to a three-dimensional applied force by reducing the problem to a series of two-dimensional problems. The number of strain gauges necessary to handle the three dimensional case increases significantly (see Figure 7). At each of positions A through I there are four gauges, while at both J and K there are 2 gauges. The gauge number, sensitive axis and mounted surface of each gauge is given in Table 1. Redundant strain gauges are needed at locations B, D, and F because gauge pairs are required in both sum and difference bridges, which cannot be accomplished with a single pair of gauges. Free-body diagrams from a number of different views are given in Appendix A. These free-body diagrams illustrate the force and moment balance necessary to relate strain to applied force.

From the derived equations in Appendix A, seven equations in thirteen variables (D_1 to D_{13}) can be written:

$$\begin{aligned} F_x &= k_3(D_3) + k_4(D_4) \\ F_y &= k_5(D_5) + k_6(D_6) \\ F_z &= k_1(D_1) + k_2(D_2) \\ F_{xz}a &= k_7(D_7) \\ F_{xz}b &= k_8(D_8) + k_9(D_9) \\ F_{yz}d &= k_{10}(D_{10}) + k_{11}(D_{11}) \\ F_{xy}f &= k_{12}(D_{12}) + k_{13}(D_{13}) \end{aligned} \tag{6}$$

where D_1 through D_{13} are combinations of strain sums and differences. Note that moments involving F_{xz} appear twice in the equation set. This redundant measure was used to increase confidence in the line-of-action estimate for the force in the sagittal plane (our analysis plane). The above system of equations can be expressed in matrix form as follows:

$$\mathbf{F} = \mathbf{DK} \tag{7}$$

where:

$$\mathbf{F} = \begin{bmatrix} F_x & F_y & F_z & F_{xz}a & F_{xz}b & F_{yz}d & F_{xy}f \end{bmatrix}$$

= force components and moments

$$\mathbf{D} = \begin{bmatrix} D_1 & D_2 & \cdots & D_{13} \end{bmatrix}$$

= combined strain gauge outputs

$$\mathbf{K} = \begin{bmatrix} 0 & 0 & k_1 & 0 & 0 & 0 & 0 \\ 0 & 0 & k_2 & 0 & 0 & 0 & 0 \\ k_3 & 0 & 0 & 0 & 0 & 0 & 0 \\ k_4 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & k_5 & 0 & 0 & 0 & 0 & 0 \\ 0 & k_6 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & k_7 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & k_8 & 0 & 0 \\ 0 & 0 & 0 & 0 & k_9 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & k_{10} & 0 \\ 0 & 0 & 0 & 0 & 0 & k_{11} & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & k_{12} \\ 0 & 0 & 0 & 0 & 0 & 0 & k_{13} \end{bmatrix}$$

= theoretical calibration matrix

Calibration and Error Estimates - The value of k_1 to k_{13} in the theoretical calibration matrix relate the combined strain gauge outputs to the internal axial forces and bending moments and could be determined analytically. However, misalignment of strain gauges and the head restraint structure itself will cause strain gauges to respond to forces perpendicular to their sensitive axes. This cross-talk results in non-zero elements throughout the $\mathbf{K}$ matrix which cannot be determined analytically. Therefore, an empirical calibration procedure was used to determine the elements of the calibration matrix $\mathbf{K}$:

$$\mathbf{K} = \begin{bmatrix} k_{1,1} & k_{1,2} & k_{1,3} & \cdots & k_{1,7} \\ k_{2,1} & k_{2,2} & k_{2,3} & \cdots & k_{2,7} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ k_{13,1} & k_{13,2} & k_{13,3} & \cdots & k_{13,7} \end{bmatrix} \tag{8}$$

A minimum of 13 sets of calibration data in which $\mathbf{F}$ and $\mathbf{D}$ are known are needed to determine $\mathbf{K}$. However for a robust estimate of $\mathbf{K}$, more than 13 data sets should be used and a least-squares solution for $\mathbf{K}$ determined. A least-squares estimate of $\mathbf{K}$ is calculated from the following equation:

$$\mathbf{K} = \left(\mathbf{d}^{\mathrm{T}}\mathbf{d}\right)^{-1}\mathbf{d}^{\mathrm{T}}\mathbf{f} \tag{9}$$

where:

$$\mathbf{d} = \begin{bmatrix} D_{1,1} & D_{2,1} & D_{3,1} & \cdots & D_{13,1} \\ D_{1,2} & D_{2,2} & D_{3,2} & \cdots & D_{13,2} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ D_{1,n} & D_{2,n} & D_{3,n} & \cdots & D_{13,n} \end{bmatrix}$$

= strain gauge data from n calibration runs

$$\mathbf{f} = \begin{bmatrix} F'_{x,1} & F'_{y,1} & F'_{z,1} & \cdots & \left(F_{xy}f\right)'_1 \\ F'_{x,2} & F'_{y,2} & F'_{z,2} & \cdots & \left(F_{xy}f\right)'_2 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ F'_{x,n} & F'_{y,n} & F'_{z,n} & \cdots & \left(F_{xy}f\right)'_n \end{bmatrix}$$

= applied forces and moments from n calibration runs

To assess the error in the calculated forces and moments, a standard deviation (σ) for each force and moment component was calculated:

$$\sigma_{F_x} = \sqrt{\frac{\sum_{i=1}^{n}\left(F_{xi} - F'_{xi}\right)^2}{n-p}}$$

$$\sigma_{F_y} = \sqrt{\frac{\sum_{i=1}^{n}\left(F_{yi} - F'_{yi}\right)^2}{n-p}} \tag{10}$$

$$\vdots$$

$$\sigma_{F_{xy}f} = \sqrt{\frac{\sum_{i=1}^{n}\left[\left(F_{xy}f\right)_i - \left(F_{xy}f\right)'_i\right]^2}{n-p}}$$

where:

F_{xi} = calculated force in x-direction for calibration i
F'_{xi} = actual force in x-direction for calibration i
n = number of points in the calibration data set
p = number of calculated parameters = 13

IMPLEMENTATION

STRUCTURAL MODIFICATIONS - To simplify the impact response of the head restraint, the mounting arrangement of the inboard post was modified to match the locking outboard post. This modification eliminated vertical motion of the inboard post during the impact and prevented the head restraint from asymmetrical distortion. The steel mounting brackets were replaced by steel and aluminum components to improve strain gauge sensitivity (see Figure 9). The position and orientation of the head restraint were not altered by these modifications. The steel mounting block was welded onto the seat back frame and the aluminum "dog-bones" were screwed into the new mounting blocks. A sheet-metal guard was attached to the front of the seat-back frame to protect the mounts and head restraint posts from occupant loading through the seat back foam.

STRAIN GAUGES - Strain gauges were applied to the head restraint tubes, "dog-bones" and seat back tube at the locations shown in Figures 7 and 9 and listed in Table 1. A total of 40 strain gauges were applied. The strain gauges were manufactured by JP Technologies. Pace 06-062AH-350 gauges were used on the steel seat back and head restraint tubes and Pace 13-062AH-350 gauges were used on the aluminum "dog-bones". Both types of gauges had a grid length of 1.6 mm, an overall length of less than 5 mm, and a nominal resistance of 350 ohms. Insulated, solid-copper, 34-gauge leads were soldered to the strain gauge terminals and run to terminal strips located within 3 cm. Shielded, 22-gauge, four-conductor, stranded wire was run from the terminal strips to a signal conditioning board mounted behind the seat. Two gauges were run in each four-conductor cable.

Bean-brand CA-200SL adhesive and catalyst were used to fix the strain gauges and terminal strips to prepared metal surfaces. This cyanoacrylate-based glue required neither baking nor extended cure. Gauges and lead wires were coated with Bean Gagekote #7 - a two-part epoxy material which protects the gauges and lead wires from mechanical loads and the effects of humidity. A strain-gauged "dog-bone" is shown in Figure 10.

BRIDGE CIRCUITS - Each gauge had a nominal resistance of 350 ohms, however after mounting its resistance was slightly altered by strains induced by adhesive cure or structure pre-load. This initial offset in each Wheatstone bridge was balanced using an external resistor network immediately prior to each human subject test or series of calibration tests. The output signals from the bridge circuits were amplified 82 times before entering the analog math circuits. The bridge balance and amplifying circuit is shown in Figure 11.

ANALOG MATH CIRCUITS - The signals from the forty strain gauges (ε_1 to ε_{40}) were reduced to thirteen output signals (D_1 to D_{13}) using board-based math. Low signal levels, coupled with the necessity to record the differences between some gauges and bridge outputs dictated that analog algebraic circuitry be used. Analog math improved the signal-to-noise ratio and minimized quantization errors in the digital data acquisition system. Operational amplifiers were configured for analog signal addition and subtraction as shown in Figure 12. These circuits were arranged on a single printed circuit board to produce the appropriate combinations of signals at the thirteen outputs (Figure 13).

CALIBRATION PROCEDURE - To solve for the calibration matrix $\mathbf{K}$, a series of known forces were applied at known locations in known directions and the combined strain gauge outputs measured. A dynamic load pulse similar to that expected during an actual head impact was chosen to generate the calibration data. The seat back was rigidly supported at mid-height to eliminate rearward deflection at the seat hinge for the calibration procedure.

To apply a load to the head restraint, three eyebolts were fixed to the rigid plastic core through the back of the head restraint. A cable/pulley arrangement with an in-line load cell (Artech 20210 S-type load cell) was used to apply a dynamic loading pulse to the back of the head restraint. The pulley was attached to a frame with multiple pulley attachment points. By combining 15 pulley positions and 3 eyebolt locations, 45 loading conditions could be applied to the seat back (Figure 14), of which 32 were used for each calibration run.

The direction of the applied force and point of application for each pulley/eyebolt combination was measured with a three-dimensional digitizing arm with an accuracy of ±0.76 mm. This resulted in calibration force direction estimates within ±0.2 degrees. The locations about which the moment equations were developed (shown in Appendix A) were also recorded. With this data, the magnitude of the force components (F_x, F_y, and F_z) and offsets (a, b, d, and f) for each of the 32 calibration loading conditions were calculated. Forces varied between 37.5 degrees either side of horizontal and 30 degrees above and 55 degrees below the horizontal rearward loading direction (Figure 14).

RESULTS

Eleven sets of calibration tests were performed over the eight week testing schedule. For each calibration test, the load cell output and thirteen combined strain gauge outputs were recorded. A sample set of time-varying signals is shown in the top row of graphs in Figure 15. In order to determine the calibration matrix $\mathbf{K}$, the $\mathbf{d}$ and $\mathbf{f}$ matrices were generated from the 32 dynamic data sets.

Because of the dynamic nature of the calibration load, each time-varying data set represented many redundant measures of the same loading condition. These redundant data allowed us to examine the effect of using a number of time slices per calibration data set. The improved fit between the applied force (thin line) and

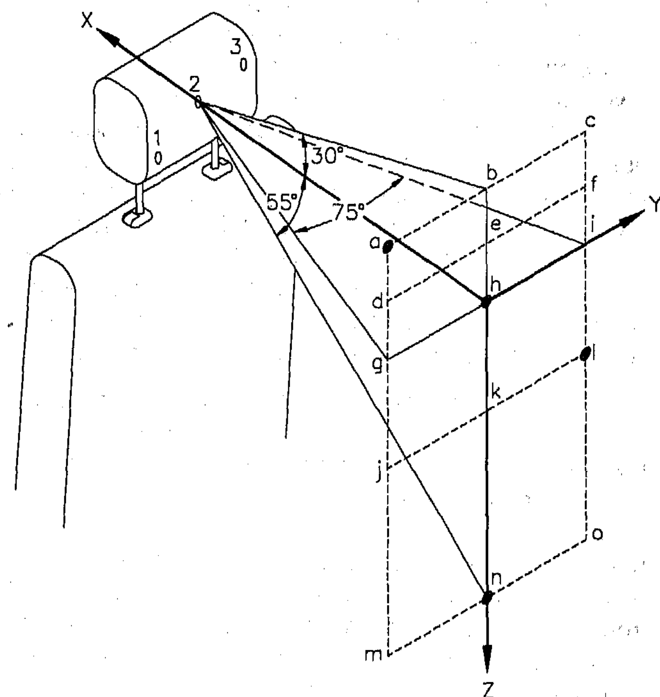

Figure 14. Calibration loading configuration showing the three eyebolt locations on the head restraint and the 15 pulley attachment locations on the frame located behind the seat. Calibrations loading conditions are described using the letter and number corresponding to the pulley and eyebolt used, i.e., h2 is horizontal rearward force. Circled pulley positions correspond to data presented in Figures 17 and 18.

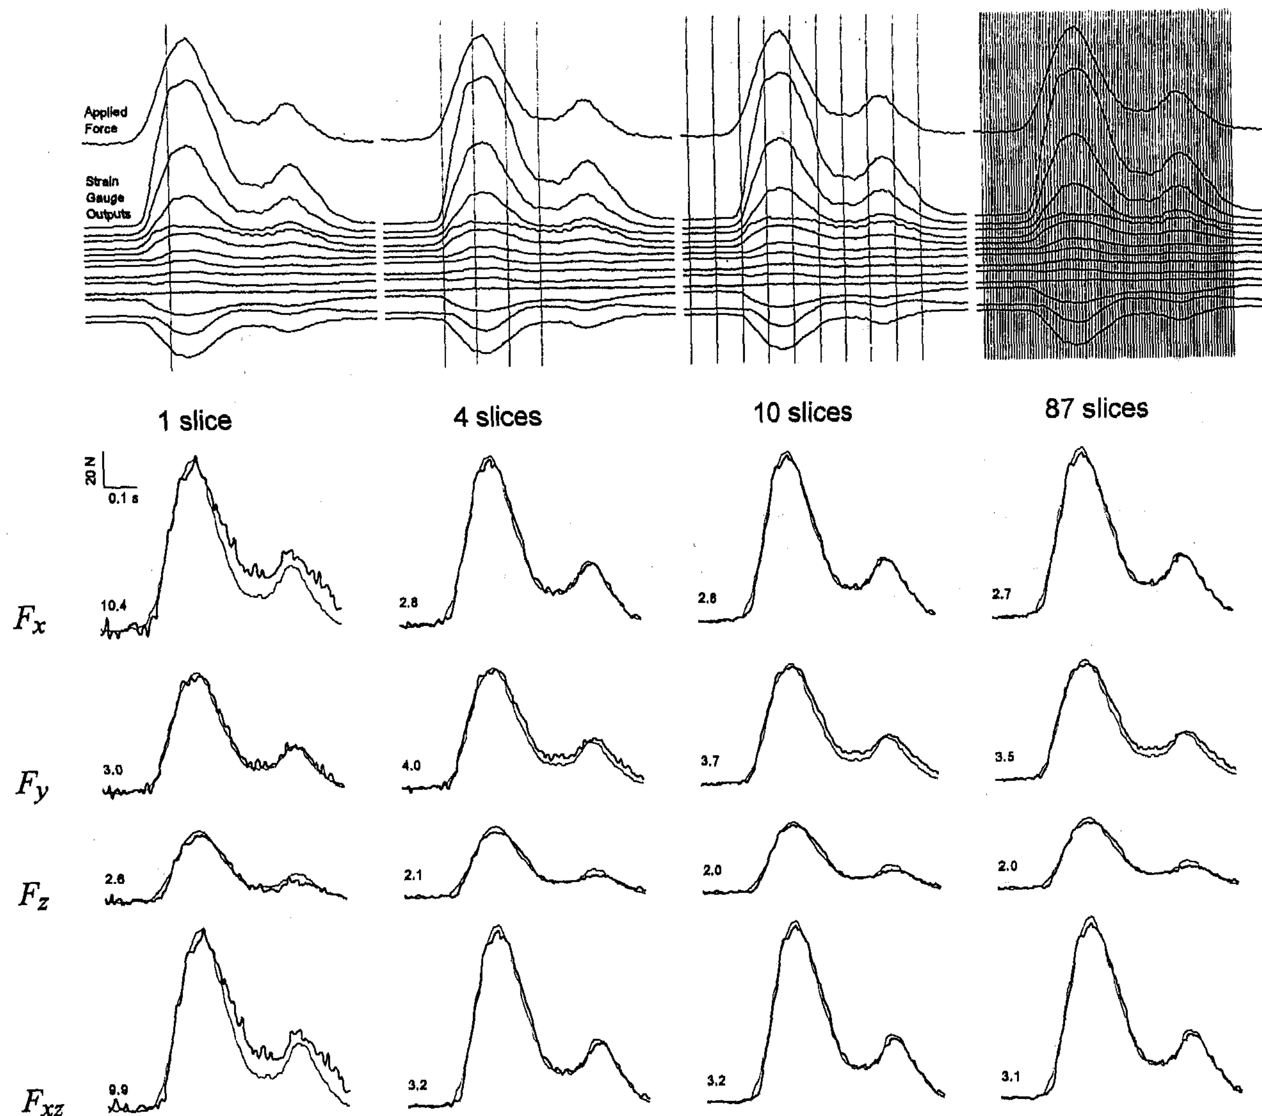

Figure 15. Calibration results using a different numbers of observations (slices) from each time-varying load applied during a single calibration set of 32 applied loads. The load shown is from pulley/eyebolt location I2 during calibration set 11. The top row depicts the same data set with 1, 4, 10, and 87 slices used for the calibration. Results for each force component F_x, F_y, F_z and the combined force F_{xz} in the sagittal plane are shown in the four lower rows for the four different number of observations used. In the four lower graphs, the actual applied load (thin line) and the calculated load (thick line) are shown. Standard deviations (shown at the left of each graph) between the signals indicate diminishing improvement with increased number of slices.

Table 2. Standard deviation of the calculated force components F_x, F_y and F_z and angle θ_y of the combined force F_{xz} in the sagittal plane for each calibration data set.

Calibration	F_x (N)	F_y (N)	F_z (N)	θ_y (deg)
1	1.9	1.6	1.6	3.1
2	2.8	2.8	2.0	2.3
3	2.3	2.0	1.9	2.9
4	2.4	1.9	1.8	3.0
5	2.0	1.9	1.7	2.9
6	2.5	2.0	1.7	2.7
7	3.1	2.2	2.1	3.1
8	2.6	2.1	1.8	3.0
9	2.9	2.0	1.9	3.2
10	3.0	2.1	1.7	3.2
11	3.0	2.2	2.0	3.3
All	2.6	2.1	1.8	3.0

Table 3. Standard deviation of the calculated line-of-action offsets *a*, *b*, *d* and *f* from the points about which the moments were calculated in Appendix A.

Calibration	*a* (mm)	*b* (mm)	*d* (mm)	*f* (mm)
1	3.5	4.3	23.9	16.1
2	4.1	5.0	22.1	14.5
3	3.9	4.8	25.5	15.3
4	4.0	5.0	24.7	15.9
5	4.4	5.4	23.7	12.9
6	3.8	4.8	25.6	15.0
7	4.2	5.0	26.4	15.9
8	4.7	5.6	27.0	14.5
9	5.2	6.5	25.1	16.3
10	5.1	6.3	26.0	17.0

All	4.4	5.3	25.1	15.3

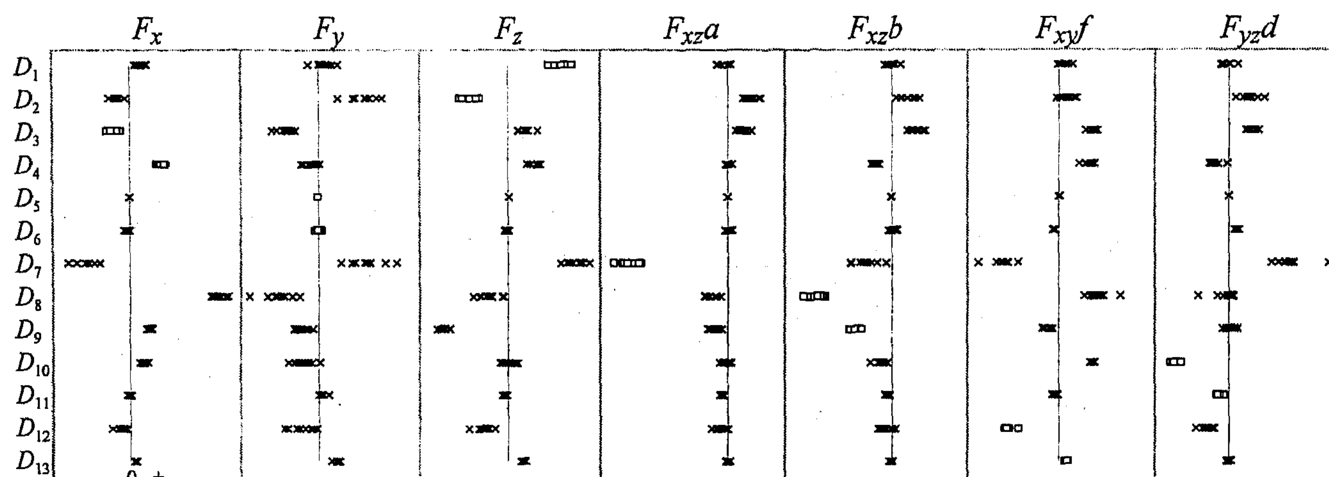

Figure 16. Comparison of calibration matrices from data sets 3 through 11. Each horizontal grouping of points represents the variation in a common element across all 9 matrices. The elements are arranged identically to the K-matrix in equation 7 to allow direct comparison between actual and theoretical quantities, i.e., the top left group corresponds to $k_{1,1}$ and the bottom right group corresponds to $k_{13,7}$ from equation 8. Elements represented by a square symbol correspond to elements k_1 through k_{13} in equation 7.

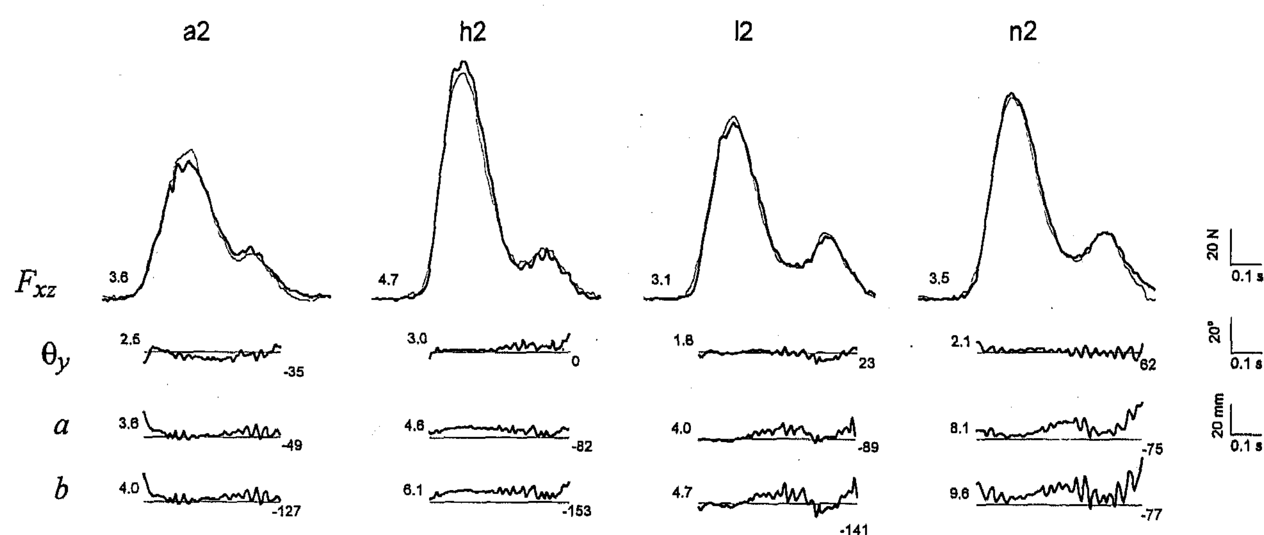

Figure 17. Comparison between actual (thin line) and calculated (thick line) parameters F_{xz}, θ_y, a and b for $\mathbf{K}_{11}$ and calibration data set 11. From left to right, the data represents pulley/eyebolt combinations a2, h2, l2 and n2 in Figure 14. The graphs for θ_y, a and b are truncated because the denominator used in their calculation tends to zero when no load is applied and therefore becomes unstable. Data is shown for loads greater than 10 N. Standard deviations between the two signals are shown to the left of each graph. The value of the actual parameter (thin line) for θ_y, a and b is shown to the right of each graph.

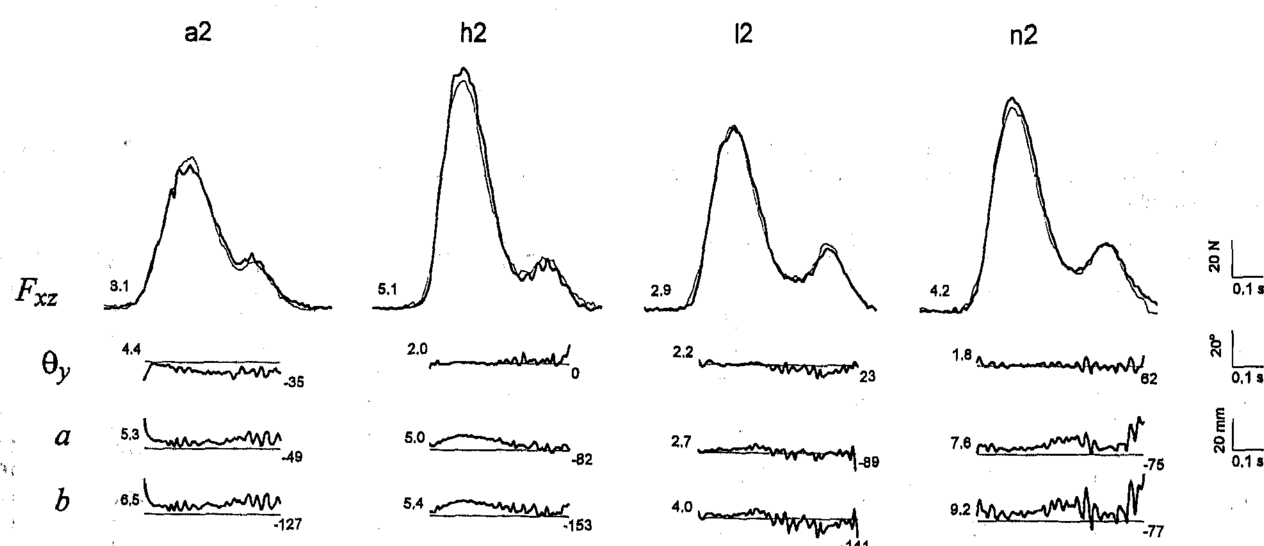

Figure 18. Same as Figure 17, except calculated values obtained by applying $\mathbf{K}_3$ to calibration data set 11.

calculated force (thick line) by increasing the number of time slices is shown in the bottom four rows of Figure 15. The standard deviations in Figure 15 show that increasing slices improves the fit between actual and calculated forces, but that this effect diminishes above 10 slices.

ERROR ESTIMATES - The standard deviations of the calculated force components were determined with Equation 10 and are summarized in Table 2. The standard deviations in the line-of-action offsets are shown in Table 3. Standard deviations of about ±2 N were achieved for the force components and ±3 degrees for the force direction in the xz-plane. The standard deviations for the line-of-action offsets were about ±5 mm in the xz-plane (moments about the y-axis), however they were three to five times larger for moments about the x- and z-axes. These larger deviations may be a result of a calibration procedure which focused on sagittal plane loading rather than a uniform distribution of loading in 3-space.

Calibration matrices were calculated for each of the 11 calibration runs using 87 slices. Nine of the 11 matrices are compared in Figure 16 (the first two calibration matrices can not be compared to the final nine due to a change in amplification gain made to one of the strain gauge output channels). Figure 16 indicates variation between the calibration matrices. To examine the effect of this variation, two calibration matrices ($\mathbf{K}_3$ and $\mathbf{K}_{11}$) were applied to the data set for calibration run 11 and differences in the ultimate calculated parameters for our sagittal plane analysis (F_{xz}, θ_y, a, and b) were examined (see Figures 17 and 18). Differences between $\mathbf{K}_3$ and $\mathbf{K}_{11}$ were representative of variations between the nine matrices and were used for this comparison because they were chronologically the furthest apart.

Figure 17 represents the best possible result because the calibration matrix was calculated from the same data to which it is being applied. Figure 18 shows what $\mathbf{K}_3$ predicts for the same data. A comparison of the standard deviations between the applied and calculated quantities indicates repeatable results despite differences between calibration matrices.

SAMPLE DATA - The head restraint data acquired during a rear-end automobile collision was processed with the calibration matrix from the closest chronological calibration data set. For this test, a female subject (162 cm, 65 kg) was exposed to an 8 km/h speed change. The resulting head restraint forces are shown in Figure 19. The rise in head restraint force in advance of head contact is caused by inertial loading and must be subtracted from the calculated force before it is mapped to the subject's head reference frame. The net force in the xz-plane is also shown, along with the direction θ_y of the force and the line-of-action offsets a and b. Note that the loading direction remains within the calibration envelope shown in Figure 14.

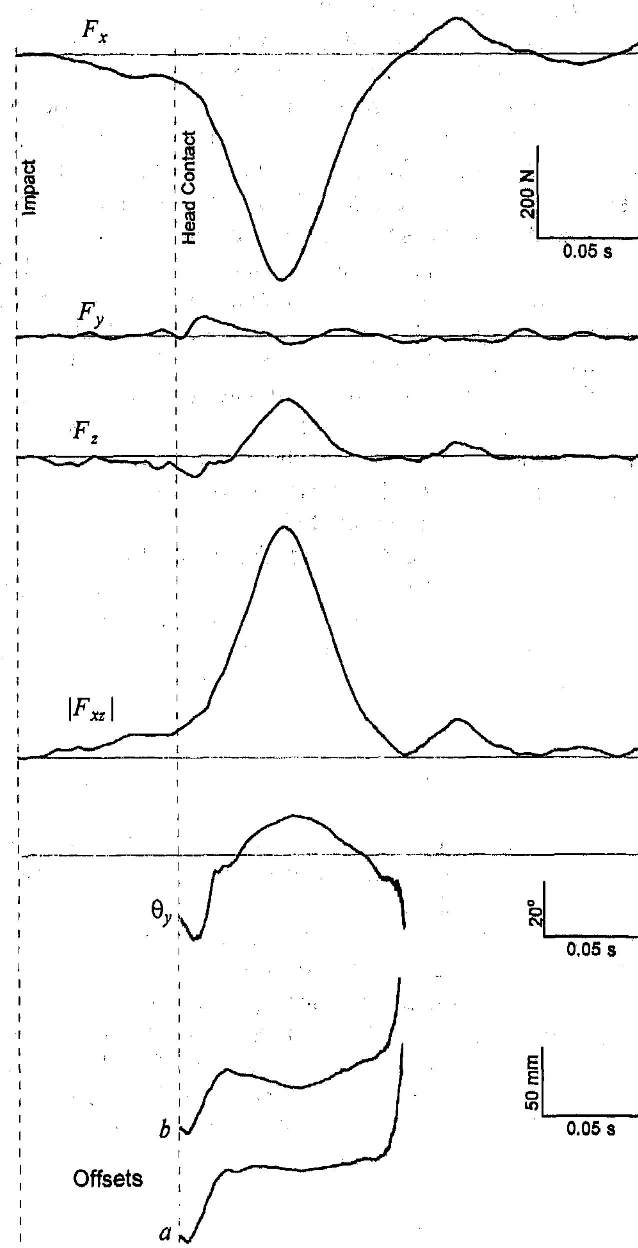

Figure 19. Sample data from rear-end collision with speed change of 8 km/h. Rise in F_x between impact and head restraint contact is due to inertial loading. Data for θ_y, a, and b not shown for forces less than 10 N.

DISCUSSION

The only problem with the strain gauges during the testing schedule involved the lead wires. The Gagekote material cracked at a point of flexure and caused an imbedded lead wire to break. All of the lead wires on the head restraint gauges were replaced and were not re-treated with Gagekote.

The strain gauges became noticeably warm during operation. To minimize the transient effects of heating and cooling during the test, the gauges were allowed to reach a constant temperature before each test.

Two of the combined strain gauge outputs (D_6 and D_{11}) occasionally responded non-linearly to the applied force. This is believed to be due to slight shifting of the head restraint posts within the plastic sleeves during loading. This shifting is a result of normal play in the mounting system. The plastic sleeves were left in the system for two reasons: they contain the height adjustment mechanism, and our objective was to keep as many of the original head restraint components in the system as possible. As a result of the non-linear behavior in signals D_6 and D_{11}, near-zero coefficients in the calibration matrix were generated (see Figure 16).

Some of the strain gauge outputs remained very low throughout the calibration force applications. A least squares solution for such a channel produced a near-zero coefficient since there was little information about the applied force in the output signal.

Future work could include eliminating the play due to the plastic sleeves and making use of the data currently ignored because of non-linearities. Alternatively, these and other low-output channels could be removed from the calibration data and smaller $\mathbf{K}$-matrices calculated.

CONCLUSIONS

The use of strain gauges to measure the magnitude, direction and line of action of a force applied to a head restraint has been demonstrated. A dynamic calibration procedure was developed and least-squares calibration matrices were calculated.

Standard deviations for predicting the force components F_x, F_y and F_z and line-of-action offsets a, b, d and f are estimated to be ±2.6 N, ±2.1 N, ±1.8 N, ±4.4 mm, ±5.3 mm, ±25.1 mm and ±15.3 mm respectively. The standard deviation for predicting θ_y is estimated to be ±3.0 degrees.

ABSTRACT

Three-dimensional simulation models of a driver's right upper extremity interacting with a deploying airbag have been set up and run with the Articulated Total Body program. The goal of this study is to examine the significance of various occupant and airbag parameters during deployment, such as grip strength, upper extremity position, shoulder compliance, flap position, flap aggressivity, and deployment speed. Given a range of 250 N to 650 N, the grip strength did not affect the resultant loads. Also, the contact force and torque at the c.g. of the forearm are not sensitive to shoulder joint compliance. The flap aggressivity and the position of the airbag module relative to the upper extremity are most important in affecting the interaction. This study is used to justify cadaveric experiments involving disarticulated upper extremities.

INTRODUCTION

Motivation for this research stems from the high incidence of upper extremity injuries from airbags as seen in the literature [1-6]. The bones of importance in the upper extremity are the humerus of the upper arm and the radius and ulna of the forearm [7]. In the literature cases most fractures occur at the distal third in both the humerus and radius. Kuppa et al analyzed several accident data bases including NASS, NHTSA Special Investigations, and NHTSA sponsored studies and Jackson Memorial, University of Maryland and the University of New Jersey [8]. Kuppa found that 1.1% of drivers who were restrained only by a seatbelt experienced an upper extremity injury; however, in the presence of a deploying airbag, 4.4% of drivers showed upper extremity injuries. Two modes have been suggested for these injuries. The first is direct contact with the airbag, the type examined in this paper, and may occur while executing a left turn with the right hand, thus placing the forearm directly over the module. The second, indirect contact injuries, involves upper extremity contact with another object in the automobile subsequent to interaction with the airbag.

Saul et al. used an instrumented Hybrid III upper extremity to examine this interaction [9]. Using strain gauges and accelerometers, they found that bending moments and accelerations could be accurately recorded. Moreover, a correlation was found between these values and the airbag's inflator properties, flap, and steering wheel orientation.

Several studies examine the joint kinematics within the upper extremity and provide useful modeling data [10-16]. Additionally, the Research Arm Injury Device (RAID) was developed by Conrad Technologies Inc. and NHTSA to examine the upper extremity-airbag interaction [8]. This device determined that the two most critical factors were the orientation of the arm with respect to the airbag module and the separation distance between the two.

MODEL DESCRIPTION

Using the Articulated Total Body (ATB) multi-body dynamics program, a three-dimensional model was created to study the interaction between a driver's upper extremity and a deploying airbag. The model's initial conditions are shown in Figures 1 and 2.

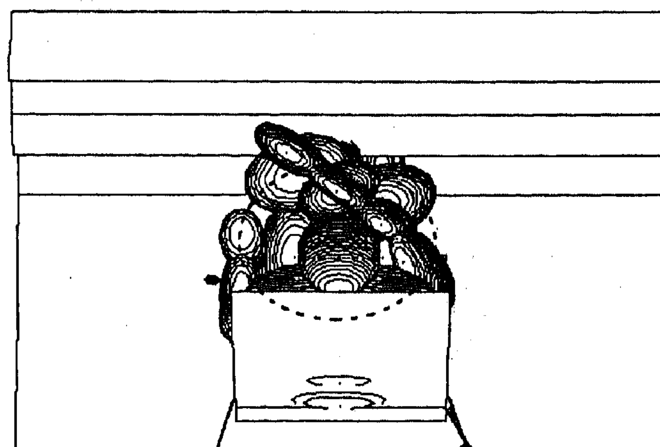

Figure 1. Rear View of Model Showing Upper Extremity Across Airbag Flap

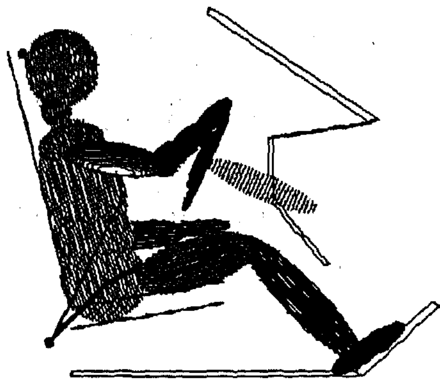

Figure 2. Side View of Model with Initial Upper Extremity Orientation

OCCUPANT JOINTS - The full occupant body has been retained for simulations involving a vehicle deceleration pulse, but the model can be restrained to allow movement of the right upper extremity only. The shoulder is modeled as a ball joint with some front-to-back (X-direction) compliance. This additional degree-of-freedom has been provided to simulate the flexibility associated with the clavicle, but it can also be locked to simulate a test with the shoulder fixed in space.

Friction in the joints is currently set to a 1 g level, but it can be increased to simulate muscle tension. The elbow is treated as a pin joint and the wrist as a ball joint. The right forearm has been divided into two segments connected by a locked joint at the forearm c.g. location. This permits force and torques experienced at the c.g. to be "measured" since ATB outputs the forces and torques that it applies to the associated segments in order to maintain the joint's locked condition. In principle, this joint can be made to unlock, or "break", when the applied torque exceeds a pre defined level; however, this would confound the prediction of potential peak loads for the various initial conditions.

GRIP STRENGTH - Gripping of the wheel rim by the driver's hand is simulated by a spring between the hand segment and the upper wheel segment. The spring force is defined by a tabulated function which reaches a maximum value that is associated with the grip strength. If the spring is stretched further, the force drops to zero to simulate the hand releasing from the rim. At present, the steering wheel is being treated as rigid.

AIRBAG MODEL - The airbag model is comprised of seven segments. Five of these segments, a center segment and four side segments, are soft, with contact properties approximating the fully deployed bag. Another segment represents the steering wheel "flap" that covers the bag module. Finally, the last segment is a special "punch" that is used to open the flap. See Figure 3 for a sketch of the model. Bag deployment is simulated by applying time-dependent external force functions to the five, soft bag segments. The center segment is driven backward toward the driver while the side segments, which are initially inside the center segment, are deployed sideways. Punch-through begins around 20 ms after simulated impact so that times can be related to times in a full sled or vehicle test. The functions are presently chosen so that the bag is almost completely deployed in 45 ms. The motion of each bag segment is finally arrested when a spring-damper, acting as a tether reaches equilibrium with the forcing function.

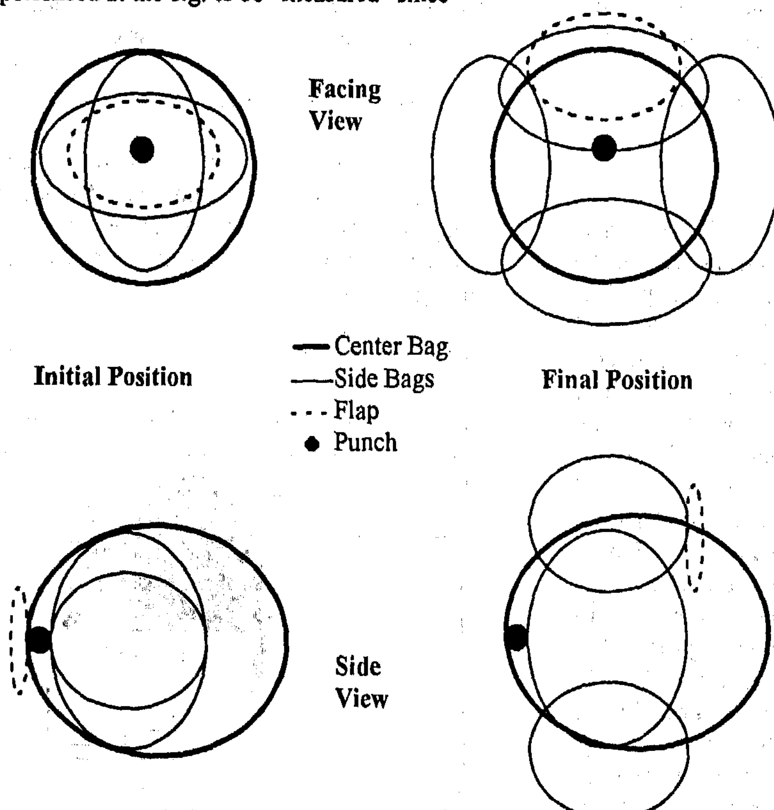

Figure 3. Airbag Model Consisting of Seven Segments: One Center Bag, Four Side Bags, One Flap, and One Punch

The punch segment offers considerable flexibility when studying the opening of the flap. It is connected to the center segment by a sliding, or "slip", joint and contacts the forward side of the flap as the center segment moves rearward. Relative motion between the center and punch segments is prevented for punch-to-flap force levels below the slip joint's locking force; after which, restraint is governed by a spring-damper. This design provides the capability to model a release, or plateau, of the bag-to-flap pressure as the flap opens. Initially the bag and flap move as one, but once a sufficient gap has opened the bag can begin billowing out sideways even though the flap may be restrained by the driver's upper extremity. Tests are needed, but it is reasonable to assume that the bag force against the flap does not increase significantly after punchout. The flap in the present model is fairly stiff, but the contact force between the flap and the upper extremity can be modified to simulate flap compliance.

EXAMPLE - Figure 4 shows the baseline model in action at the beginning, middle, and end of airbag deployment. The bag module is centered relative to the steering wheel and the grip strength of 650 N represents a relatively strong male driver [17].

The pictures in Figure 4 demonstrate that the model behavior is qualitatively realistic as compared to laboratory tests. Two results that are readily obvious are the lack of shoulder movement during the flap contact phase and the fact that even a "strong" grip is quickly released. With the basic functionality of the model established, it can be exercised to study the sensitivity of upper extremity loading to various parameters which are Table 1.

The parameters are listed in order of estimated importance. Upper extremity position is placed first since this study is only concerned with upper extremities in front of a deploying bag. However, it is not a parameter to be subjected to much variation since the upper extremity must be assumed to be in a high risk, worst case position that places it across the center of the wheel, in front of the deploying bag.

PARAMETER STUDY RESULTS

Simulations have been run with variations made to parameters 3, 4, 6, 7, 8 and 9. One of the initial goals of the simulation project was to determine if upper extremity-only component testing, with a shoulder joint fixed in space, could adequately replicate the upper extremity-to-airbag interaction. Figure 5 clearly demonstrates that, since significant upper extremity-to-airbag contact happens early in the crash event, the results obtained from the component test and the full-body, full-motion test are almost identical. Furthermore, Figures 6 and 7 show that there is also very little sensitivity of the upper extremity-to-flap contact force, or the C.G. torque, to a fixed or translating shoulder joint. In animations made from the simulations, motion of the translating shoulder joint is clearly visible, but the peak loading between the upper extremity and the flap has already occurred. These results strongly support the validity of upper extremity-only component testing, with non-translating shoulder joints.

Table 1. Summary of Available Model Parameters

1. Upper extremity position
2. Airbag deployment speed
3. Flap aggressivity (upper extremity contact stiffness and "punch through" behavior)
4. Bag module position (centered, high, low, etc.)
5. Flap size
6. Grip strength
7. Wrist and elbow stiffness (via friction variable)
8. Shoulder motion (locked or compliant in X-direction)
9. Torso motion relative to vehicle
10. Bag stiffness (for upper extremity contact)

Figures 6 and 7 also verify the relatively low importance assigned to grip strength and wrist torque. Of some interest for experimental testing, are the sharp peaks that appear around 37 ms in the C.G. torque plot. These peaks, which exceed the magnitude of the initial flap-contact peaks, are an artifact of having a hard-stop model for the wrist joint in order to represent the metal-to-metal contact of the actual Hybrid-III wrist stop. The human wrist has a distributed mass over several joints and would not show these spikes. In Figure 8, it is demonstrated that a much softer joint stop, as expected in a human wrist, eliminates this peak.

As expected, upper extremity loads show a much higher sensitivity to flap aggressivity (Figure 9), which is represented here by the flap-to-bag force plateau. Other factors which directly affect this occupant parameter are bag deployment speed and flap stiffness. While upper extremity-to-airbag loads can also be several thousand Newtons, it is the localized nature of flap contact which is significant and which increases the probability of breakage.

The results do show some sensitivity to bag module position (Figure 10), but further study is needed in order to make definite conclusions. A higher module position, in which the airbag seam is moved distally towards the wrist, reduces the contact force, but laboratory tests have demonstrated that bone fracture still occurs in this case. This may be due to narrowing of the upper extremity bones near the wrist. A low module position, on the other hand, produces little change in contact force, but the probability of injury may decrease due to increased bone cross-sectional area near the elbow, as well as additional support from elbow joint.

CONCLUSIONS AND RECOMMENDATIONS

The results obtained in this study support the use of disarticulated at the shoulder upper extremity component tests when conducting research into upper extremity-airbag interactions. The use of more complicated, full-body, full-motion tests is not expected to yield significantly different results, but it will increase the cost and data-variability associated with each experiment.

Peak loading of the upper extremity is associated with the airbag module flap, and occurs within 5 msec of punch-out. From this observation it seems that the most fruitful area for future research is the minimization of this contact force. Thus far, the variables which have been studied that are most significant include the coupling between the bag and flap, and the position of the bag module. Over a reasonable range of values, grip strength and wrist torque play a negligible role with regard to the flap contact force.

This ATB model in conjunction with laboratory testing can be used to examine other variables in the future. Additional tests may study various airbag deployment speeds, different flap tear-seam orientation (vertical instead of horizontal), or flap size (two small flaps versus one large flap).

ABSTRACT

A study of frontal collisions using the NASS data base showed that there were four times as many arm injuries to belt restrained drivers who had an air bag deploy than for the drivers who were simply belted. By far, the distal forearm/hand was the most commonly injured region. Hard copy review identified two modes of arm injury related to the deploying air bag: 1) The arm is directly contacted by the air bag module and/or flap cover, and 2) The arm is flung away and contacts an interior car surface.

Based on the field studies, a mechanical device called the Research Arm Injury Device (RAID) was fabricated to assess the aggressivity of air bags from different manufacturers.

Results from static air bag deployment tests with the RAID suggested that the RAID was able to clearly distinguish between the aggressive and non-aggressive air bags. Maximum moments ranging between 100 Nm and 650 Nm, and hand fling velocity ranging between 30 and 120 km/h were measured on the RAID in these tests. In general, the aggressive air bags imparted a maximum moment on the RAID above 300 Nm and a hand fling velocity above 70 km/h.

Two factors were identified as critical to the test setup. The first was the orientation of the arm with respect to the air bag module. The second was the distance of the arm from the plane of the air bag module face. The maximum moment and fling velocity increased when the initial distance between the RAID and the air bag module was reduced.

INTRODUCTION

Though recent studies [1] suggest that air bags have reduced the number of fatalities, preliminary reports by Huelke [2,3] from a limited number of accident cases involving deployed air bags suggested that air bags may cause upper extremity injuries. These accident cases also suggested that the intensity and frequency of air bag related upper extremity injuries may be related to the velocity of impact, occupant stature and gender, and various other parameters. Since these case studies were anecdotal and limited in number, no conclusive statement could be made.

The objective of this research effort was to get a better understanding of the problem related to upper extremity trauma induced by the air bag and develop a Research Arm Injury Device (RAID) to study this phenomenon. This objective was achieved in two phases.

Phase I: In order to better understand upper extremity injuries associated with a deploying air bag various accident data bases were examined. In addition, detailed review of accident cases in the NASS data base and NHTSA sponsored hospital and special investigation data bases were conducted.

Phase II: The objective in this phase was to develop the Research Arm Injury device and to study arm/air bag interaction and assess the relative aggressivity of different air bags.

PHASE I: REVIEW OF ACCIDENT DATA

The objective of this phase was accomplished by analyzing various accident databases, including NASS, NHTSA Special Investigations and from NHTSA-sponsored hospital studies at Jackson Memorial, and the MD and NJ Trauma Centers. Examining the arm trauma to drivers whose air bags deployed provided valuable information for the development of the RAID.

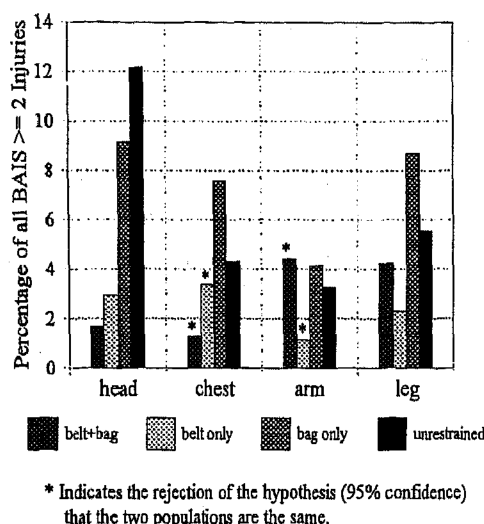

Figure 1: Distribution of BAIS≥2 injuries. 1988-94 weighted NASS files.

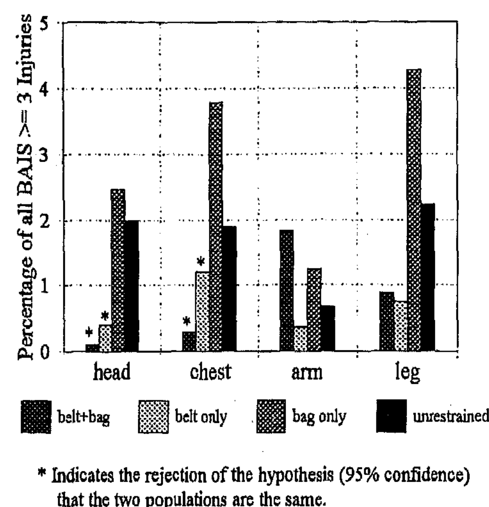

Figure 2: Distribution of BAIS≥3 injuries. 1988-94 weighted NASS files.

ANALYSIS OF NASS DATABASE - First, a general overview of the incidence of injury was performed. The National Accident Sampling System (NASS) was used to generate the distribution of injuries to various body regions of drivers under different restraint conditions. Computer records were examined from the years 1988-1994 to quantify the prevalence of injuries to drivers (over the age of 15) in passenger cars. Frontal impacts with a primary direction of force between 11 and 1 o'clock were considered. In addition, the selected drivers must not have been ejected from the vehicle or been involved in a rollover collision.

Four restraint categories were considered - 1. Unrestrained: The driver was not restrained by any belt and the air bag was not present or did not deploy, 2. Bag only: The driver was not restrained by any belt and the air bag deployed, 3. Belt only: The driver was restrained by the shoulder and lap belt and an air bag was not present or did not deploy, 4. Belt+bag: The driver was restrained by the shoulder and lap belt and the air bag deployed.

Four body regions were considered in the analysis - 1. Head (head, face, neck), 2. Chest (abdomen, chest, back, shoulder), 3. Arm (wrist, hand, upper limb, elbow, upper arms, forearm, and humerus), 4. Leg (pelvis, knee, lower limb, thigh, ankle/foot).

The data were analyzed using the maximum injury to each body region (BAIS) based on the Abbreviated Injury Scale. For example, if there were two injuries to a defined body region, then the injury with the larger AIS would be the BAIS value. The BAIS can be thought of as a modified-MAIS (Maximum Injury to a Body Region) such that for each driver, there are four maximum AIS values instead of one value. Drivers who were not injured at all had a BAIS value equal to zero in each of the body regions. The frequency of injury at BAIS≥2 and BAIS≥3 was computed as

$$Freq. = \frac{no.\ of\ drivers\ with\ injuries}{total\ no.\ of\ drivers\ in\ each\ restraint\ system}$$

The percentage frequency of injury at BAIS≥2 and 3 for various restraint conditions are presented in Figures 1 and 2. The percentage of BAIS≥2 (and BAIS≥3) injury for a particular body region was compared between two restraint systems and statistical significance at the 95 percent confidence level were computed. It was found that 1.1% of drivers restrained by a 3-point belt only experienced an upper extremity injury; however, 4.4% of drivers restrained by a deploying air bag and 3-point belt sustained a BAIS≥2 upper extremity injury. The difference in these proportions was found to be statistically significant.

DETAILED CASE REVIEWS - Analysis of the NASS data base suggested that belt restrained drivers are four times more likely to experience upper extremity trauma when an air bag deploys than when no air bag deploys. In order to investigate in detail the cause of these arm injuries, individual cases of drivers who sustained arm injuries while restrained by air bags were culled from the database sources. These selected files were then examined in detail. About one hundred cases (65 from NASS) were selected for in depth review. Each of these cases met the selection criteria that an air bag deployed and there was an arm injury of AIS≥2.

Injury mechanisms were determined based on information from: (1) interview with the driver, (2) exterior and interior vehicle damage, and (3) all available medical records. From the examination of these select accident cases, this study linked three principle injury mechanisms involving air bag deployment. The first mechanism consisted of injuries resulting from direct contact of the arm with the module cover and/or bag. The other two resulted from the arm being flung against interior car parts: either projected upwards toward the front windshield/A-pillar, or flung by the air bag toward the left side door. These three mechanisms are depicted in Figure 3. Of the 65 selected accident cases in NASS, approximately half (32 cases) were judged to be related to the three principal injury mechanisms involving air bag deployment, as shown in Figure 4.

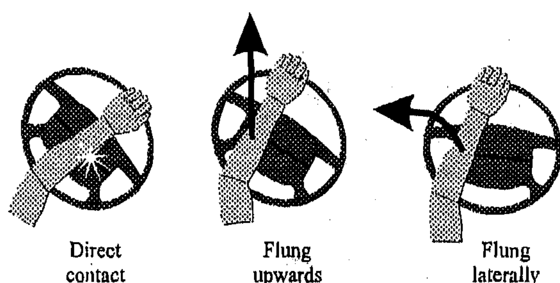

Figure 3: Three principal mechanisms of upper exremity injury due to air bag deployment.

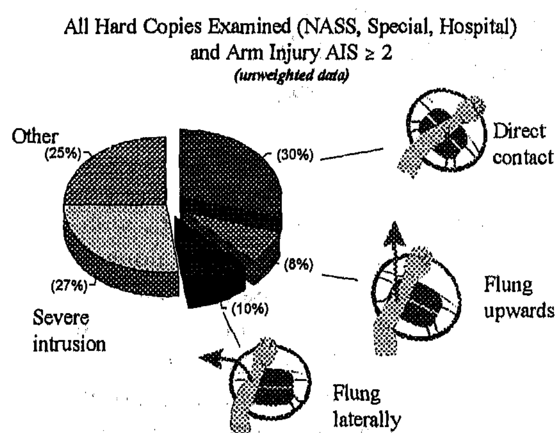

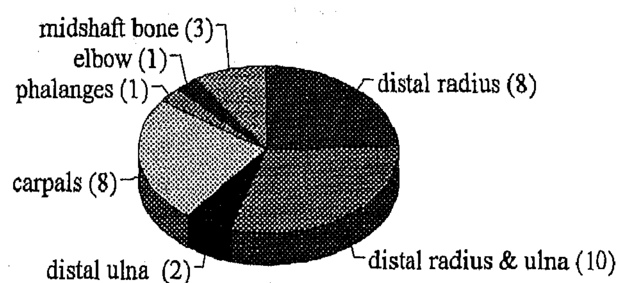

Figure 4: Distribution of injury mechanisms in the selected accident cases from NASS.

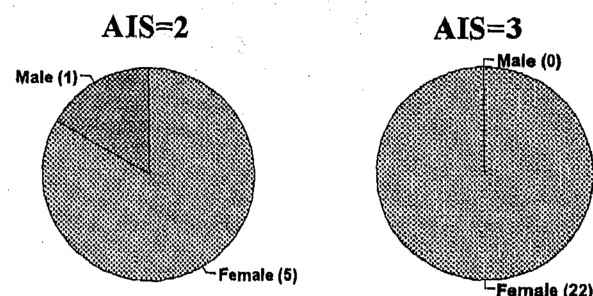

In the 32 accident cases in NASS related to the three principal injury mechanisms, the vast majority of the injuries were fractures of the distal portion of the limb, as shown in Figure 5. Wrist injuries were more common in mechanisms where the forearm was flung by the deploying air bag. In accidents cases with $\Delta V \leq 24$ km/h (from all data bases where the three primary mechanisms were judged to be the cause of AIS≥2 upper extremity trauma), injury occurred primarily in females, as can be seen in Figure 6. Almost all these drivers were female who were under 5'6" and less than 135 lbs.

87% of all fractures were to the distal end.

Contains 32 unweighted NASS (88-94) cases where the injury could be related to the deploying bag. There is one case with multiple (2) entries in the pie.

Figure 5: Location of fractures in the 32 NASS cases related to the three principal injury mechanisms.

Vast majority were under 5'6" and under 135lb.

PHASE II: THE RESEARCH ARM INJURY DEVICE

The detailed study of NASS cases suggested two distinct types of upper extremity injury mechanisms related to air bag deployment. The first type of mechanism is where the arm is directly contacted by

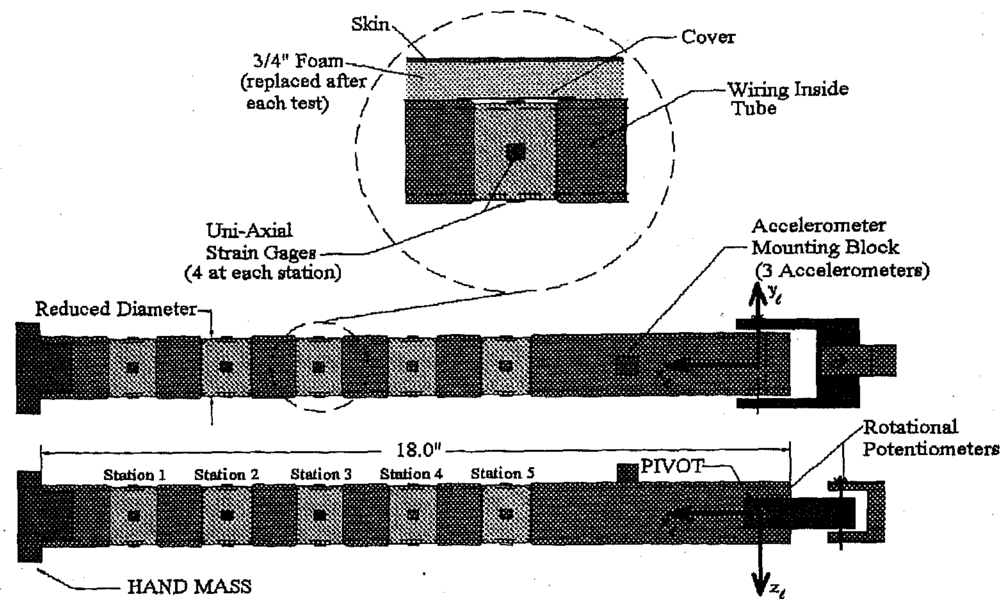

Figure 7: The Research Arm Injury Device

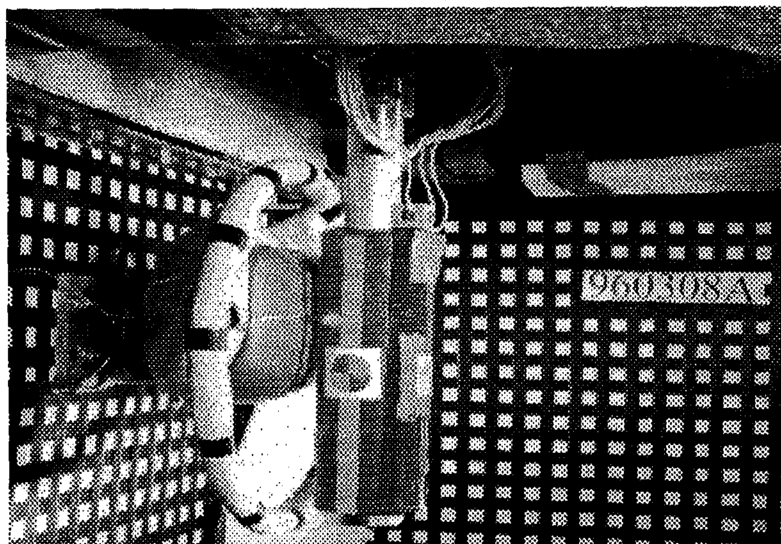

Figure 8: Side view of the RAID test setup.

the deploying bag and/or module flap cover. This results in high bending moments on the arm causing injury in some instances. The second type of mechanism involves the arm being flung away at a high velocity and impacts some portion of the vehicle interior or the driver body. The objective in this phase of the research program was to develop a simple research tool to evaluate the relative severity of air bags from different manufacturers taking into consideration these established modes of upper extremity trauma.

DESCRIPTION OF THE RAID - The Research Arm Injury Device or RAID was developed as an investigative tool to study arm-air bag interactions. The RAID is made from an aluminum tube with double pivot attachment to allow motion along two axes. It has the approximate cross-sectional properties and weight (1.6 kg) of a human forearm. A small mass (0.5 kg) is attached to the free end of the RAID to simulate the hand. The length of the RAID was extended to 46 cm to protect the pivot attachments from the deploying air bag. The RAID instrumentation includes five stations of diametrically opposed strain gages to measure moments along two axes. In addition, the pivot rotations are measured by two angular potentiometers and the accelerations are measured by a triaxial accelerometer block attached approximately at mid-length of the RAID. The RAID is covered with 2 cm of foam and rubber

skin similar to that on the Hybrid III mid-forearm. Figure 7 illustrates the details of the RAID.

EXPERIMENTAL SETUP - A side view of the test setup with the RAID is shown in Figure 8. The RAID was hung vertically down in front of the steering wheel and was allowed to rotate at the pivots in two directions as shown in the figure. It was possible to move the RAID in any direction to achieve the correct positioning with respect to the air bag module. The distance from the surface of the RAID to the plane of the steering wheel rim was changed according to test specifications. The steering wheel was rotated to achieve the desired test configuration (the orientation and position of the module tear seam with respect to the RAID). A load cell was located behind the steering wheel to measure reaction forces. The time of air bag cover opening was determined using break wires over the tear seam. A backstop with foam padding was used to stop the RAID after the air bag propelled it. The tests with the RAID were captured on film at 1000 frames per second by two high speed cameras for the front and side views.

SELECTION OF AIR BAGS - Six different air bag modules were selected for testing. The selection of the air bags was based in part upon the results from the NASS analysis and also upon tank test data. The System L was identified as a less aggressive bag from the NASS studies. The System J, System T, and the System P air bags were identified as less aggressive by the manufacturer. The System H and the System K were identified as aggressive air bags from the NASS studies as well as from tank test data. System H has a large heavy asymmetric module cover and System K has a very high tank pressure. These features make the Sytems H and K modules aggresssive in nature.

Table 1 presents various characteristics of these air bag modules. Figure 9 shows roughly scaled sketches of the different modules and covers. All modules except the System J air bag have an "H" tear pattern. The System J has an "I" tear pattern.

TEST CONFIGURATION - Thirty-four tests were conducted with the RAID using different air bag modules in different test configurations and distances from the plane of the steering wheel rim. A test configuration is defined as the orientation and position of the air bag module tear seam with respect to the RAID. After experimenting with various configurations, three main configurations, shown in Figure 10, were selected to compare air bag aggressivity.

Configuration I was designed to represent a person turning the wheel with their arm in front of the steering wheel. This configuration consists of a hand at 11 o'clock and an elbow at 4 o'clock, with the steering wheel rotated counter clockwise by 90 degrees from the neutral position.

Configurations V and VI were designed to study the most severe interaction of the arm with the air bag. Configuration V consists of the forearm located over the center of the module and oriented perpendicular to the tear seam of the module. Configuration VI consists of the forearm located over the center of the module and oriented parallel to the tear seam of the module. As a driver in a vehicle makes various maneuvers and adjustments, his or her arms are in continuous motion, so these configurations are thought to be plausible, although possibly less likely.

In addition to varying the test configurations, the distance of the RAID from the plane of the steering wheel rim was varied. Tests were conducted with the distance of the RAID from the plane of the steering wheel rim at 1.3 cm, 7.6 cm, and 12.7 cm.

TEST RESULTS - Results from static air bag deployment with the RAID suggested that the RAID was able to clearly distinguish between aggressive and non-aggressive air bags. The maximum moments, hand velocity, resultant acceleration, and steering column force were consistently higher for the aggressive air bags than the air bags identified as non-aggressive, as shown in Figures 11 to 14. The hand velocity was computed using the rotational potentiometer data.

Maximum moments ranging between 100 Nm and 650 Nm, and hand fling velocity ranging between 30 and 120 km/hr were measured on the RAID in these tests.

All the air bag module covers opened between 3 - 5 msec after the firing pulse. The maximum moments and accelerations occurred very early in the event - 5 to 20 msec (during the punch-out phase.) The maximum hand velocity occurred later when the RAID was propelled by the air bag and it was no longer in contact with the bag. The maximum velocity occurred between 30 - 40 msec. The maximum moments and velocity occurred earlier for the aggressive air bags than for the non-aggressive air bags.

When the initial distance of the RAID from the plane of the steering wheel rim was increased from 1.3 cm to 7.6 cm, the maximum moments, maximum accelerations, and maximum hand velocity decreased considerably. Further increasing the initial distance of the RAID from the air bag module to 12.7 cm did

Thickness of flaps	0.32	0.44	0.51	0.32
Vertical height of air bag	68.6	69.9	63.5	66.0
horizontal width of air bag	68.6	63.5	66.0	63.5
number of tethers	4	2	3	none
length of tethers	26.7	27.9	31.8	--

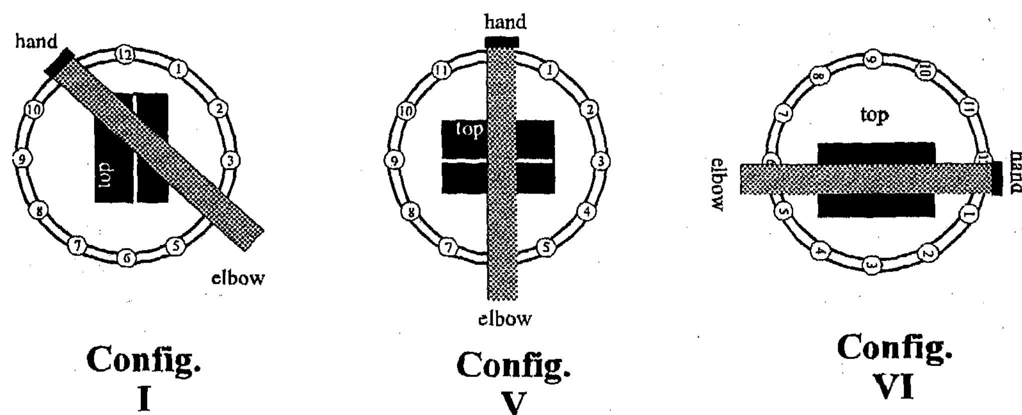

Figure 10: Three test configurations with the RAID.

not change the maximum values of moments, accelerations, and velocity.

The maximum moment measured was located at station 4 which is 20 cm from the hand mass of the RAID. This station was approximately located at the air bag tear seam where the greatest effect of the punch out due to module cover opening was experienced. Figure 15 presents the peak moments at each station for the tests with the System L air bag in various configurations. As can be noted from Figure 15 the moments are lower for the tests where the initial distance of the RAID from the air bag module was increased so that the cover flaps did not impinge it during the punch out phase.

Two major parameters measured on the RAID were identified to clearly distinguish between the aggressive and non-aggressive air bags. They are the maximum resultant moment and the maximum hand velocity. Figure 16 presents the maximum moment versus maximum hand velocity for all the tests in Configurations I, V, and VI. This figure suggests that the aggressive air bags imparted a maximum moment on the RAID above 300 Nm and a hand fling velocity above 75 km/h. In general, the maximum moments and hand velocity decreased when the initial distance between the air bag module cover and the RAID was increased.

The orientation and the distance of the arm with respect to the air bag module were identified as critical to the test setup. Of all the test configurations examined, configuration V was most severe. Repeatability tests were conducted with the System J and System K air bags. Good repeatability in the acceleration, moments, and rotation signals were evident.

ESTIMATION OF FRACTURE TOLERANCE OF THE HUMAN FOREARM

The relative severity of the various air bag modules can be determined from the RAID tests. However, in order to ascertain whether a particular air bag module would cause injury to the forearm, the fracture tolerance of the human forearm had to be determined.

As a first step, the fracture tolerance of the human forearm was estimated from static 3-point bending test data of isolated bones reported by Yamada [4] and Melvin [5]. Melvin reported the breaking load in bending of the radius and ulna of male and female human post-mortem specimens. Assuming the bending strength of the radius and ulna to be additive and assuming a dynamic factor of 1.5 as suggested by Melvin, the dynamic fracture tolerance of the human forearm was estimated to be 115 Nm for male specimens and 90 Nm for female specimens. This is similar to the forearm injury reference value of 120 Nm suggested by Saul [6].

Figure 11 suggests that all the air bags tested produced bending moments on the RAID which exceeded the estimated fracture strength of the forearm. The RAID was designed as a simple investigative tool and not necessarily a biofidelic device. Hence, the responses measured on the RAID may not represent human response. In order to identify whether a certain air bag would injure the human forearm, it would be necessary to scale the RAID response to represent that of a human forearm.

CONCLUSIONS

Detailed study of the NASS database suggested that arm injuries occur with greater frequency in

drivers whose vehicle is equipped with a deploying air bag. In addition, results of the study suggested that belt restrained drivers who had an air bag deploy are four times more likely to experience arm injuries than belt restrained drivers without a deployed air bag. The three most common arm injury mechanisms due to air bag deployment are: (1) Direct contact with the air bag and/or flap, (2) The arm is flung upwards and hits the A-pillar or front windshield, and (3) The arm is flung to the side. The distal portion of the upper extremity was the most commonly encountered injury in these cases. At low velocities (less than 15 mph), AIS=3 injuries have thus far only occurred in females, most of whom were small in stature and weight.

A mechanical device called the Research Arm Injury Device was developed to test air bag aggressivity. Preliminary testing with the RAID suggested that this device was able to distinguish between aggressive and non-aggressive air bags with reasonable accuracy. Maximum moments ranging between 100 Nm and 650 Nm, and hand fling velocity ranging between 30 and 120 km/hr were measured on the RAID in these tests.

The orientation of the arm with respect to the air bag module and the distance of the arm from the air bag module were identified as critical to the test setup. The most severe case occurred when the RAID was directly over the center of the module and the tear seam was perpendicular to the RAID. When the initial distance between the RAID and the air bag module was increased, the maximum moment, acceleration, steering column loads, and hand velocity decreased.

The punch out phase when the deploying air bag/module cover first interacts with the RAID during its deployment was when the RAID experienced maximum moments and velocities. The punch-out phase is therefore the most critical period of air bag deployment for causing trauma to the upper extremities.

FUTURE RESEARCH

The estimated dynamic fracture tolerance is based on broad assumptions using static 3-point bending tests of isolated bones. In order to get more accurate estimates of dynamic fracture tolerance, dynamic 3-point bending tests of the whole forearm should be conducted. Preliminary data from such tests suggest an average dynamic fracture tolerance of 125 Nm.

Since the RAID is not biofidelic, the moments measured on the RAID may not be the moments which a human arm would experience when at close proximity to the air bag module in a realistic situation. Hence, in order to interpret the results from the RAID tests to determine the injury causing potential of particular air bag modules, testing with human cadaver forearms should be conducted in conjunction with the RAID tests to associate forearm trauma with the moments measured on the RAID. Preliminary data from upper extremity component tests suggest that the air bags identified as more aggressive from the RAID tests do indeed cause fractures to the cadaver forearm.
